Family VI. **Dermabacteraceae** Stackebrandt, Rainey and Ward-Rainey 1997, 485^{VP} emend. Zhi, Li and Stackebrandt 2009, 597

Michael Goodfellow

Der.ma.bac.te.ra.ce′a.e. N.L. masc. n. *Dermabacter* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Dermabacteraceae* the *Dermabacter* family.

Gram-stain-positive, non-acid-fast, nonsporeforming, nonmotile actinomycetes which contain ***meso*-diaminopimelic acid as the cell wall diamino acid and two residues of dicarboxylic acids in the interpeptide bridge (A4γ peptidoglycan), straight-chain saturated, iso-, and anteiso-branched fatty acids, unsaturated menaquinones with 7–9 isoprene units, but not mycolic acids. The pattern of rRNA gene signatures consists of nucleotides at positions 120 (A), 131:231 (G–C), 196 (U), 342:347 (C–G), 444:490 (A–U), 580:761 (U–A), 602:636 (C–G), 670:736 (A–U), 822:878 (G–C), 823:877 (G–C), 826:874 (C–G), 827 (U), 843 (C), 950:1231 (U–G), 1047:1210 (G–C), 1109 (C), 1145 (G), 1309:1328 (G–U), 1361 (G) and 1383 (C)**.

Source: a wide range of natural habitats and clinical material.

DNA G+C content (mol%): 62–72 (T_m).

Type genus: **Dermabacter** Jones and Collins 1989, 93^{VP} (Effective publication: Jones and Collins 1988, 54).

Further descriptive information

The family contains the genus *Dermabacter* Jones and Collins 1988 and the genus *Brachybacterium* Collins et al. 1988 (Figure 155). These taxa form a distinct phyletic line in the 16S rRNA *Micrococcineae* (elevated to order *Micrococcales* in the present volume) gene tree (Cai and Collins, 1994; Schubert et al., 1996). The family can be distinguished from other families classified in the order *Micrococcales* by a set of 16S rRNA signature nucleotides (Zhi et al., 2009) and by a combination of chemotaxonomic markers (see sections on other families classified in the order *Micrococcales*).

Acknowledgements

Thanks are due to Ingrid Goth, Peter Schumann, and Peter Kämpfer for helping improve the original draft of this chapter and to the latter for providing Figure 155.

Genus I. **Dermabacter** Jones and Collins 1989, 93^{VP} (Effective publication: Jones and Collins 1988, 54.)

Michael Goodfellow

Der.ma.bac′ter. Gr. n. *derma* skin; N.L. masc. n. *bacter* masc. equivalent of the Gr. neut. dim. n. *baktron* small rodlet; N.L. masc. n. *Dermabacter* small rod living on skin.

Facultatively anaerobic, catalase-positive, oxidase-negative actinomycetes which ferment a range of sugars and **decarboxylate lysine and ornithine. Cell wall peptidoglycan contains *meso*-diaminopimelic acid, alanine, and glutamic acid. Long-chain fatty acids are predominantly of the iso-, anteiso-methyl branched type. The major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and a diglucosyldiacylglycerol with some phospholipids. Unsaturated menaquinones with nine isoprene units predominate, though corresponding components with seven and eight isoprene units occur in substantial amounts**. The phylogenetic position of *Dermabacter*, as determined by 16S rRNA gene sequence analysis, is in the family *Dermabacteraceae*.

Source: skin of healthy adults.

DNA G+C content (mol%): 62.0–63.0 (T_m).

Type species: **Dermabacter hominis** Jones and Collins 1989, 93^{VP} (Effective publication: corrig. Jones and Collins 1988, 54.).

Further descriptive information

The genus *Dermabacter* forms a separate line of descent within the order *Micrococcales* and is most closely related to the genus *Brachybacterium* (see Figure 155) (Buczolits et al., 2003; Collins et al., 1988; Heyrman et al., 2002). These taxa, together with the genera *Demetria*, *Dermacoccus*, and *Kytococcus*, form the family *Dermabacteraceae*. The genus, which is monospecific, was proposed to accommodate four strains of coryneform bacteria isolated from the skin of healthy adults (Jones and Collins, 1988). Sometime later it was discovered that strains dating back to the 1970s with phenotypic properties similar to *Dermabacter hominis* had been referred to the Laboratory Center for Disease Control in Canada and to the Communicable Disease Center in the USA (Bernard et al., 1994; Funke et al., 1997). These strains, isolated primarily from blood cultures and less commonly from other body sites of patients in Belgium, Canada, Sweden, and the USA, were provisionally designated CDC coryneform groups 3 (xylose fermenter) and 5 (xylose nonfermenter). Subsequently, 15 Swiss clinical isolates belonging to these taxa were classified as *Dermabacter hominis* based on chemotaxonomic and 16S rRNA gene sequence data (Funke et al., 1994). Similar results were reported by Gruner et al. (1994) who also found that 22 out of 30 strains of CDC groups 3 and 5 could be designated *Dermabacter hominis* based on DNA–DNA relatedness data; the remaining strains were considered to belong to other *Dermabacter* species even though they could not be separated from *Dermabacter hominis* using fatty acid and phenotypic data.

Dermabacter strains form small, convex, grayish-white colonies which have a distinct pungent odor (Bernard et al., 1994). They ferment a broad range of sugars (Funke et al., 1994; Jones and Collins, 1988), produce lysine and ornithine decarboxylases (Bernard et al., 1994; Funke et al., 1994) and acetate and lactate as major products of glucose metabolism (Funke et al., 1994). In general, they are susceptible to cephalosporins, glycopeptides, teichoplanin, and vancomycin, whereas the activities of ciprofloxacin, contrimoxazole, erythromycin, gentamicin, pipemidic acid, sulfamethoxazole, and tetracycline

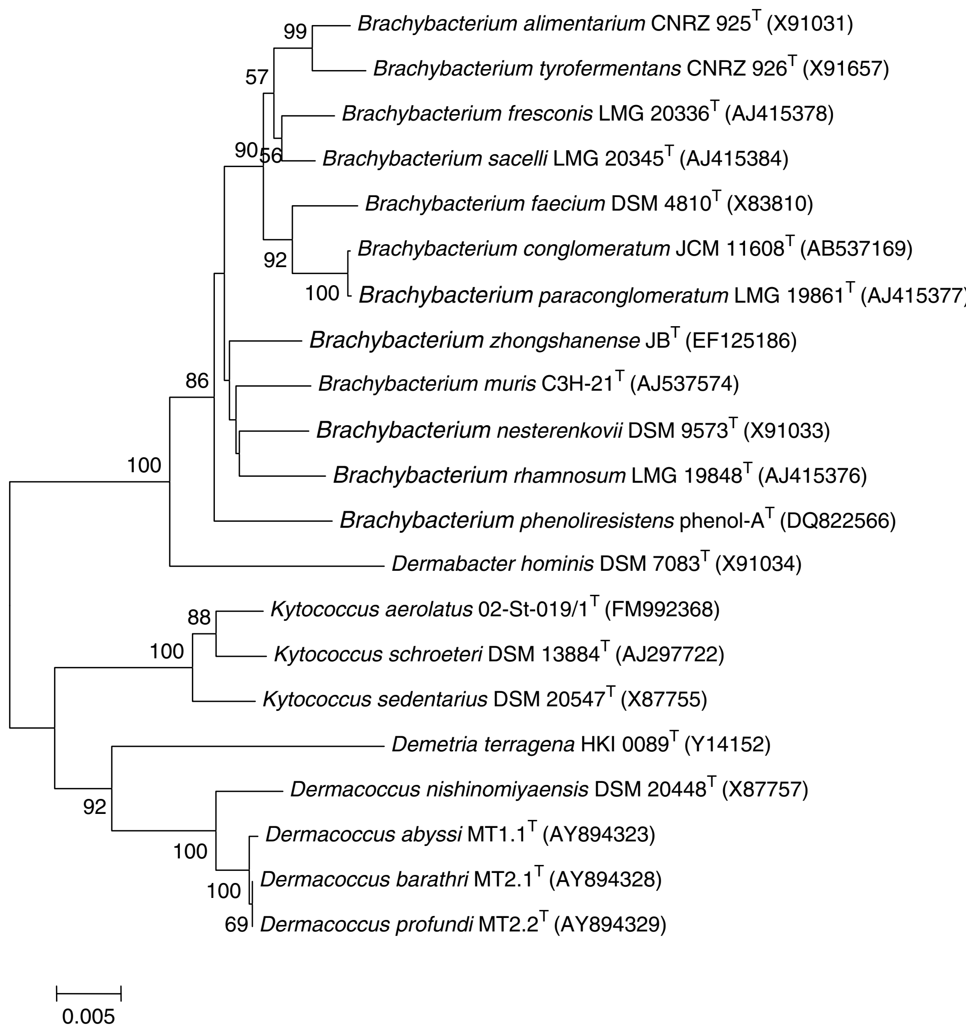

FIGURE 155. Phylogenetic analysis based on 16S rRNA gene sequences available from the European Molecular Biology Laboratory data library (accession numbers are given in brackets). Multiple alignment, distance calculations (distance options according to the Kimura-2 model), and clustering with the neighbor-joining method were performed by using the software package MEGA (Molecular Evolutionary Genetics Analysis) version 4 (Tamura et al., 2007). Bootstrap values based on 1000 replications are listed as percentages at the branching points. Bar = 0.005 nucleotide substitutions per nucleotide position.

are limited, as recorded by their Mic_{80} values (Funke et al., 1996; Troxler et al., 2001).

The peptidoglycan of dermabacters contains *meso*-diaminopimelic acid, alanine and glutamic acid; this is consistent with the directly cross-linked murein type A1γ (Jones and Collins, 1988). They contain major proportions of anteiso- and iso-methyl branched fatty acids, but lack mycolic acids (Bernard et al., 1994; Funke et al., 1994; Jones and Collins, 1988). This fatty acid profile is sufficiently distinctive to separate members of the genus from related taxa using the Microbial Identification (MIDI) system (Bernard et al., 1994). The predominant component in the menaquinone profile is MK-7, though substantial amounts of MK-7 and MK-8 are present (Jones and Collins, 1988). These workers found that the polar lipid patterns of dermabacters contained major amounts of diphosphatidylglycerol, phosphatidylglycerol, several unknown phospholipids, and a single glycolipid which had the chromatographic mobility of diglycosyldiacylglycerol.

Initially, *Dermabacter hominis* strains were considered to be nonpathogenic, though their isolation from blood cultures and other bodily sites of patients such as abscesses, eyes, skin lesions, and wounds, implied clinical significance (Funke et al., 1994, 1997; Gruner et al., 1994). The organism is now considered to be an opportunistic human pathogen which can cause abscesses (Bavbek et al., 1998), bacteremia (Gomez-Garces et al., 2001), chronic osteomyelitis (Van Bosterhaut et al., 2002), and peritoneal-dialysis associated peritonitis (Radtke et al., 2001). In addition, *Dermabacter*-like strains cause chronic inflammation of the integument, septicemia, and, notably, cheilitis in lizards (Koplos et al., 2000; Pasmans et al., 2004, 2008). Cheilitis appears to be highly contagious with morbidity and mortality rates of 100% in the desert agama (*Agama impalearis*) (Pasmans et al., 2004).

Enrichment and isolation procedures

Dermabacter strains can be isolated from clinical material including blood by plating onto standard media such as Columbia agar supplemented with sheep blood and incubating aerobically at 37°C with 5% CO_2. They also grow on Columbia chocolate and MacConkey agars.

Maintenance procedures

Dermabacter strains may be lyophilized or preserved as glycerol cultures at −80°C using standard procedures.

Differentiation of the genus *Dermabacter* from other genera

16S rRNA gene sequencing provides an effective way of distinguishing *Dermabacter* strains from related taxa. They can be separated from related taxa using a combination of chemical markers, quantitative analysis of fatty acid profiles (Bernard et al., 1994), and from their nearest phylogenetic neighbor, the genus *Brachybacterium*, on the basis of colony morphology, major fatty acids, G+C content, and menaquinone and cell wall peptidoglycan types (see Table 117, below).

TABLE 117. Chemotaxonomic traits suitable for phenotypical differentiation between *Brachybacterium* and its next phylogenetic relative *Dermabacter*

Characteristic	*Brachybacterium*[a]	*Dermabacter*[b]
Major fatty acid	$C_{15:0}$ anteiso or $C_{15:0}$ anteiso and $C_{17:0}$ anteiso	$C_{17:0}$ anteiso
Quinone system	MK-7 or MK-7 and MK-8	MK-9 or MK-9 and MK-8
Number of glycolipids in the polar lipid profile	2–5	1
DNA G+C content (mol%)	68–73	62
Peptidoglycan type	A4γ[c] (interpeptide bridge consisting of D-Asp-D-Glu or D-Glu–D-Glu)	A1γ[c] (directly cross-linked)

[a]Data from Collins et al. (1988), Gvozdyak et al. (1992), Takeuchi et al. (1995), Schubert et al. (1996), Heyrman et al. (2002), Buczolits et al. (2003), Chou et al. (2007), and Zhang et al. (2007).

[b]Data from Jones and Collins (1988).

[c]For explanation, see Schleifer and Kandler (1972).

List of species of the genus *Dermabacter*

1. **Dermabacter hominis** Jones and Collins 1989, 93[VP] (Effective publication: corrig. Jones and Collins 1988, 54)

ho′mi.nis. L. n. *homo* man; L. gen. n. *hominis* of man, signifying the isolation of strains from human skin.

Gram-stain-positive, nonmotile organism which forms short rods and coccoid elements. Grows at 37°C, but not at 10°C; some strains grow at 45°C. Grows in the presence of 5% (w/v) NaCl.

Esculin is hydrolyzed, but hippurate and urea are not. Gelatin is liquefied and lecithinase is produced. Does not reduce nitrate. Negative for CAMP, indole, and Voges–Proskauer tests and for the production of arginine dehydrolase and tryptophan deaminase. Positive for alkaline phosphatase, esterase (C4), β-galactosidase, α-and β-glucosidases, α-mannosidase, and *N*-acetyl-β-glucosaminidase, but negative for acid phosphatase, L-chymotrypsin, cystine arylamidase, L-fucosidase, β-glucuronisidase, lipase (C14), and valine arylamidase (API ZYM tests). DNA and starch are degraded, but cellulose, tyrosine, and xanthine are not. Acid is produced from *N*-acetylglucosamine, amygdalin, cellobiose, fructose, galactose, β-gentiobiose, glucose, lactose, maltose, mannose, melezitose, melibiose, raffinose, ribose, sucrose, trehalose, and turanose, but not from adonitol, D- or L-arabinose, D- or L-arabitol, dulcitol, erythritol, D- or L-fucose, glycerol, glycogen, 2- and 5-ceto-gluconate, gluconate, inositol, inulin, mannitol, α-methyl-D-mannoside, β-methyl-D-xyloside, rhamnose, sorbitol, tagalose, xylose, or xylitol. Does not use citrate as a sole carbon source.

Cellular fatty acids contain major proportions of 14-methylhexadecanoic ($C_{17:0}$ anteiso) and 12-methyltetradecanoic ($C_{15:0}$ anteiso) acids.

Additional chemotaxonomic and phenotypic data are cited in the genus description and in the text.

Source: human skin, blood cultures, and other body parts of humans, and from blood cultures and integuments of lizards.

DNA G+C content (mol%) 61–63 (T_m).

Type strain: S69, ATCC 49369, CCUG 32998, CIP 105144, DSM 7083, JCM 7448, NCIMB 13131.

Sequence accession no. (16S rRNA gene): X76728, X91034.

Additional comments: Dermabacter hominis was incorrectly cited as *Dermabacter hominus* in Validation List no. 28 (Euzéby and Kudo, 2001).

Genus II. **Brachybacterium** Collins, Brown and Jones 1988, 46[VP]

Sandra Buczolits and Hans Jürgen Busse

Bra.chy.bac.te′ri.um. Gr. adj. *brachys* short; L. neut. dim. n. *bacterium* rod; N.L. neut. n. *Brachybacterium* a small rodlet.

Cells vary in shape from coccoid forms in the stationary phase, which occur in large agglomerations, to club-shaped rods in the exponential phase, which occur predominantly in pairs or agglomerations. Cells are nonmotile, nonsporeforming, and stain Gram-positive. Surface colonies are small, white to yellow, circular, convex, and smooth.

Essentially aerobic, but may show growth under microaerophilic conditions. The temperature range for growth is 4–42°C, with optimal growth at 25–35°C. Can **grow at pH 6.0–9.0** and in the **presence of up to 15% NaCl**. **Catalase-positive and oxidase-negative.**

Acid is produced from D-glucose, D-galactose, and L-arabinose. Esculin is hydrolyzed. Tyrosine, chitin, and cellulose are not hydrolyzed. Voges–Proskauer-negative. Nonhemolytic.

Cell wall peptidoglycan contains ***meso*-diaminopimelic acid, alanine, and glutamic acid; aspartic acid may be present**. Mycolic acids are absent. **The principal menaquinone is MK-7**. The **fatty acid profile** consists of the predominant compound **$C_{15:0}$ anteiso with significant amounts $C_{16:0}$ iso and $C_{17:0}$ anteiso**. The **polar lipid profile** is composed of **diphosphatidylglycerol, phosphatidylglycerol, and two unknown glycolipids**. **Spermine and spermidine** are the **predominant components of the polyamine pattern**.

DNA G+C content (mol%): 68–73.

Type species: **Brachybacterium faecium** Collins, Brown and Jones 1988, 46[VP].

Further descriptive information

The genus *Brachybacterium* encompasses a separate line of descent within the *Micrococcales*, with *Dermabacter hominis* as the next phylogenetic relative (Buczolits et al., 2003; Heyrman et al., 2002). The species share more than 96% 16S rRNA gene sequence similarities and less than 95% with *Dermabacter hominis*. Genus and first species, *Brachybacterium faecium*, were described by Collins et al. (1988) based on the unique characteristics of three strains which had been isolated from poultry deep litter (Schefferle, 1966). In the following, one of these strains was described to represent a novel species, *Brachybacterium paraconglomeratum*, and the second strain was assigned to the reclassified species *Brachybacterium conglomeratum* (formerly "*Micrococcus conglomeratus*") which had been isolated from oil brine. The same authors (Takeuchi et al., 1995) also described another novel species of the genus, *Brachybacterium rhamnosum*, which had been isolated from corn steep liquor. Other species of the genus such as *Brachybacterium nesterenkovii*, *Brachybacterium alimentarium*, *Brachybacterium tyrofermentans*, *Brachybacterium fresconis*, *Brachybacterium sacelli*, *Brachybacterium muris*, *Brachybacterium phenoliresistens*, and *Brachybacterium zhongshanense* were recovered from cheese, from the surface of French Gruyère and Beaufort cheeses, from a medieval wall painting of the chapel of castle Herberstein (Austria), from the liver of a laboratory mouse, oil-contaminated sand (Pintunt County, Taiwan), and from river sediments (Zhongshan City, China), respectively (Buczolits et al., 2003; Chou et al., 2007; Gvozdyak et al., 1992; Heyrman et al., 2002; Schubert et al., 1996; Zhang et al., 2007). Strains of the genus were also detected in numerous sites: a surgical ward (Xu et al., 2004), Antarctic sea ice brine (Junge et al., 1998), melt water from accretion ice (Lake Vostok, the largest subglacial lake in Antarctica) at a depth of approximately 3.5 km (Christner et al., 2001), a flowerpot-using fed-batch reactors for composting of household biowaste (Hiraishi et al., 2003), Wijdefjord, Spitzbergen, capable of hydrolyzing amylopectin, pullulan, and skim milk (Groudieva et al., 2004), and Mediterranean sediments (Suess et al., 2004). Based on deposited 16S rRNA gene sequences, brachybacteria were also detected in sewage sludge compost (strain SSCS6, accession no. AB210986), in a commercial nitrifying inoculum (strain R-23117, accession no. AJ786820; strain R-23108, accession no. AJ786818), in sea sediment (strain BBH3, accession no. DQ358873), at the west coast of India (*Brachybacterium* sp. DV1, accession no. DQ190429), in a space craft assembly facility (SAFR 049, accession no. AY167842), as a jellyfish-degrading bacterium (TN-2003; accession no. AB101583), and from undesignated sources (*Brachybacterium* sp. LB25, accession no. AB257583; strain B-116, accession no. DQ399745; *Brachybacterium* sp. B-4021, accession no. DQ347542; *Brachybacterium* sp. B-4051, accession no. DQ347546).

All species exhibit a quinone system consisting of the predominant compound menaquinone MK-7; moderate amounts of MK-8 may be present as well. Fatty acid profiles are predominated by the presence of iso- and anteiso methyl-branched acids. Common to the species of the genus is the presence of diphosphatidylglycerol, phosphatidylglycerol, and some unknown phospho- and glycolipids in their polar lipid profiles, but the presence of other unknown polar lipids appears useful for discrimination between species. The peptidogylcan type is A4γ, but variations were identified in the composition of the interpeptide bridge. The muramic residues can be either *N*-acetylated or *N*-glycolated (Buczolits et al., 2003; Collins et al., 1988; Gvozdyak et al., 1992; Heyrman et al., 2002; Schubert et al., 1996; Takeuchi et al., 1995). The presence of teichoic acids with the unusual compound erythritol as the polyol and diaminoglucuronic acid as a substituent in *Brachybacterium alimentarium* and *Brachybacterium tyrofermentans* was reported by Schubert et al. (1996, 1993).

Cystathionine lyase activity, assumed to play an important role in the development of the flavor of certain cheeses, has been reported for two *Brachybacterium* strains (Curtin et al., 2001). Certain strains of *Brachybacterium conglomeratum* and *Brachybacterium tyrofermentans* are suspected to be able to carry out the proteolytic degradation of infectious prion protein PRP[SC] (Müller-Hellwig et al., 2006).

Enrichment and isolation procedures

No specific isolation medium has been described so far. Good growth occurs on PYES* agar, TSA (trypticase soy agar), and

*0.3% peptone, 0.3% yeast extract, 0.23% Na_2-succinate, 1.5% agar, pH 7.2.

R2A agar. Addition of 5–7.5% NaCl (w/v) supports growth of most *Brachybacterium* strains, but *Brachybacterium nesterenkovii* strains grow best in the presence of 0–0.5% NaCl (w/v), and *Brachybacterium phenoliresistens* grows best in the presence of 2–3% NaCl (w/v). Temperature range for growth of *Brachybacterium* strains is 4–42°C, but 28°C may be suitable to grow all strains.

Pathogenicity. No reports on pathogenicity of *Brachybacterium* species have been published so far. However, one case has been reported showing that *Brachybacterium paraconglomeratum* has been isolated from a hospital environment (Xu et al., 2004).

Maintenance procedures

Brachybacterium cultures may be lyophilized or stored as glycerol cultures at −80°C by common procedures used for many bacteria.

Differentiation of genus *Brachybacterium* from other genera

Brachybacterium may be distinguished from other genera in the family *Micrococcaceae* and its next phylogenetic neighbor, *Dermabacter hominis*, by cell-wall peptidoglycan, menaquinone type, colony pigmentation, major fatty acid, and DNA G+C content (Table 117).

List of species of the genus *Brachybacterium*

1. **Brachybacterium faecium** Collins, Brown and Jones 1988, 46[VP]

fae′ci.um. L. n. *faex* feces, dregs; L. gen. pl. n. *faecium* of dregs, of feces.

Surface colonies are small, gray, white or pale lemon, low convex, and smooth. Cells vary in shape from coccoid forms in the stationary phase to rods (0.5–0.75 × 1.5–2.5 μm) in the exponential phase. Cells are Gram-stain-positive, non-acid-fast, and nonmotile. Aerobic (but may show weak anaerobic growth). Optimum temperature 25–30°C. No growth in the presence of thallous acetate (0.01%) or sodium azide (0.01%). Grows well in the presence of 15% NaCl. Does not grow at pH 5.0 and pH 10.0. Catalase is produced; oxidase is not produced. Acid is produced from L-arabinose, D-galactose, D-glucose, and maltose. Acid is not produced from adonitol, dulcitol, inositol, salicin, and sorbose. Some strains produce acid from cellobiose and sucrose. Catalase-positive. Negative for desoxyribonuclease, oxidase, phosphatase, and sulfatase. Esculin and starch are hydrolyzed. Cellulose, chitin, gelatin, tyrosine, and xanthine are not hydrolyzed. Some strains degrade arginine, hippurate, urea, uric acid, and casein. Some strains reduce nitrate to nitrite. H_2S is not produced. Voges–Proskauer-negative.

Cell-wall peptidoglycan is based on *meso*-diaminopimelic acid. Galactose and glucose are the wall sugars. Mycolic acids are not present. The principal menaquinone is MK-7. The long-chain fatty acids are primarily of the straight-chain saturated, iso-and anteiso-methyl branched types, with 12-methyltetradecanoic ($C_{15:0}$ anteiso) and 14-methylhexadecanoic ($C_{17:0}$ anteiso) acids predominating. The major polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, several phospholipids, and several glycolipids and unknown lipids.

Characteristics differentiating the species of *Brachybacterium* are listed in Table 118.

Source: poultry deep litter.

DNA G+C content (mol%): 68–71.5 (T_m).

Type strain: Schefferle 6-10, ATCC 43885, CCUG 32293, CIP 103333, DSM 4810, IEGM 403, NBRC 14762, JCM 11609, NCIMB 9860, VKM Ac-1423.

Sequence accession no. (16S rRNA gene): X83810, X91032.

2. **Brachybacterium alimentarium** Schubert, Ludwig, Springer, Kroppenstedt, Accolas and Fiedler 1996, 86[VP]

a.li.men.ta′ri.um. L. neut. adj. *alimentarium* pertaining to food.

Surface colonies are medium sized, vivid lemon colored, low convex, and smooth. Cells vary in shape from coccoid forms in the stationary phase, which occur in small clusters of 4–8 cells, to club-shaped rods in the exponential phase, which occur in pairs. Facultatively anaerobic. The optimum temperature is 30°C, and the optimum pH is 7.3. Grows well in the presence of 15% NaCl. Grows weakly at pH 5.0, but not at pH 10.0. Catalase and urease are produced; oxidase is not produced. Starch, esculin, casein, gelatin, and Tween 20 are hydrolyzed. Tween 80 and tributyrin are not hydrolyzed. Nitrate is reduced to nitrite. Acid is produced from D-arabinose, L-arabinose, D-galactose, D-glucose, D-mannose, melibiose, raffinose, L-rhamnose, D-ribose, and D-xylose but not from D-fructose, lactose, maltose, sucrose, and D-sorbitol.

The cell-wall peptidoglycan is based on *meso*-diaminopimelic acid with a D-Asp–D-Glu interpeptide bridge (variation A4γ). Two teichoic acids are present; one contains erythritol and *N*,*N*9-diacetyl-2,3-diamino-2,3-dideoxyglucuronic acid, and the other contains *N*-acetylglucosamine and galactose as sugar constituents. The principal menaquinone is MK-7; MK-8 is present in substantial amounts. The long-chain fatty acids are primarily straight-chain, saturated, iso- and anteiso-methyl, branched fatty acids, with 12-methyltetradecanoic ($C_{15:0}$ anteiso) acid predominating. The major polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, a phospholipid, glycolipids, and unknown lipids.

[b]Buczolits et al. (2003).

[c]Takeuchi et al. (1995).

[d]Chou et al. (2007).

[e]Zhang et al. (2007).

Cells are Gram-stain-positive, nonmotile, and nonspore-forming. In the stationary growth phase, cells are coccoid; however, when a culture is transferred to fresh medium, the cells become oval or rod-shaped. Colonies are circular, entire, low convex, smooth, opaque, and whitish yellow or pale brown. Aerobic or facultatively anaerobic. Catalase and urease are produced; oxidase is not produced. Grows well in the presence of 15% NaCl. Some strains grow at pH 5.0 and pH 10.0. Starch and esculin are hydrolyzed, but Tween 20 and Tween 40 are not hydrolyzed. Some strains hydrolyze Tween 60 and Tween 80. Nitrate is reduced to nitrite. Acid is produced from L-arabinose, D-galactose, and

D-glucose. Acid is not produced from trehalose, mannitol, sorbitol, and xylitol.

The cell-wall peptidoglycan is based on *meso*-diaminopimelic acid. The cell wall sugars are galactose and glucose. The cell wall muramic acid occurs in the *N*-glycolyl form. Mycolic acids are absent. The principal menaquinone is MK-7. The long-chain fatty acids are primarily straight-chain, saturated, iso and anteiso methyl-branched fatty acids; $C_{15:0}$ anteiso and $C_{17:0}$ anteiso are the predominant fatty acids. The major polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, several glycolipids, phospholipids, unidentified aminophosphoglycolipids, and unknown lipids.

Type strain: AJ 1015, Komagata 5-2, CCM 2589, CCUG 50160, CCUG 50354, CIP 104400, DSM 10241, NBRC 15472, JCM 11608, VKM Ac-1975.

Sequence accession no. (16S rRNA gene): AB537169.

4. **Brachybacterium fresconis** Heyrman, Balcaen, De Vos, Schumann and Swings 2002, 1644[VP]

fres.co′nis. N.L. gen. n. *fresconis* pertaining or belonging to fresco(es).

Cells vary in shape from coccoid forms (single or in agglomerates) in the stationary phase, to short rods in the exponential phase. Cells are nonmotile, nonsporeforming, and stain Gram-positive. Colonies on marine agar after 24 h are small (<1 mm), cream-colored, smooth, glistening, circular in outline, and low convex. No growth in an anaerobic chamber on marine agar. The temperature range for growth is 5–40°C, with optimal growth between 20 and 30°C. Grows well in the presence of 15% NaCl. Grows at pH 5.0 and pH 10.0. Catalase and urease are produced; oxidase is not produced. Esculin and gelatin are hydrolyzed, starch, casein, Tween 20, and Tween 80 are not hydrolyzed. Nitrate is reduced to nitrite. Indole is not produced. Arginine dihydrolase-negative, and β-galactosidase-positive. Assimilation of arabinose, glucose, maltose, and mannose is positive; caprate, citrate, and malate are not assimilated. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid and is of the type A4γ (*m*-Dpm ← D-Glu ← D-Glu) with glycine bound to the *a*-carboxyl group of D-glutamic acid at position 2 of the peptide subunit. Muramic acid residues are glycolylated. Mycolic acids are absent. The principal menaquinone is MK-7; MK-8 is present in substantial amounts, and MK-7(H_2) in minor amounts. The main fatty acid is $C_{15:0}$ anteiso. The major polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, phospholipids, glycolipids, and unknown lipids.

Source: a medieval wall painting.

DNA G+C content (mol%): 70.4 (HPLC).

Type strain: DSM 14564, JCM 12138, LMG 20336.

Sequence accession no. (16S rRNA gene): AJ415378.

5. **Brachybacterium muris** Buczolits, Schumann, Weidler, Radax and Busse 2003, 1959[VP]

mu′ris. L. gen. n. *muris* of the mouse; the type strain was isolated from a mouse.

Cells are small, coccoid to ovoid, 1.2–1.5 µm in diameter. Cells occur singly, in pairs, or in agglomerates. Gram-stain-positive and nonsporeforming. Motility is not observed. Cells grow best on sheep blood agar plates and Brucella broth supplemented with 8% fetal bovine serum. Colonies on PYES agar are translucent, have light-yellow pigmentation, and are circular, convex, and smooth. Best growth is observed under microaerobic conditions; moderate growth is observed under aerobic conditions, but no growth occurs anaerobically. Colony diameters on sheep blood agar are 3–5 mm after 4 days incubation at 37°C under microaerobic conditions. The temperature range for growth is 15–42°C, with optimal growth between 25 and 37°C; no growth at 4°C. No growth is observed at pH 5.0, but the strain grows at pH 10.0. Does not grow in the presence of 15% NaCl.

Catalase is produced; oxidase and urease are not produced. Esculin, starch, Tween 20, and Tween 80 are hydrolyzed; casein is not hydrolyzed. Nitrate is not reduced to nitrite. Indole is not produced. Acid is produced from L-arabinose, D-arabinose, D-fructose, D-galactose, D-glucose, lactose, maltose, D-mannose, L-rhamnose, D-ribose, and sucrose, but not from melibiose, raffinose, D-xylose, and D-sorbitol.

The diagnostic cell-wall diamino acid is *meso*-diaminopimelic acid, and the peptidoglycan type is A31.3 (variation A4γ) containing the amino acids *meso*-diaminopimelic acid, alanine, glycine, aspartic acid, and glutamic acid. Muramic acid residues are *N*-acetylated and not *N*-glycolated. Mycolic acids are absent. The principal menaquinone is MK-7; MK-8 and MK-6 are present in minor amounts. The fatty acid profile consists of the predominant compound $C_{15:0}$ anteiso with significant amounts of $C_{14:0}$ iso, $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$ anteiso, and $C_{19:0}$. The polar lipid profile is composed of diphosphatidylglycerol, phosphatidylglycerol, three unknown glycolipids, two unknown phospholipids, and six unidentified polar lipids. Spermine and spermidine are the predominant components of the polyamine pattern.

Source: the liver of a laboratory mouse strain.

DNA G+C content (mol%): not available.

Type strain: C3H-21, CCM 7047, CCUG 50352, DSM 15460, JCM 14117.

Sequence accession no. (16S rRNA gene): AJ537574.

6. **Brachybacterium nesterenkovii** Gvozdyak, Nogina and Schumann 1992, 77[VP]

nes.te.ren.ko′vi.i. N.L. gen. masc. n. *nesterenkovii* of Nesterenko, named for O.A. Nesterenko, a Ukrainian microbiologist who has made a valuable contribution to the systematics of coryneform and nocardioform bacteria.

In the stationary growth phase, cells are coccoid (diameter 0.5–1 µm). During the exponential growth phase the cells are coccoid, oval, angular, and short rods that vary in size from strain to strain (up to 2 µm long). V-shaped cells are observed.

Colonies are matte and convex with regular edges; their surfaces are usually smooth but may be rough. The colony diameter on beef extract agar is up to 1.5 mm (rarely, 3 mm). The color of the colonies is lemon yellow on beef extract

agar and milk agar and pale grayish on glucose-asparagine agar. Facultatively anaerobic. Gram-stain-positive, non-acid-fast, nonmotile, and nonsporeforming. Grows well at 18–37°C. Grows on medium containing 20 μg of furazolidone per ml, and forms acid from glycerol in the presence of erythromycin. Does not grow on Simmons citrate agar. Grows weakly at pH 5.0, but not at pH 10.0. Catalase is produced; oxidase and urease are not produced. Acid is produced aerobically from L-arabinose, D-galactose, D-glucose, maltose, D-ribose, sucrose, and glycerol. D-Arabinose, erythrose, melezitose, rhamnose, L-sorbose, trehalose, adonitol, D-arabitol, L-arabitol, dulcitol, inositol, mannitol, and sorbitol are not attacked. Variable results are observed for acid formation from D-mannose, D-melibiose, D-xylose, salicin, and starch. Utilizes tartrate, oxaloacetate, and maleate. Some strains poorly utilize acetate, lactate, pyruvate, and succinate. Negative for phenylalanine deaminase and for lysine and ornithine decarboxylase. Ammonia production from arginine is detected 21 days after inoculation. Esculin is hydrolyzed. Tyrosine, gelatin, xanthine, hypoxanthine, Tween 40, Tween 60, and Tween 80 are not hydrolyzed. Tween 20 is hydrolyzed from some strains. Negative for lecithinase, hydrogen sulfide, and acetoin.

Susceptible to ampicillin, oxacillin, methicillin, carbenicillin, benzylpenicillin, streptomycin, neomycin, kanamycin, erythromycin, oleandomycin, rifampin, lincomycin, ristomycin, tetracycline, and chloramphenicol. Not susceptible to polymyxin.

The cell-wall peptidoglycan is based on *meso*-diaminopimelic acid with alanine and glutamic acid but without glycine. There are significant amounts of glucose, galactose, and rhamnose in the cells. Mycolic acids are absent. The principal menaquinone is MK-7. The main fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso. The major polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, several phospholipids, and several glycolipids, and unknown lipids.

DNA G+C content (mol%): 68.6 (HPLC).

Type strain: ATCC 51843, CIP 103334, DSM 46341, IEGM 404, NBRC 15224, JCM 11649, LMG 19861, NCIMB 9861, VKM Ac-1425.

Sequence accession no. (16S rRNA gene): AJ415377.

8. **Brachybacterium phenoliresistens** Chou, Lin, Lin, Sheu, Wei, Arun, Young and Chen 2007, 2677[VP]

phe.no.li.re.sis′tens. N.L. neut. n. *phenol* phenol; L. part. adj. *resistens* resisting; N.L. part. adj. *phenoliresistens* phenol resisting, referring to the organism's ability to resist phenol.

Cells are small, coccoid to ovoid shaped, 0.8–1.3 μm in diameter. Cells occur singly, in pairs or as agglomerates. Facultatively anaerobic. Gram-stain-positive (Gram staining and KOH test), nonmotile, and nonsporeforming. Colonies on marine 2216 agar are pale yellow, circular, and convex in shape with entire edges. Colonies are approximately 0.9–2.1 mm in diameter on marine 2216 agar after 48 h incubation at 28°C. No accumulation of poly-β-hydroxybutyrate granules is observed. Flexirubin-type pigments are present. Optimum growth occurs aerobically, while only moderate anaerobic growth is observed. Good growth occurs at temperatures of 4–40°C, 0.5–7.0% NaCl, and pH 5.0–10.0. Optimum growth occurs at 28–35°C, 2–3% NaCl, and pH 7.0. Acid is produced from arabinose, fructose, mannose, raffinose, rhamnose, sucrose, xylose, cellobiose, galactose, glucose, lactose, and trehalose, but not from ribose or sorbitol. Positive for catalase, DNase, and hydrolysis of starch and Tween 20. Weakly positive for hydrolysis of casein and Tween 40. Negative for oxidase, nitrate reduction, nitrite reduction, lipase (corn oil), and hydrolysis of Tweens 60 and 80. In the API Coryne system, positive for hydrolysis of pyrazinamidase, pyrrolidonyl arylamidase, alkaline phosphatase, β-glucuronidase, β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, and esculin; acid production from D-glucose, D-xylose, D-mannitol, maltose, D-lactose, and sucrose. Negative for nitrate reduction, urease, gelatin hydrolysis, and acid production from D-ribose and glycogen. With the API 20E system, positive for ONPG test, acetoin production, and acid production from glucose, mannitol, inositol, rhamnose, sucrose, amygdalin, and arabinose, but negative for nitrate reduction, arginine dihydrolase, lysine decarboxylase, orni-

thine decarboxylase, citrate utilization, H_2S production, urease, tryptophan deaminase, indole production, gelatinase, and acid production from sorbitol and melibiose. Positive enzyme reactions (API ZYM) for alkaline phosphatase, C4 esterase, C8 lipase, leucine arylamidase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase; weak positive reactions for C14 lipase, valine arylamidase, cystine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and β-glucuronidase, but negative reactions for trypsin and α-chymotrypsin. The following carbon substrates (Biolog GP2) are oxidized: β-cyclodextrin, dextrin, glycogen, Tween 40, *N*-acetyl-D-glucosamine, L-arabinose, D-arabitol, arbutin, D-cellobiose, D-fructose, D-galactose, gentiobiose, α-D-glucose, maltose, maltotriose, D-mannitol, D-mannose, D-melezitose, methyl β-D-glucoside, palatinose, D-psicose, D-raffinose, salicin, D-sorbitol, stachyose, sucrose, trehalose, turanose, xylitol, pyruvic acid methyl ester, glycerol, adenosine, and 2′-deoxyadenosine. Unable to oxidize α-cyclodextrin, inulin, mannan, Tween 80, *N*-acetyl-β-D-mannosamine, amygdalin, L-fucose, D-galacturonic acid, D-gluconic acid, *myo*-inositol, α-D-lactose, lactulose, D-melibiose, methyl α-D-galactoside, methyl β-D-galactoside, 3-methyl D-glucose, methyl α-D-glucoside, methyl α-D-mannoside, L-rhamnose, D-ribose, sedoheptulosan, D-tagatose, D-xylose, acetic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, p-hydroxyphenylacetic acid, α-ketoglutaric acid, α-ketovaleric acid, lactamide, D-lactic acid methyl ester, L-lactic acid, D-malic acid, L-malic acid, succinic acid monomethyl ester, propionic acid, pyruvic acid, succinamic acid, succinic acid, *N*-acetyl-L-glutamic acid, L-alaninamide, D-alanine, L-alanine, L-alanyl glycine, L-asparagine, L-glutamic acid, glycyl L-glutamic acid, L-pyroglutamic acid, L-serine, putrescine, 2,3-butanediol, inosine, thymidine, uridine, adenosine, uridine 5′-monophosphate, D-fructose 6-phosphate, α-D-glucose 1-phosphate, D-glucose 6-phosphate, or DL-α-glycerol phosphate. Resistant to ampicillin, gentamicin, nalidixic acid, and tetracycline, but sensitive to chloramphenicol, erythromycin, kanamycin, novobiocin, penicillin G, rifampin, and streptomycin.

The diagnostic cell-wall diamino acid is *meso*-diaminopimelic acid, and the peptidoglycan type is variation A4γ containing amino acids *meso*-diaminopimelic acid, alanine, glycine, aspartic acid, and glutamic acid. The polar lipid profile consists of diphosphatidylglycerol, phosphatidylglycerol, three unknown glycolipids, and one unknown phospholipid. The predominant fatty acid is $C_{15:0}$ anteiso with significant amounts of $C_{16:0}$ iso, $C_{14:0}$ iso, and $C_{17:0}$ anteiso. The major menaquinone is MK-7.

Source: oil-contaminated coastal sand, Pingtung County, Taiwan.

DNA G+C content (mol%): 70.8 (HPLC).

Type strain: phenol-A, BCRC 17589, JCM 15157, LMG 23707.

Sequence accession no. (16S rRNA gene): DQ822566.

9. **Brachybacterium rhamnosum** Takeuchi, Fang and Yokota 1995, 167[VP]

rham.nos′um. L. n. *rhamnosum* rhamnose, referring to the abundance of rhamnose in the cell wall.

Cells are Gram-stain-positive, nonmotile, and nonsporeforming. In the stationary growth phase, cells are coccoid; however, when a culture is transferred to fresh medium, the cells become oval or rod-shaped. Colonies are circular, entire, low convex, smooth, opaque, and whitish yellow. Aerobic or facultatively anaerobic. Catalase and urease are produced; oxidase is not produced. Does not grow in the presence of 15% NaCl. Grows at pH 5.0, but not at pH 10.0. Starch, esculin, and casein are hydrolyzed, but Tween 20, Tween 40, Tween 60, and Tween 80 are not hydrolyzed. H_2S is produced. Nitrate is reduced to nitrite. Acid is produced from L-arabinose, cellobiose, D-fructose, D-galactose, D-glucose, maltose, D-mannose, melibiose, melezitose, raffinose, D-ribose, salicin, sucrose, trehalose, D-xylose, adonitol, inositol, and sorbitol. Acid is not produced from D-arabinose, lactose, and L-rhamnose.

The cell-wall peptidoglycan is based on *meso*-diaminopimelic acid. The cell wall sugars are galactose, glucose, and rhamnose. The cell wall muramic acid occurs in the *N*-glycolyl form. Mycolic acids are absent. The principal menaquinone is MK-7. The long-chain fatty acids are primarily straight-chain, saturated, iso and anteiso methyl-branched fatty acids; $C_{15:0}$ anteiso and $C_{17:0}$ anteiso are the predominant fatty acids. The major polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, several phospholipids, and several glycolipids and unknown lipids.

Source: commercially available corn steep liquor.

DNA G+C content (mol%): 71.5 (HPLC).

Type strain: H-6S, ATCC 51844, CIP 104398, DSM 10240, NBRC 15203, JCM 11650, LMG 19848, VKM Ac-1976.

Sequence accession no. (16S rRNA gene): AJ415376.

10. **Brachybacterium sacelli** Heyrman, Balcaen, De Vos, Schumann and Swings 2002, 1644[VP]

sa.cel′li. L. gen. n. *sacelli* of the chapel.

Cells vary in shape from coccoid forms (single or in agglomerates) in the stationary phase, to short rods in the exponential phase. Cells are nonmotile, nonsporeforming, and stain Gram-positive. Colonies on marine agar after 24 h are small (<1 mm), cream-colored, smooth, glistening, circular in outline, and low convex. No growth in an anaerobic chamber on marine agar. The temperature range for growth is 5–40°C, with optimal growth between 20 and 30°C. Grows well in the presence of 15% NaCl. Grows at pH 5.0, but not at pH 10.0. Catalase is produced, oxidase and urease are not produced. Esculin is hydrolyzed, starch, casein, Tween 20, Tween 80, and gelatin are not hydrolyzed. Nitrate is reduced to nitrite. Indole is not produced. Arginine dihydrolase-negative, and β-galactosidase-positive. Strains assimilate gluconate, maltose, mannose, mannitol, and *N*-acetylglucosamine, but not adipate, arabinose, caprate, citrate, glucose, and malate.

The cell-wall peptidoglycan contains *meso*-diaminopimelic acid and is of the type A4γ (*m*-Dpm ← D-Glu ← D-Glu) with glycine bound to the *a*-carboxyl group of D-glutamic acid at position 2 of the peptide subunit. Muramic acid residues are glycolylated. Mycolic acids are absent. The principal menaquinone is MK-7 in combination with either MK-8 in lower but still considerable amounts, or in approximately equal amounts. MK-7(H_2) or MK-9 are present in minor

amounts in some strains. The main fatty acid is $C_{15:0}$ anteiso. The major polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, phospholipids, glycolipids, and unknown lipids.

Source: a medieval wall painting.

DNA G+C content (mol%): 70.3 (HPLC).

Type strain: CCUG 50347, DSM 14566, JCM 12139, LMG 20345.

Sequence accession no. (16S rRNA gene): AJ415384.

11. **Brachybacterium tyrofermentans** Schubert, Ludwig, Springer, Kroppenstedt, Accolas and Fiedler 1996, 86[VP]

ty.ro.fer.men′tans. Gr. n. *tyros* cheese; L. part. adj. *fermentans* leavening; N.L. part. adj. *tyrofermentans* fermenting cheese.

Surface colonies are medium sized, pale flaxen, low convex, and smooth. Cells vary in shape from coccoid forms in the stationary phase, which occur in large agglomerations, to club-shaped rods in the exponential phase, which occur predominantly in pairs or agglomerations of four cells. Facultative anaerobic. The optimum temperature is 30°C, and the optimum pH is 7.3. Grows weakly in the presence of 15% NaCl. Does not grow at pH 5.0 and pH 10.0. Catalase is produced; oxidase and urease are not produced. Esculin and gelatin are hydrolyzed. Starch, casein, Tween 20, Tween 80, and tributyrin are not hydrolyzed. Tyrosine and xanthine are not utilized. Nitrate and nitrite are reduced. Acid is produced from L-arabinose, D-galactose, D-glucose, D-mannose, melibiose, raffinose, L-rhamnose, and D-ribose, but not from D-arabinose, D-fructose, lactose, maltose, sucrose, D-xylose, and D-sorbitol.

The cell-wall peptidoglycan is based on *meso*-diaminopimelic acid with a D-Asp–D-Glu interpeptide bridge (variation A4γ). One teichoic acid structure is present; this structure contains erythritol, *N*-acetylglucosamine, and *N*,*N*9-diacetyl-2,3-diamino-2,3-dideoxyglucuronic acid. The principal menaquinone is MK-7. The long-chain fatty acids are primarily straight-chain, saturated, iso- and anteiso-methyl, branched fatty acids, with 12-methyltetradecanoic ($C_{15:0}$ anteiso) acid predominating. The major polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, phospholipids, glycolipids, and unknown lipids.

Source: the surfaces of Beaufort and Gruyère cheeses.

DNA G+C content (mol%): 73.0 (T_m).

Type strain: ATCC 700068, CCUG 50353, CIP 104812, CNRZ 926, DSM 10673, NBRC 16119, JCM 11610, LMG 19552.

Sequence accession no. (16S rRNA gene): X91657.

12. **Brachybacterium zhongshanense** Zhang, Zeng, Cai, Deng, Luo and Sun 2007, 2523[VP]

zhong.shan.en′se. N.L. neut. adj. *zhongshanense* pertaining to Zhongshan, a city in China, from where the type strain was isolated.

Cells vary in shape from coccoid forms (irregular) in the stationary phase to short rods in the exponential phase. Cells are nonmotile, Gram-stain-positive, and non-sporeforming. Colonies on LB plates are cream-colored, smooth, glistening, and grow well in an anaerobic chamber on LB plates. Temperature range for good growth is 25–40°C; no growth occurs at 4 or 45°C. Grows in 0–10% (w/v) NaCl. Grows well at pH 5.0–8.0 and weakly at pH 9.0–11.0; no growth is observed at pH 12.0–14.0. Catalase and urease are produced. Oxidase is not produced. Esculin and gelatin are hydrolyzed, but starch is not. Nitrate is reduced to nitrite. Indole is not produced. Positive for arginine dihydrolase and denitrification. Acid is produced from glucose. Utilizes the following carbon sources: α-cyclodextrin, β-cyclodextrin, dextrin, glycogen, inulin, amygdalin, L-arabinose, arbutin, D-cellobiose, D-fructose, D-galactose, D-galacturonic acid, gentiobiose, α-D-glucose, α-D-lactose, lactulose, maltose, maltotriose, D-mannose, D-melezitose, D-melibiose, methyl α-D-galactoside, methyl β-D-galactoside, methyl β-D-glucoside, palatinose, D-psicose, D-raffinose, stachyose, sucrose, D-tagatose, trehalose, turanose, xylitol, D-xylose, acetic acid, L-lactic acid, pyruvic acid methyl ester, pyruvic acid, glycerol, adenosine, inosine, and thymidine. Predominant fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: sediments along the Qijiang River, Zhongshan City, China.

DNA G+C content (mol%): 71.2 (T_m).

Type strain: JB, CGMCC 1.6508, DSM 18832, JCM 15471, LMG 23926.

Sequence accession no. (16S rRNA gene): EF125186.

Family VII. **Dermacoccaceae** Stackebrandt and Schumann 2000, 1285VP emend. Zhi, Li and Stackebrandt 2009, 597

Erko Stackebrandt

Der.ma.coc.ca.ce′a.e. N.L. masc. n. *Dermacoccus* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Dermacoccaceae* the *Dermacoccus* family.

Gram-stain-positive cocci to short rods; nonmotile; non-acid-fast; nonencapsulated; nonsporeforming. Chemoorganotrophic; aerobic or microaerophilic with formation of acids from some carbohydrates. Catalase positive. Mesophilic and, when tested, nonhalophilic. **The peptidoglycan type is either L-Lys–L-Ser$_{1-2}$–D-Glu or L-Lys–L-Ser$_2$(L-Ala)–D-Glu, or L-Lys–Glu$_2$, or Lys–L-Ser–D-Asp, variation A4α.** When tested, muramic acid is acetylated; mycolic acids and teichoic acids are absent. **The menaquinones are either hydrogenated or completely unsaturated. Main fatty acids are anteiso-methyl and iso-methyl-branched; straight-chain saturated and monounsaturated fatty acid may occur.** Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol; phosphatidyl-ethanolamine and two unknown phospholipids occur in one genus.

The pattern of 16S rRNA gene signatures consists of nucleotides at positions 120 (A), 131:231 (A–G), 196 (C), 342:347 (C–G), 444:490 (A–U), 580:761 (U–A), 602:636 (C–G), 670:736 (A–U), 822:878 (G–C), 823:877 (G–C), 826:874 (C–G), 827 (U), 843 (c), 950:1231 (U–A), 1047:1210 (G–C), 1109 (C), 1145 (G), 1309:1328 (G–C), 1361 (G), and 1383 (C) (Zhi et al., 2009).

DNA G+C content (mol%): 66–71.

Type genus: **Dermacoccus** Stackebrandt, Koch, Gvozdiak and Schumann 1995, 689VP.

Taxonomic comments

According to the taxonomic outline for this volume, the family *Dermacoccaceae* Stackebrandt and Schumann 2000 is a member of the order *Micrococcales* (elevated from suborder *Micrococcineae* of Stackebrandt et al., 1997), originally established on the basis of 16S rRNA gene sequence signatures. In the first attempt to use such signatures for an intra-class taxonomic structure of the *Actinobacteria* (Stackebrandt et al., 1997), the genera *Dermacoccus* and *Kytococcus* were placed within the family *Dermatophilaceae*. However, with the description of the genus *Demetria* and several other new genera of the *Micrococcineae*, the necessity to describe novel families within the suborder became obvious. Based upon a revised set of signature nucleotides, the genera *Dermacoccus* and *Kytococcus* were removed from *Dermatophilaceae* and formed, together with *Demetria*, the family *Dermacoccaceae* (Stackebrandt and Schumann, 2000).

The high degree of sequence similarity shared between type strains of genera of *Micrococcineae* made the topologies of phylogenetic trees prone to the number and selection of organisms of the suborder and outside reference organisms. In certain dendrograms *Serinicoccus marinus*, a member of *Intrasporangiaceae*, clustered with all three members of *Dermacoccaceae* (ARB, Ludwig et al., 2004; Mayilraj et al., 2006) while, in another dendrogram, *Serinicoccus marinus* branched outside the radiation of *Dermacoccaceae* [with *Ornithinobacterium humiphilum* (Yi et al., 2004)]. However, most of the recently published studies on novel taxa of *Micrococcineae* (now *Micrococcales*) did not include both members of *Dermacoccaceae* and *Seriniccocus marinus*. In the absence of members of *Dermacoccaceae*, *Seriniccocus marinus* did often cluster with *Ornithinimicrobium* species (Montero-Barrientos et al., 2005; Jung et al., 2006; Lee, 2006; Liu et al., 2008; Groth and Kämpfer, 2012, this volume), but not exclusively (Lee and Lee, 2007).

As shown by Groth and Kämpfer (2012, this volume) and Schumann (2012, this volume) in the descriptions of *Intrasporangiaceae* and *Serinicoccus*, respectively, the presence of ornithine as diagnostic amino acid in the peptidoglycan links *Serinibacter marinus* to certain members of *Intrasporangiaceae*; also, members of *Dermacoccaceae* do not match the revised set of signature nucleotides of *Intrasporangiaceae* (Groth and Kämpfer, 2012) and *Serinicoccus marinus* fails to match the set provided for *Dermacoccaceae* (Zhi et al., 2009).

The main characteristics differentiating members of *Dermacoccaceae* and phylogenetically related genera are depicted by Schumann (2012, this volume) in the description of *Serinicoccus*, while Groth and Kämpfer (2012, this volume) provide an overview of the morphological and chemotaxonomic heterogeneity of the family *Intrasporangiaceae*.

Genus I. **Dermacoccus** Stackebrandt, Koch, Gvozdiak and Schumann 1995, 689VP

Erko Stackebrandt

Der.ma.coc′cus. N.L. n. *derma* skin: Gr. masc. n. *kokkos* a grain, berry: N.L. masc. n. *Dermacoccus* coccus living on skin.

Cells are coccoid. Gram-stain-positive. Nonencapsulated. Nonsporeforming. **Chemoorganotrophic; aerobic; rarely weak growth occurs under microaerophilic conditions.** Catalase positive. Nonhalophilic. Mesophilic. **The peptidoglycan type is type L-Lys–L-Ser$_{1-2}$–D-Glu or L-Lys–L-Ser$_2$(L-Ala)–D-Glu, variation A4α.** Muramic acid is acetylated. Mycolic acids and teichoic acids are absent. Galactosamine is the major constituent of cell wall polysaccharide. **The menaquinones are hydrogenated; the predominant menaquinone is MK-8(H$_2$).** The cytochromes are cytochromes aa_3, c_{549}, c_{555}, b_{559}, b_{564}, and d_{626} (one type strain analyzed).

The polar lipids include diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol. **The major fatty acids are $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$ iso, and $C_{17:0}$ ante.** If present, the long-chain aliphatic hydrocarbons are C22 and C23 hydrocarbons, as well as minor amounts of C25, C26, and C27 hydrocarbons.

DNA G+C content (mol%): 65.2–71.1.

Type species: **Dermacoccus nishinomiyaensis** (Oda 1935) Stackebrandt, Koch, Gvozdiak and Schumann 1995, 689[VP] emend. Kocur, Schleifer and Kloos 1975, 291 (*Micrococcus nishinomiyaensis* Oda 1935, 1202).

Further descriptive information

Originally described by Oda (1935) on the basis of a single strain, the species *Micrococcus nishinomiyaensis* was emended by Kocur et al. (1975) on the basis of the characterization of 31 strains isolated from human skin (Kloos et al., 1974). Subsequent chemotaxonomic (Faller et al., 1980) and 16S rRNA gene sequence analysis (Koch et al., 1994) data have shown the taxonomic separateness of *Micrococcus nishinomiyaensis* from authentic *Micrococcus* species, leading to its reclassification as *Dermacoccus nishinomiyaensis* (Stackebrandt et al., 1995). This genus, together with *Kytococcus* (Stackebrandt et al., 1995) and *Demetria* (Groth et al., 1997a) were enclosed in the family *Dermacoccaceae* on the basis of phylogenetic relatedness and the presence of a unique set of nucleotides of the 16S rRNA gene sequences (Stackebrandt and Schumann, 2000).

The strains affiliated to the species differ in chemotaxonomic and physiological properties which, however, may be within the range of intra-species diversity (Kocur et al., 1975). Only two of the 31 strains investigated show a profile identical to that of the type strain Oda no. 59^T in the 24 properties tested. None of the strains produce acid from glucose anaerobically, but about one third of the strains are able to produce acid aerobically. The interpeptide bridge of peptidoglycan shows some variations. While the majority of strains show an L-Ser–L-Ser_2–D-Glu composition, two strains have an L-Ser–D-Glu variation and, in five strains, a part of the second serine residue is replaced by L-alanine [L-Ser–L-Ser (L-Ala)–D-Glu]. With respect to the fatty acid composition of *Dermacoccus nishinomiyaensis*, the literature indicates conflicting results: while Stackebrandt et al. (1995) indicates the presence of a significant amount of unsaturated branched-chain acids, notably $C_{17:0}$ iso (11–33% of total), this component is neither detected in *Dermacoccus nishinomiyaensis* nor in the type strains of *Dermacoccus abyssi* (Pathom-aree et al., 2006a) *Dermacoccus barathi*, and *Dermacoccus profundi* (Pathom-aree et al., 2006b). These authors discuss the possibility that growth conditions may influence the composition of fatty acids in dermacocci and related organisms.

While most strains have been isolated from the skin of humans, one report indicates the presence of *Dermacoccus* species (5.5% of 369 strains isolated) in salt used in the production of Spanish dry-cured ham (Cordero and Zumalacarregui, 2000). As these findings conflict with the lack of growth of *Dermacoccus nishinomiyaensis* strains in 7.5% NaCl (Kocur et al., 1975), it can be assumed that either the Spanish isolates belong to a new taxon or these organisms are transient but not actively growing on the surface of salted ham.

The production of monensin has been reported for three *Dermacoccus nishinomiyaensis* strains (Pospisil et al., 1998).

Phylogenetic analysis indicates a very high similarity between the type strains of *Dermacoccus profundi* MT2.2^T and *Dermacoccus barathri* MT2.1^T which share 99.9% 16S rRNA gene similarity and differ in a single nucleotide only. Almost as highly related is *Dermacoccus abyssi* MT1-1^T (99.8%), while *Dermacoccus nishinomiyaensis* DSM 20448^T is slightly more distantly related (98.5–98.6%) (Pathom-aree et al., 2006a, 2006b). Despite the high gene sequence similarities, all strains are genomically well separated, as DNA–DNA reassociation experiments among the four type strains of the genus (Pathom-aree et al., 2006a, 2006b), using the microplate method of Ezaki et al. (1989), shows less than 25% DNA–DNA reassociation similarities.

Dermacoccus abysii MT1-1^T grows well at 40 Mpa and can be considered a piezotolerant actinobacterium. At this pressure, strains of *Dermacoccus nishinomiyaensis* DSM 20448^T show a decrease in cell numbers (Pathom-aree et al., 2006a); information on the other two type strains is not available (Pathom-aree et al., 2006b).

Enrichment and isolation procedures

Samples from human skin were obtained by sterile cotton swabs moistened with a sterile detergent containing 0.1% Triton X-100 (Packard) in 0.075 M phosphate buffer, pH 7.9. Each swab was used to inoculate the surface of an agar plate (10 cm diameter) which was incubated at 34°C for 4 d (Kloos et al., 1974). The isolation medium was non-selective, containing gram per liter: peptone (Difco), 10; yeast extract (Difco), 5; sodium chloride, 5; glucose, 1; agar (Difco), 15.

Strains of the other three species were isolated from a sediment sample from the Mariana Trench (Challenger deep) at a depth of 10,898 m using sterilized mud samplers and the remotely operated submersible *Kaiko* (Kato et al., 1997). The sample (2 ml) was transported to the UK in an insulated container at 4°C and then stored at −20°C. The strains were isolated from a suspension of the sediment sample used to inoculate a raffinose-histidine agar plate (Vickers et al., 1984) supplemented with cycloheximide and nystatin. The isolates were maintained on glucose-yeast extract agar plates (Gordon and Mihm, 1962) at room temperature and as glycerol suspensions (20%, v/v) at −20°C.

Maintenance procedures

Serial transfers on nutrient agar at 4-week intervals followed by maintenance at 4°C are recommended. Storage of cells as 20% (w/v) glycerol suspensions at −20°C and at −80°C is a suitable preservation method. Long-term preservation methods include freeze-drying in skim milk and maintenance in liquid nitrogen at −196°C.

Differentiation of the genus *Dermacoccus* from other genera

By comparative 16S rRNA gene sequence analysis, the genus *Dermacoccus* is about equidistantly related to the genera of the family *Dermacoccaceae*, i.e. *Kytococcus* and *Demetria*. Including the sequences of the type species of all genera of *Micrococcineae* (now *Micrococcales*) into a neighbor-joining analysis (not shown), *Serinicoccus* appears to be the nearest genus outside the family. This contrasts the study by Yi et al. (2004) in which the type species *Serinicoccus marinus* branched adjacent to *Ornithinomicrobium*. As the same publication, however, also finds *Kytococcus sedentarius* to branch outside the family *Dermacoccaceae*, the inclusion of only a small number of reference sequences may cause an erroneous branching pattern. Depending on the selection of reference organisms and treeing algorithm used, the topology of phylogenetic trees may differ significantly. None of the deeper branchings are of statistical significance, and in no case will a species from a neighboring genus be so close to *Dermacoccus* species that it may be regarded a member of *Dermacoccus*. As seen in Table 119 of the description of *Dermacoccaceae*, *Dermacoccus*, *Kytococcus*, and *Demetria* contain L-lysine as diagnostic amino acid, while L-ornithine is present in *Ornithinococcus*, *Serinicoccus*, and *Ornithinomicrobium*. The latter two genera and *Demetria* possess MK-8(H_4) as major menaquinone; *Dermacoccus* possesses MK-8(H_2), while *Kytococcus* has fully saturated menaquinones. Sufficient differences occur in the combination of phylogenetic position, morphological traits, and chemotaxonomic markers to unambiguously affiliate new isolates to the genus *Dermacoccus*.

List of species of the genus *Dermacoccus*

1. **Dermacoccus nishinomiyaensis** (Oda 1935) Stackebrandt, Koch, Gvozdiak and Schumann 1995, 689^{VP} emend. Kocur, Schleifer and Kloos 1975, 291 (*Micrococcus nishinomiyaensis* Oda 1935, 1202)

ni.shi.no.mi.ya.en′sis. N.L. masc. adj. *nishinomiyaensis* pertaining to Nishinomiya, a city in Japan.

In addition to the properties given in the genus description, this species has the following properties. Percentages in parentheses indicate the percent of the 32 strains studied which are positive for the character cited (Kocur et al., 1975). Cells are spherical (diameter, 0.9–1.6 mm) and occur in pairs, tetrads, or irregular clusters of tetrads. Colonies are up to 2 mm in diameter, circular, entire, slightly convex, smooth with glistening (rarely matt) surfaces, and bright orange. Colony morphology and color become more distinct with age; cell morphology is not culture age or medium dependent. Some strains produce a water-soluble orange exopigment. Slight turbidity and a deposit occur during growth in nutrient broth.

The final pH in glucose broth is 5.4–6.9. Growth is weak or absent on inorganic nitrogen agar and growth does not occur on Simmons' citrate agar (85%); benzidine test is positive. Negative for free or bound coagulase, phosphatase, lecithinase, arginine dihydrolase, ornithine and lysine decarboxylases, phenylalanine deaminase, β-galactosidase, and DNase. Most strains produce urease (80%). Gelatin is hydrolyzed (100%), but esculin is not hydrolyzed. Hydrolysis of starch (35%) and Tween 80 is variable (60%). Acetoin, indole, and hydrogen sulfide are not produced. Does not utilize sucrose, lactose, galactose, rhamnose, xylose, glycerol, and mannitol. Most strains do not utilize fructose and mannose. Utilization of glucose and galactose is variable. Reduction of nitrate to nitrite is variable (67%); nitrite reduction negative. Methyl red test is negative. Cysteine or methionine and niacin are required. Growth is stimulated by tryptophan, valine, aspartic acid, glutamic acid, proline, and lysine. Susceptible to novobiocin and neomycin. Most strains are susceptible to erythromycin, penicillin, streptomycin, and chloramphenicol; resistant to furazolidone, resistant or slightly resistant to lysozyme, and weakly resistant to methicillin. Grows well in the presence of up to 5% NaCl; no growth occurs in the presence of 7% NaCl. Grows well at 25–37°C. Saprophytic. Nonhemolytic.

Source: type strain isolated from water using for brewing sake. Other strains isolated from skin of humans and other sources.

DNA G+C content (mol%): 67.8 (T_m).

Type strain: Oda no. 59, ATCC 29093, CCM 2140, CCUG 33028, CIP 81.71, DSM 20448, IEGM 393, NBRC 15356, JCM 11613, LMG 14222, NCTC 11039, VKM B-1818.

Sequence accession no. (16S rRNA gene): X87757.

2. **Dermacoccus abyssi** Pathom-aree, Nogi, Sutcliffe, Ward, Horikoshi, Bull and Goodfellow 2006a, 1235[VP]

a.bys′si. L. gen. n. *abyssi* of an abyss.

Non-acid–alcohol-fast, nonmotile actinomycete. Forms coccoid cells (diameter 0.8–1.5 μm) that occur in irregular clusters. Cream to pale yellow, circular, entire, convex, smooth, glistening colonies are formed on glucose-yeast extract agar after 5 d at 28°C. Grows well on tryptic soy agar but poorly on inorganic nitrogen agar. Growth occurs between 10 and 37°C, with optimum growth around 28°C. In addition to the properties given in the genus description, this species has the following properties. Casein, cellulose, hypoxanthine, starch, and uric acid are degraded. Growth occurs in the presence of 7.5% NaCl. Piezotolerant grows well in glucose-yeast extract broth at 40 MPa. Additional phenotypic properties are shown in Table 119.

Source: sediment collected from the Challenger Deep of the Mariana Trench at a depth of 10,898 m.

DNA G+C content (mol%): 65.2 (HPLC).

Type strain: MT1.1, DSM 17573, JCM 14339, NCIMB 14084.

Sequence accession no. (16S rRNA gene): AY894323.

3. **Dermacoccus barathri** Pathom-aree, Nogi, Ward, Horikoshi, Bull and Goodfellow 2006b, 2306[VP]

ba.ra′thri. L. neut. n. *barathrum* a deep pit, an abyss; L. gen. n. *barathri* of an abyss.

Aerobic, Gram-stain-positive, non-acid–alcohol-fast, nonmotile actinomycete that forms coccoid cells (diameter 0.8–1.5 μm) that occur in irregular clusters. Light yellow, circular, entire, convex, smooth, glistening colonies are formed on glucose-yeast extract agar after 5 d at 28°C. Grows well on tryptic soy agar, but poorly on inorganic nitrogen agar. Growth occurs between 10 and 37°C, with an optimum around 28°C. In addition to the properties given in the genus description, hypoxanthine, Tween 20, Tween 40, and uric acid are degraded. Acid is not formed from (+)-D-arabinose, (+)-D-arabitol, (−)-L-arabitol, (+)-D-cellobiose, dextran, *meso*-erythritol, (+)-D-fructose, (+)-D-galactose, (+)-D-glucose, glycerol, glycogen, *myo*-inositol, inulin, (+)-D-maltose, (+)-D-mannitol, (+)-D-mannose, (+)-D-melezitose, (+)-D-melibiose, (+)-D-raffinose, (−)-L-rhamnose, (+)-D-salicin, (+)-D-sucrose, (+)-D-trehalose, (+)-D-sorbitol, (+)-L-sorbose, xylitol, or (+)-D-xylose. Additional phenotypic properties are shown in Table 119.

Source: sediment collected from the Challenger Deep of the Mariana Trench at a depth of 10,898 m.

DNA G+C content (mol%): 66.8 (HPLC).

Type strain: MT2.1, DSM 17574, JCM 14588, NCIMB 14081.

Sequence accession no. (16S rRNA gene): AY894328.

4. **Dermacoccus profundi** Pathom-aree, Nogi, Ward, Horikoshi, Bull and Goodfellow 2006b, 2306[VP]

pro.fun′di. L. neut. n. *profundum* depth, abyss; L. gen. n. *profundi* of an abyss.

Aerobic, Gram-stain-positive, non-acid–alcohol-fast, nonmotile actinomycete that forms coccoid cells (diameter 0.8–1.5 μm) that occur in irregular clusters. Brilliant yellow, irregular, entire, pulvinate, rough colonies with matted surfaces are formed on glucose-yeast extract agar after 5 days at 28°C. Grows well on tryptic soy agar but poorly on inorganic nitrogen agar. Growth occurs between 10 and 37°C, with an optimum around 28°C. In addition to the properties given in the genus description, hypoxanthine, Tween 20, Tween 40, and uric acid are degraded. Acid is not formed from (+)-D-arabinose, (+)-D-arabitol, (−)-L-arabitol, (+)-D-cellobiose, dextran, *meso*-erythritol, (+)-D-fructose, (+)-D-galactose, (+)-D-glucose, glycerol, glycogen, *myo*-inositol, inulin, (+)-D-maltose, (+)-D-mannitol, (+)-D-mannose, (+)-D-melezitose, (+)-D-melibiose, (+)-D-raffinose, (−)-L-rhamnose, (+)-D-salicin, (+)-D-sucrose, (+)-D-trehalose, (+)-D-sorbitol, (+)-L-sorbose, xylitol, or (+)-D-xylose. Additional phenotypic properties are shown in Table 119.

Source: sediment collected from the Challenger Deep of the Mariana Trench at a depth of 10,898 m.

DNA G+C content (mol%): 69.1 (HPLC).

Type strain: MT2.2, DSM 17575, JCM 14589, NCIMB 14126.

Sequence accession no. (16S rRNA gene): AY894329.

Genus II. **Demetria** Groth, Schumann, Rainey, Martin, Schuetze and Augsten 1997a, 1132[VP]

Ingrid Groth and Peter Kämpfer

De.me′tri.a. Gr. n. *Demeter* Greek god of agriculture and wives; L. fem. suff. *-ia* suff. denoting belonging to; N.L. fem. *Demetria* a bacterium being responsible for fertility.

Cells are irregularly **coccoid to rod-shaped**, 0.8–1.2 × 0.8–3.0 μm. They occur singly, in pairs, short chains, or in small irregular clusters. Gram-stain-positive. Not acid fast. Nonsporeforming. **Nonmotile. Aerobic to microaerobic**. Colonies are circular, smooth, convex, white to pale yellow, and 1–3 mm in diameter. Optimum temperature for growth is 28°C; no growth occurs at 37°C. **Oxidase negative, catalase positive**. The **peptidoglycan type is A4α** with L-lysine as the characteristic diamino acid. The **acyl type is acetyl**. **Galactose** is the only whole-cell sugar. The only **respiratory quinone** is **MK-8(H_4).** The **polar lipids** are composed of **phosphaditylinositol, phophaditylglycerol, diphophaditylglycerol, phosphatidylethanolamine, and two unknown phospholipids**. The cellular fatty acid profile is complex with large amounts of saturated and monounsaturated straight-chain acids and smaller amounts of iso- and anteiso-branched-chain acids. Mycolic acids are absent. Based on 16S rRNA gene sequence comparison, the genus *Demetria* is most closely related to members of the genera *Dermacoccus* and *Kytococcus*.

DNA G+C content (mol%): 66.

Type species: **Demetria terragena** Groth, Schumann, Rainey, Martin, Schuetze and Augsten 1997a, 1132[VP].

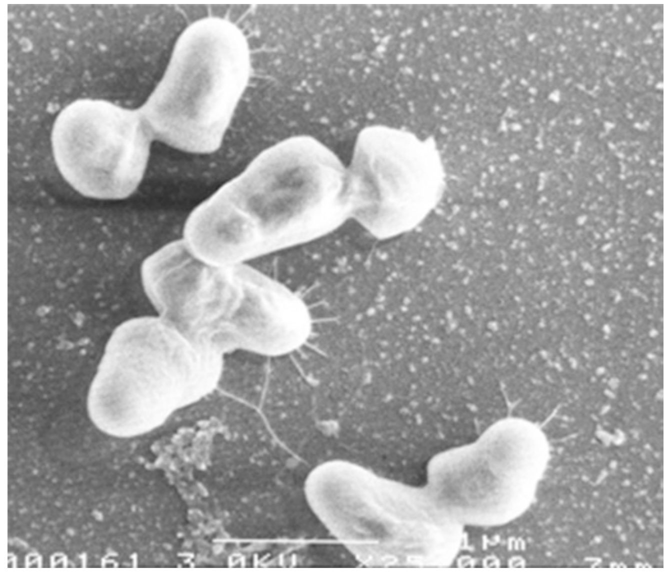

FIGURE 156. Scanning electron micrograph of cells from a 48-h-old culture of *Demetria terragena* DSM 12295[T] grown at 28°C on R agar. Bar = 1 μm.

Further descriptive information

At present the genus is represented by the type species *Demetria terragena* and accommodates a single strain. 16S rRNA gene sequence comparison shows that this strain forms a distinct lineage within the order *Micrococcales* (formerly suborder *Micrococcineae* of Stackebrandt et al., 1997) adjacent to those of members of the genera *Dermacoccus* (Stackebrandt et al., 1995) and *Kytococcus* (Stackebrandt et al., 1995). The 16S rRNA gene sequence similarities between *Demetria* and the species of the most closely related genus *Dermacoccus* are 96.6–96.7%, and those to the slightly less closely related species of the genus *Kytococcus* 95.4–95.8%. The genera of the family *Dermabacteraceae*, *Dermabacter* and *Brachybacterium* share with *Demetria* 16S rRNA gene sequence similarities of 94.3% and 93.9–95.1%, respectively.

Cells of *Demetria terragena* are typically characterized by filopodia at their bottom sides (Figure 156) which are different from the spiky structures reported for *Bogoriella caseilytica* (Groth et al., 1997b). The peptidoglycan of *Demetria* contains Lys, Ala, Asp, Glu, and Ser in a molar ratio of 0.8:1.8:1.2:1.0:0.8. The interpeptide bridge consists of L-Lys–L-Ser–D-Asp which is in accordance with variation A11.36 of the peptidoglycan type A4α (DSMZ Catalogue of Strains, 1998, or http://www.dsmz.de/species/murein.htm). The cellular fatty acid profile is characterized by the predominance of $C_{18:1}$, $C_{18:0}$, $C_{17:0}$ and smaller amounts of $C_{17:0}$ anteiso, $C_{16:0}$, $C_{16:0}$ iso, and $C_{17:0}$ iso. *Demetria terragena* grows well on complex organic media containing peptone, yeast extract, and meat extract as nitrogen sources and utilizes a broad spectrum of different carbon sources.

Enrichment and isolation procedures

Demetria terragena grows readily in complex liquid or on solidified media, i.e. Bacto nutrient agar* (Difco), rich (R) medium† (Yamada and Komagata, 1972), Bacto tryptic soy broth‡ (Difco), and peptone-yeast extract brain heart infusion medium§ (PY-BHI, Yokota et al., 1993). *Demetria terragena* was isolated from a sample of frozen compost soil on nutrient agar** using a standard dilution plate procedure.

Maintenance procedures

Cultures of *Demetria terragena* can be maintained by serial transfers on complex agar media. Growth on agar slants in screw-capped tubes can be kept for about 2–4 weeks at 4°C. Long-term preservation of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

*Bacto nutrient agar consists of (g/l): Bacto beef extract, 3.0; Bacto peptone, 5.0, and Bacto agar, 15.0 (all from Difco); pH 6.8.

†Rich (R) medium consists of (g/l): Bacto peptone (Difco), 10.0; yeast extract (Difco), 5.0; Casamino acids (Difco), 5.0; beef extract (Difco), 2.0; malt extract (Difco), 5.0; glycerol, 2.0; $MgSO_4 \cdot 7H_2O$, 1.0; Tween 80, 0.05, and agar, 20.0; pH 7.2.

‡Bacto tryptic soy broth consists of (g/l): Bacto tryptone, 17.0; Bacto soytone, 3.0; glucose, 2.5; NaCl, 5.0, and K_2HPO_4, 2.5 (all from Difco); pH 7.3.

§Peptone-yeast extract-brain heart infusion medium consists of (g/l): peptone, 10.0; yeast extract, 2.0; Bacto brain heart infusion (Difco), 2.0; NaCl, 2.0, and glucose, 2.0; pH 7.0.

**Nutrient agar consists of (g/l): peptone, 20.0; NaCl, 5.0, and agar, 12.0; pH 7.2.

Differentiation of the genus *Demetria* from other genera

The distinct phylogenetic position of *Demetria terragena* within the cluster of the genera *Dermacoccus* and *Kytococcus* is shown in the 16S rRNA sequence based tree of the family *Dermabacteraceae* (Figure 155, above) Furthermore, *Demetria* can readily be distinguished from these two genera by the presence of the rare structure of the peptidoglycan (murein type A11.36) in combination with the major menaquinone MK-8(H_4), and by the morphological and chemotaxonomic characteristics listed in Table 120. It should be mentioned in this connection that a similar combination of peptidoglycan type A4α (Schleifer and Kandler, 1972) and the predominating menaquinone MK-8(H_4) has been found in *Beutenbergia cavernae* (Groth et al., 1999), in *Bogoriella caseilytica* (Groth et al., 1997b) and *Georgenia muralis* (Altenburger et al., 2002), which are members of the families *Beutenbergiaceae* and *Bogoriellaceae*, respectively (Hamada et al., 2009). However, these organisms can clearly be differentiated from *Demetria terragena* and from each other both by their separate lineages in the phylogenetic tree of the order *Micrococcales* and by a broad spectrum of phenotypic characteristics (Altenburger et al., 2002; Groth et al., 1997b, 1999; Stackebrandt and Schumann, 2000). On the basis of the chemotaxonomic properties *Demetria* can also readily be distinguished from the genera *Dermabacter* (Jones and Collins, 1988) and *Brachybacterium* (Collins et al., 1988). The monospecific genus *Dermabacter*, with the type species *Dermabacter hominis*, is characterized by a directly cross-linked peptidoglycan based on *meso*-diaminopimelic acid, type A1γ (Schleifer and Kandler, 1972), major menaquinones consisting of MK-9, together with MK-8 and MK-7 in substantial amounts, polar lipids consisting of PG, DPG, PLs and GL, and $C_{17:0}$ anteiso, $C_{15:0}$ anteiso, and $C_{16:0}$ iso as the predominant fatty acids (Jones and Collins, 1988). Strains of the genus *Brachybacterium* are characterized by the peptidoglycan type A4γ based on *meso*-diaminopimelic acid, a muramic acid that occurs mainly in the *N*-glycolated form, MK-7 as the principal menaquinone, polar lipids consisting of PG, DPG and GL, and a fatty acid profile which is dominated by $C_{15:0}$ anteiso and $C_{17:0}$ anteiso (Collins et al., 1988; Gvozdyak et al., 1992; Schubert et al., 1996; Takeuchi et al., 1995).

Taxonomic comments

The genus *Demetria* was established in 1997 for a single strain isolated from compost soil which could be clearly differentiated from all previously described actinobacteria on the basis of genotypic and phenotypic characteristics. At that time, the phylogenetic tree based on 16S rRNA gene sequences showed that *Demetria terragena* clustered together with the genera *Dermacoccus*, *Kytococcus*, and *Dermatophilus* (Van Saceghem, 1915). These three genera represented the family *Dermatophilaceae* at the time of the description of *Demetria* (Stackebrandt et al., 1997). The affiliation of *Demetria terragena* to the *Dermatophilaceae* was supported both by high 16S rRNA gene similarities to these genera and the presence of all signature nucleotides defined for this family (Stackebrandt et al., 1997). Later it became obvious from new 16S rRNA gene sequences added to the database of the actinomycetes that the type genus *Dermatophilus* clustered separately from the genera *Dermacoccus*, *Kytococcus*, and *Demetria*. Based on this finding, Stackebrandt and Schumann (2000) split the family *Dermatophilaceae* into the family *Dermatophilaceae* and the new family *Dermacoccaceae*. The family *Dermatophilaceae* comprised the sole genus *Dermatophilus* and the family *Dermacoccaceae* was represented by the genera *Dermacoccus*, *Kytococcus*, and *Demetria*. Recent phylogenetic studies revealed that *Kineosphaera* (Liu et al., 2002) is a member of the family *Dermatophilaceae*, and that *Dermacoccus*, *Kytococcus*, and *Demetria* should be included in the family *Dermabacteraceae*.

List of species of the genus *Demetria*

1. **Demetria terragena** Groth, Schumann, Rainey, Martin, Schuetze and Augsten 1997a, 1132[VP]

ter.ra.ge′na. L. n. *terra* soil; L. suff. *-genus*, *-a*, *-um* suffix denoting an origin; N.L. fem. adj. *terragena* coming from soil.

Description is the same as for the genus. In addition, the strain shows the following phenotypic characteristics: acids are produced from D-fructose, D-galactose, D-glucose, glycerol, D-mannitol, D-mannose, and D-ribose. No acid production from L-arabinose, D-cellobiose, dextrin, D-glucitol, inulin, lactose, maltose, D-raffinose, L-rhamnose, salicin, sucrose, potato starch, trehalose, and D-xylose. Acetate, aconitate, citrate, malate, and succinate are utilized as sole carbon sources; benzoate, formate, and DL-tartrate are not utilized. Nitrate is not reduced to nitrite. Hydrogen sulfide is produced; indole is not produced. Methyl red and Voges–Proskauer reactions are negative. Casein, potato starch, tyrosine, xanthine, and Tween 80 are decomposed; adenine, hypoxanthine, esculin, gelatin, hippurate, and urea are not decomposed. NaCl in combination with rich (R) medium is well tolerated up to 8%. 72h-old cultures display positive enzymic reactions in the API ZYM assay (bioMerieux) for alkaline phosphatase, chymotrypsin, esterase-lipase (C8), leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and α-glucosidase. Weakly positive reactions are recorded for esterase (C4), lipase (C14), valine arylamidase, trypsin, and α-mannosidase. Negative results are obtained for cystine arylamidase, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosamidase, and α-fucosidase. Cells are susceptible to the following antibiotics: ampicillin (10 μg/disc), chloramphenicol (30 μg/disc), ciprofloxacin (5 μg/disc), erythromycin (15 μg/disc), gentamicin (10 μg/disc), kanamycin (30 μg/disc), lincomycin (2 μg/disc), neomycin (30 μg/disc), nitrofuran (300 μg/disc), oxacillin (5 μg/disc), oxytetracycline (30 μg/disc), penicillin G (2 IU/disc), polymyxin B (300 IU/disc), rifampin (2 μg/disc), and streptomycin (10 μg/disc).

DNA G+C content (mol%): 66 (HPLC).

Type strain: 2002-046, HKI 0089, CIP 105501, DSM 11295, NBRC 16164, JCM 11480.

Sequence accession no. (16S rRNA gene): Y14152.

Genus III. **Kytococcus** Stackebrandt, Koch, Gvozdiak and Schumann 1995, 687[VP]

Erko Stackebrandt

Ky.to.coc′cus. Gr. neut. n. *kytos* skin (*sic*); Gr. masc. n. *kokkos* a grain; N.L. masc. n. *Kytococcus* a coccus from skin.

Cells are coccoid. Gram-stain-positive. Nonencapsulated. Nonsporeforming. Nonmotile. **Chemoorganotrophic; metabolism is strictly respiratory**. Aerobic. Catalase positive. Nonhalophilic. Mesophilic. **The peptidoglycan type is type L-Lys–Glu$_2$**, variation A4a. Mycolic acids and teichoic acids are absent. **Menaquinones with 7, 8, 9, and 10 completely unsaturated isoprene units (MK-7, MK-8, MK-9, and MK-10) predominate**. **The major cellular fatty acids are $C_{17:1}$ iso, $C_{17:0}$ anteiso, and $C_{17:0}$ iso**. In addition, significant amounts of $C_{15:0}$ iso, or $C_{17:0}$ and $C_{15:0}$ may be present. The cytochromes of the type species are cytochromes aa_3, c_{626}, c_{550}, b_{557}, b_{561}, and b_{564}. The type species contains the polar lipids diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol. The major aliphatic hydrocarbons of the type species are C_{30}–C_{33} hydrocarbons. Phylogenetically a member of the family *Dermacoccaceae*, order *Actinomycetales*.

DNA G+C content (mol%): 68–69.

Type species: **Kytococcus sedentarius** (ZoBell and Upham 1944) Stackebrandt, Koch, Gvozdiak and Schumann, 1995, 687[VP] (*Micrococcus sedentarius* ZoBell and Upham 1944; Kloos, Tornabene and Schleifer 1974, 84).

Further descriptive information

Micrococcus sedentarius was described by ZoBell and Upham (1944) based on a single strain designated 541 (ATCC 14392; CCM 314) that was isolated from a submerged slide in sea water. Isolation of micrococci from the skin of healthy people in the USA resulted in the characterization of several strains that matched the original description of *Micrococcus sedentarius*. Consequently, Kloos et al. (1974) validly published the name *Micrococcus sedentarius*, describing strain 541[T] (ATCC 14392[T]; CCM 314[T]) as the type strain. Of the properties investigated for the 20 strains including the type strain, some were variable. The type strain did not produce an exopigment and was weakly nitrate reduction positive (the majority of strains were negative), but was similar to the majority of strains in growth on 10% NaCl agar, oxidase negative reaction, and lack of acid formation from glucose and lactose.

Comparative analysis of the 16S rRNA gene sequences of *Micrococcus* species led to the dissection of the genus, leaving only *Micrococcus luteus* and *Micrococcus lylae* as authentic members of the genus (Stackebrandt et al., 1995). Though superficially resembling *Micrococcus* species, the phylogenetic distance of the other species was so large and the chemotaxonomic differences so profound that it was justified to reclassify *Micrococcus kristinae*, *Micrococcus varians*, and *Micrococcus roseus* as members of *Kocuria*, *Micrococcus nishinomiyaensis* as a member of *Dermacoccus*, and *Micrococcus sedentarius* as a member of *Kytococcus*, i.e. *Kytococcus sedentarius*.

While the strains investigated in the early study by Kloos et al. (1974) were obtained from apparently healthy people, there is a report on a possible involvement of a *Kytococcus sedentarius* strain in the pathogenesis of hemorrhagic pneumonia. This organism, identified by morphology and 16S rRNA gene sequences, was isolated from blood cultures and was recovered post-mortem from lung and spleen tissues (Levenga et al., 2004). Other cases

describe the presence of *Micrococcus sedentarius* in endocarditis (Old and McNeill, 1979) and in shunt infection (Leport et al., 1989). The association of *Kytococcus sedentatius* with "pitted keratolysis," a condition characterized by malodor and erosion of the soles of the feet, has been discussed by Nordstrom et al. (1987). Isolated strains from the foot were proteolytic and were able to degrade callus *in vitro* (Holland et al., 1992). Two keratin-degrading enzymes (serine proteases), capable of degrading human callus, have been identified (Longshaw et al., 2002). The pathogenic potential of members of *Kytococcus* has recently been strengthened by the description of *Kytococcus schroeteri* for strains isolated from patients with endocarditis (Becker et al., 2002; Becker et al., 2003) and bacteremic pneumonia (Mohammedi et al., 2005).

The type strains of *Kytococcus sedentarius* and *Kytococcus schroeteri* are 97.9% similar in their 16S rRNA genes sequences. Moderately high values are found when compared with several members of the family *Dermacoccaceae* (*Dermacoccus*: 94.3–96.6% and *Demetria*: 92.4–93.2%) and neighboring genera, e.g. members of *Dermatophilaceae* (*Dermatophilus* and *Kineosphaera*: 91.5–92.5%); *Serinicoccus*, 93.0%; *Ornithinomicrobium*, 93.7–94.0%; and *Intrasporangium*, 94.0–94.7%. The DNA–DNA reassociation values for the type strains of *Kytococcus* species is 45.5%.

Enrichment and isolation procedures

For the isolation of human and mammalian strains, the PY medium described by Kloos and Musselwhite (1975) is recommended: peptone (Difco), 10 g; yeast extract (Difco), 5 g; NaCl, 5 g; glucose, 1 g; agar (Difco), 15 g, distilled water, 1000 ml, pH 7.2–7.4. Cycloheximide (50 µg/ml) or 7% NaCl can be added to inhibit growth of fungi and spreading of bacilli, respectively. Strains of *Kytococcus schroeteri* were isolated by the Bactec 9249 system (Becton Dickinson).

Maintenance procedures

Kytococcus sedentarius is maintained on *Corynebacterium* agar (g/l: casein peptone tryptic digest, 10; yeast extract, 5; glucose, 5; NaCl, 5; agar, 15; pH 7.2–7.4) at 30°C, while *Kytococcus schroeteri* is maintained on Columbia agar (Becton Dickinson) at 37°C, supplemented with 5% sheep blood, or on nutrient broth (Oxoid). Medium-term maintenance is provided 4°C with serial transfers at 4-week intervals. Cells can be stored as 20% (w/v) glycerol suspensions at −20°C and at −80°C Long-term preservation methods include freeze-drying in skim milk and maintenance in liquid nitrogen at −196°C.

TABLE 121. Characteristics differentiating the species of the genus *Kytococcus*[a]

Characteristics	*K. sedentarius*	*K. schroeteri*
Pigmentation of colonies	Cream white/deep buttercup yellow	Muddy yellow
α-D-glucosidase	+	−
Hydrolysis of Tween 80	−	+
Menaquinone composition	MK-8, MK-9, MK-10	MK-7, MK-8, MK-9
Major fatty acids	$C_{17:0}$ anteiso, $C_{15:0}$, $C_{17:0}$, $C_{10:0}$ iso and $C_{17:1}$ iso	$C_{17:1}$ iso, $C_{17:0}$ iso, $C_{15:0}$ iso and $C_{17:0}$ anteiso

[a]Symbols: +, >85% positive; −, 0–15% positive.

Differentiation of the genus *Kytococcus* from other genera

The salient differentiating properties of members of *Dermacoccaceae* and phylogenetically related genera are indicated in the description of *Dermacoccaceae*. *Kytococcus* shares with *Dermacoccus* and *Demetria* an L-Lys residue at position 3 of the peptidoglycan side chain but differs from these organisms in the composition of the interpeptide bridge. A major difference is the presence of fully saturated menaquinones in *Kytococcus* species, while other members of the family possess MK-8(H_2 or H_4) compounds. *Kytococcus* and *Dermacoccus* species share similar polar lipids, but both genera differ in fatty acid composition among themselves and that of *Demetria* species. Genera that show a moderate relatedness with *Kytococcus* differ significantly in peptidoglycan type, menaquinone composition, and the other properties indicated in Table 121 of the family description.

Differentiation of the species of the genus *Kytococcus*

Characteristics that differentiate the two *Kytococcus* species are listed in Table 121 (from Becker et al., 2002).

List of species of the genus *Kytococcus*

1. **Kytococcus sedentarius** (ZoBell and Upham 1944) Stackebrandt, Koch, Gvozdiak and Schumann, 1995, 687[VP] (*Micrococcus sedentarius* ZoBell and Upham 1944; Kloos, Tornabene and Schleifer 1974, 84)

se.den.ta´ri.us. L. masc. adj. *sedentarius* of or belonging to sitting, sitting, sedentary.

In addition to the properties given above in the genus description, the following properties are characteristic for this species. Cells are spherical (diameter, 0.8–1.1 mm) and occur predominantly in tetrads or in tetrads in cubical packets. In smears, cells are often surrounded by a slimy Gram-stain-negative layer. Colonies are up to 3.5 mm in diameter, circular, entire, convex to pulvinate, and usually smooth and develop rather slowly. The colonies are cream white or deep buttercup yellow. Colony morphology and color become more distinct with age; cell morphology is not culture age or medium dependent. Some strains produce a brownish exopigment. Grows well in the presence of NaCl concentrations up to 10%. Growth does not occur on inorganic nitrogen agar and Simmons' citrate agar. Positive in the benzidine test. Most strains are negative in the oxidase test. Arginine dihydrolase positive. Negative for urease, lecithinase, β-galactosidase, and phosphatase. A few strains can reduce nitrate to nitrite; nitrite reduction does not occur. Hydrolyzes gelatin, but does not hydrolyze esculin, starch, and Tween 80. Acetoin is not produced. Metabolically inert for acid production from carbohydrates. No acid is produced from glucose, galactose, rhamnose, xylose, mannose, maltose, sucrose, ribose, raffinose, melibiose, arabinose,

galactose, ribitol, glucitol, galactitol, mannitol, and glycerol. Most strains do not utilize fructose and lactose. Methionine is required. Most strains require tyrosine, arginine, valine, lysine, leucine, and pantothenic acid. The optimum growth temperature range is 28–36°C. Nonhemolytic. Menaquinones are MK-8, MK-9 and MK-10. The major cellular fatty acids are $C_{17:0}$ anteiso, $C_{15:0}$, $C_{17:0}$, $C_{10:0}$ iso, and $C_{17:1}$ iso. Minor components are $C_{15:1}$, $C_{16:0}$, $C_{16:1}$, and $C_{15:0}$ iso. All strains are resistant to methicillin and penicillin G and susceptible to streptomycin, novobiocin, tetracycline, neomycin, vancomycin, and polymyxin B. Most strains are susceptible to erythromycin, kanamycin, and chloramphenicol.

DNA G+C content (mol%): 68–69 (T_m).

Type strain: 541, ATCC 14392, CCM 314, CCUG 33030, CIP 81.72, DSM 20547, NBRC 15357, JCM 11482, LMG 14228, NCTC 11040, VKM B-1316.

Sequence accession no. (16S rRNA gene): X87755.

2. **Kytococcus schroeteri** Becker, Schumann, Wüllenweber, Schulte, Weil, Stackebrandt, Peters and von Eiff 2002, 1613[VP]

schro.e′te.ri. NL. gen. masc. n. *schroeteri* of Schroeter, honoring Joseph Schroeter, a German microbiologist.

In addition to the properties given in the genus description, the species has the following properties. Cells are spherical (diameter 1.1–1.5 μm) and occur predominantly in pairs or tetrads. Colonies are up to 2–5 mm in diameter (after 48 h incubation), circular, entire, convex, and smooth and develop rather slowly. Colonies are muddy yellow. Grows well in the presence of NaCl concentrations up to 12%. No growth above 15% NaCl. Growth does not occur in Simmons' citrate agar. Oxidase negative. Positive for alkaline phosphatase, arginine dihydrolase, and pyrazinamidase. Negative for lecithinase, β-galactosidase, and urease. Nitrate is not reduced. Hydrolyzes gelatin and Tween 80, but does not hydrolyze esculin or starch. Acetoin is not produced. Metabolically inert for acid production from carbohydrates. No acid is produced from L-arabinose, D-galactose, D-glucose, maltose, D-mannose, D-melibiose, raffinose, L-rhamnose, D-ribose, sucrose, D-xylose, adonitol, glycerol, or D-mannitol. The optimum growth temperature is 37°C. Nonhemolytic. Resistant to penicillin G, oxacillin, and erythromycin, and susceptible to ampicillin, chloramphenicol, ciprofloxacin, gentamicin, tetracycline, vancomycin, and teicoplanin. Menaquinones with eight and seven completely unsaturated isoprene units (MK-8, MK-7) predominate. The major cellular fatty acids are $C_{17:1}$ iso, $C_{17:0}$ iso, $C_{15:0}$ iso, and $C_{17:0}$ anteiso. Minor components are $C_{16:0}$ iso, $C_{15:0}$ anteiso, and $C_{17.1}$ anteiso.

Source: blood from a patient with endocarditis.

DNA G+C content (mol%): not available.

Type strain: Muenster 2000, CCM 4918, DSM 13884, JCM 12136.

Sequence accession no. (16S rRNA gene): AJ297722.

Erko Stackebrandt

Der.ma.to.phi.la.ce′a.e. N.L. masc. n. *Dermatophilus* type genus of the family; suff. *-aceae* ending to denote family; N.L. pl. fem. n. *Dermatophilaceae* the *Dermatophilus* family.

The family embraces two genera which differ from each other in morphology. In *Dermatophilus*, mycelia consist of narrow tapering filaments which divide transversely and in at least two longitudinal planes to form zoospores, forming germ tubes that elongate into filaments. In *Kineosphaera*, motile cocci grow singly, in pairs, or in packets. Aerial mycelium is absent, but in *Dermatophilus* sometimes inducible by 10% CO_2. Gram-stain-positive. Not acid-fast. Chemoorganotrophic; facultatively anaerobic or strictly aerobic. Peptidoglycan type is the directly linked *meso*-diaminopimelic acid (*meso*-A_2pm). Major menaquinone is MK-8(H_4). Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol; in addition, *Kineosphaera* contains phosphatidylethanolamine and phosphatidylcholine. Major fatty acids of *Dermatophilus* strains are $C_{16:0}$, $C_{15:0}$, and $C_{14:0}$; $C_{16:0}$, $C_{17:1}$ $C_{18:1}$, and $C_{17:0}$ were reported for *Kineosphaera* species.

The family is a member of the order *Micrococcales*. The 16S rRNA gene signature nucleotides that define members of *Dermatophilaceae* are at positions 120 (A), 131:231 (Y–K), 196 (A), 342:347 (C–G), 444:490 (A–U), 580:761 (U–A), 602:636 (C–G), 670:736 (A–U), 822:878 (G–C), 823:877 (G–C), 826:874 (C–G), 827 (U), 843 (U), 950:1231 (U–A), 1047:1210 (G–C), 1109 (C), 1145 (G), 1309:1328 (G–C), 1361 (G), and 1383 (C) (Zhi et al., 2009).

Includes pathogenic organisms causing skin lesions in mammals including humans.

DNA G+C content (mol%): 57 ± 59 (T_m; *Dermatophilus*) – 71 ± 3 (HPLC; *Kineosphaera*).

Type genus: **Dermatophilus** Van Saceghem 1915, 357 emend. mut. char. Gordon 1964, 521.

Further descriptive information

Type strains of the two genera included in *Dermatophilaceae* show a moderate relatedness of 95% 16S rRNA gene sequence similarity. Members of *Dermatophilus* and *Kineosphaera* form clusters of cuboid cells or coccoid strains but differ in morphology and, except for the composition of peptidoglycan, in chemotaxonomic properties, including a broad range of DNA G+C contents. The rationale to include them into the same family is the phylogenetic position of *Kineosphaera limosa* Lpha5[T], branching adjacent to the radiation of the two type species of the genus *Dermatophilus* (Stackebrandt, 2003). Diagnostic morphological and chemotaxonomic characteristics are listed in Table 122.

Taxonomic comments

Dermatophilus congolensis was described (Van Saceghem, 1915) as the causative organism of an economically important acute, subacute, or chronic exudative and proliferative skin disease which is prevalent, but not exclusively found, in the tropics and subtropics, affecting more than 30 animal species and humans (Zaria, 1993). The disease is referred to as either streptotrichosis, pitted keratolysis, strawberry foot rot, lumpy wool, rain scald, or dermatophilosis, depending on the host infected and clinical signs. *Kineosphaera limosa* (Liu et al., 2002), isolated from a sequential batch reactor running under alternating anaerobic and aerobic conditions, has not been reported to be pathogenic.

The family *Dermatophilaceae* was first described to include the two actinomycete genera *Dermatophilus* and *Geodermatophilus* (Austwick, 1958). In the absence of phylogenetic and chemotaxonomic data, the classification was based on a single but very unique morphological feature, i.e. division in both transverse and longitudinal planes leading to the formation of packets or clusters of cuboid cells or cocci. The two species *Dermatophilus congolensis* and *Geodermatophilus obscurus* differ, however, in growth characteristics and developmental stages (Luedemann, 1968), chemical properties (Lechevalier, 1981), and phylogenetic position among the actinomycetes (Stackebrandt et al., 1983). While *Geodermatophilus obscurus* clusters with species of *Frankia* and *Blastococcus* (Ahrens and Moll, 1970) constituting an individual subline of descent (Hahn et al., 1989; Normand, 2006; Stackebrandt et al., 1983), *Dermatophilus congolensis* was found to group by itself within a broad taxon cluster that was later classified as the suborder *Micrococcineae* (Stackebrandt et al., 1997), and which has been elevated to order *Micrococcales*

TABLE 122. Morphological, metabolic, and chemotaxonomic characteristics of genera of the family *Dermatophilaceae*[a,b]

Characteristic	*Dermatophilus*	*Kineosphaera*
Morphology	Branching filaments which divide by transverse and longitudinal septa to form zoospores which form germ tubes, elongate into filaments	Gram-stain-positive motile cocci which grow in pairs and packets
Metabolism	Facultatively anaerobic; acid from glucose	Obligately aerobic; acid not produced
Polar lipids	PG, DPG, PI	PG, DPG, PI, PE, PC
Predominant cellular fatty acids	$C_{16:0}$, $C_{15:0}$, $C_{14:0}$	$C_{16:0}$, $C_{17:1}$, $C_{18:1}$, $C_{17:0}$
DNA G+C content (mol%)	57–59	71.3

[a]Abbreviations: A_2pm, diaminopimilic acid; $C_{14:0}$, tetradecanoic acid; $C_{15:0}$, pentadecanoic acid; $C_{16:0}$, hexadecanoic acid; $C_{16:0}$ iso, 14-methylpentadecanoic acid; $C_{17:0}$, heptadecanoic acid; $C_{17:0}$ iso, 15-methylhexadecanoic acid; $C_{17:0}$ anteiso, 14-methylhexadecanoic acid; $C_{17:1}$, heptadecenoic acid; $C_{17:1}$ iso, 15-methylhexadecenoic acid; $C_{18:0}$, octadecanoic acid; $C_{18:1}$, octadecenoic acid. PI, phosphatidylinositol; PG, phosphatidylglycerol; PC, phosphatidylcholine; DPG, diphosphatidylglycerol; PE, phosphatidylethanolamine; PL, unidentified phospholipid.

[b]Data from Liu et al. (2002) and Stackebrandt and Schumann (2000).

in the taxonomic roadmap to the present volume. The family *Dermatophilaceae* was emended twice, first on the basis of 16S rRNA gene signature nucleotides (Stackebrandt et al., 1997) and shortly after by a modified set of signature nucleotides (Stackebrandt and Schumann, 2000). The public database of gene sequences lists 16S rRNA gene sequences of two invalidly named taxa, i.e. "*Tonsillophilus suis*" (accession no. AB096084) (Murakami et al., 1991) and "*Dermatophilus crocodyli*" (AF226615), both branching adjacent to *Dermatophilus* type strains (Figure 157). The unresolved branching point of *Kineosphaera limosa* is discussed in the chapter on *Kineosphaera*, below. Irrespective of the treeing algorithm used [distance matrix of DeSoete (1983), neighbor-joining (Felsenstein, 1993), or maximum-likelihood (Olsen et al., 1994)] the nearest neighbors of *Dermatophilaceae* within the order *Micrococcales* are members of *Dermacoccaceae*, *Brevibacteraceae*, *Jonesiaceae*, and *Dermabacteraceae*, but neither the intra- nor the inter-family branching of the *Dermatophilaceae* lineages is supported by bootstrap values of >70%.

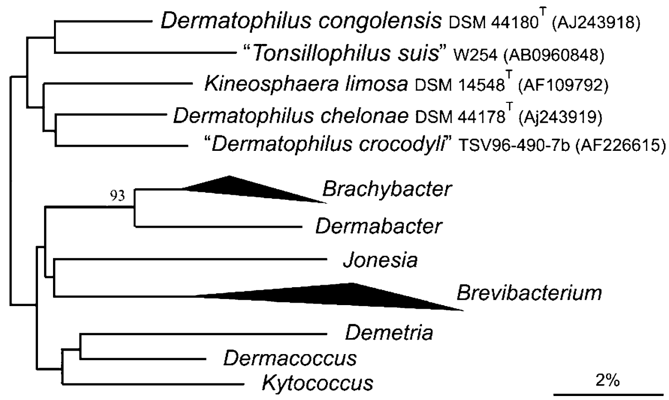

FIGURE 157. Maximum-likelihood tree of 16S rRNA gene sequences showing the nearest neighbors of members of *Dermatophilaceae*. The bootstrap value was calculated for 500 replicate trees. The bar corresponds to a 2% difference in nucleotide sequences.

Genus I. **Dermatophilus** Van Saceghem 1915, 357 emend. mut. char. Gordon 1964, 521[AL]

ERKO STACKEBRANDT

Der.ma.to.phi′lus. Gr. n. *derma -atos* skin; Gr. adj. *philos* loving; N.L. masc. n. *Dermatophilus* skin loving.

Aerial mycelium develops in atmospheres containing added CO_2. **Substrate mycelium consists of long tapering filaments, branching laterally at right angles; septa formed in transverse and in horizontal and vertical longitudinal planes giving rise to up to eight parallel rows of coccoid cells (spores), each of which becomes motile by a tuft of flagella.** Gram-stain-positive. Not acid-fast. Catalase-positive. **Aerobic and facultatively anaerobic**. Nonfermentative, but acid is produced from certain carbohydrates. Growth reported only on complex media; minimum nutritional requirements unknown. Temperature optimum ~37°C. Chondroitinase activity against chondroitin 4-sulfate positive. No hyaluronidase or elastase activity. As determined for the type species, **peptidoglycan contains *meso*-diaminopimelic acid** (*meso*-A_2pm); madurose is present in whole-cell hydrolysates; **polar lipids include phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol; major fatty acids are straight chain unsaturated $C_{16:0}$, $C_{15:0}$, and $C_{14:0}$.** Chemoorganotrophic. **Parasitic on mammals, especially domestic herbivores.** Pathology is usually limited to exudative dermatitis which may, however, be severe and life-threatening; on rare occasions causes subcutaneous abscesses and lymph node granulomas. Also found in skin lesions and abscesses in chelonids.

DNA G+C content (mol%): 57–59 (T_m).

Type species: **Dermatophilus congolensis** Van Saceghem 1915, 357 emend. mut. char. Gordon 1964, 521.

Further descriptive information

The natural habitat of the type species, *Dermatophilus congolensis*, is the diseased tissue of infected animals, where it is found in or on the integument where it causes a chronic or acute exudative dermatitis. Apparently, this bacterium does not grow saprophytically in nature. It has been isolated mainly from mammals, e.g. cattle, sheep, goats, and equines, and, less-commonly, from other sources including camels, giraffes, gazelles, rodents, monkeys, a polar bear, seals, pigs, and humans, but also from lizards (Gordon, 1976; Zaria, 1993). From a medical point of view, *Dermatophilus congolensis* is unique in that its natural growth cycle is restricted to the living layer of the epidermis. A few human isolates are known, most probably as a result of direct contact with infected animals (Kaplan, 1976). One strain, isolated from a wrist infection of an adult male, is on deposit as ATCC 14639. The second species, *Dermatophilus chelonae* has so far only been isolated from non-mammalian hosts, i.e. tortoise and turtles (Masters et al., 1995).

Attempts to find *Dermatophilus* species in soil have been unsuccessful and Masters et al. (1995) failed to isolate *Dermatophilus chelonae* from the surrounding environment of the infected cheloids, i.e. the Perth Zoo, Perth, Western Australia. As pointed out by Roberts (1967), this may be due to the inability of the organism to survive outside the host environment, especially under dry conditions.

Isolation and enrichment

Dermatophilus congolensis is readily isolated from cutaneous crusts or newly formed scabs by chopping or mincing material from the base of the scab in a small volume of sterile nutrient broth or distilled water and then plating on blood agar (5–10% defibrinated sheep blood in a blood agar base). As this material might be heavily contaminated with other bacteria, isolation requires a good streaking technique on beef infusion-horse blood agar plates which are incubated aerobically at 37°C. A modified procedure uses Haalstra's method (1965), growing the isolates on defibrinated 10% human blood agar plates containing 1.000 units of polymyxin B sulfate/ml of medium. To obtain a high yield of good-sized colonies, the plates are incubated at 37°C for about 2 d in an atmosphere of 10% CO_2 or in

a candle jar followed by a day in air. Isolation of *Dermatophilus congolensis* from old scabs is difficult because of reduced viability of aged cells or contamination of wetted scabs with other bacteria. Inoculation of the suspended scab material on the scarified skin of guinea pig or sheep and the use of the resulting scabs for unambiguous identification has been recommended by Roberts (1981). While the natural habitat of *Dermatophilus congolensis* is the diseased tissue of infected animals, it has been isolated mainly from cattle, sheep, goats, and equines, and, less- commonly, from other sources, including camels, giraffes, gazelles, rodents, monkeys, a polar bear, seals, pigs, humans, and even from the non-mammalian host sources, lizards and turtles. A compilation of recent literature is compiled by Stackebrandt (2006). A strain of *Dermatophilus chelonae* has recently been isolated from a king cobra (Wellehan et al., 2004).

Strains of *Dermatophilus chelonae* were isolated on 9% bovine blood agar (in Oxoid Columbia agar base no. 2; Masters et al., 1995). Growth is observed after 2–3 d of incubation at 37°C in the presence of 10% CO_2 or at 27°C in the ambient atmosphere. Growth also occurs in tryptose-phosphate medium supplemented with 10% ovine serum after 3 d at 37°C when the broth is inoculated with a dense suspension of zoospores.

Zoospores survive under unfavorable conditions and can resist drying. They can withstand heating at 100°C when dried, and they survive in dry scabs at temperatures of 28–31°C for up to 42 months.

Maintenance procedures

Good growth of *Dermatophilus* strains is achieved in brain heart infusion agar (Difco 0418) or trypticase soy broth agar supplemented with 5% blood. Well-grown cultures in Parafilm-sealed Erlenmeyer flasks may be kept at 4°C for several weeks and frozen at −20°C for several months. For lyophilization, good recovery rates are obtained when fresh materials from colonies on blood agar are suspended in nutrient broth. Vanbreuseghem et al. (1976) recommended maintaining a bacterial suspension in 2 ml of a mixture of equal volumes of ox serum, a 10% solution of sucrose in distilled water, and a 5% solution of neopeptone (Difco) in distilled water. Viable isolates have been maintained in this state for more than 10 years. Subcultures are made by mixing the lyophilized cells with a solution consisting of 2% glucose and 1% neopeptone in tap water. Freeze-dried cultures are stored at 8°C. Strains can also be maintained in N_2 vapor.

Differentiation of the genus *Dermatophilus* from other genera

Despite striking morphological similarities in certain stages of their life cycles, members of *Dermatophilus* and *Geodermatophilus* differ in their ecological niches, their chemotaxonomic features, colonial pigmentation, location and number of flagella, DNA base composition, mode of branching, and pathogenicity. Main chemotaxonomic differences between *Dermatophilus* and phylogenetically related and morphologically similar species are indicated in Table 123 of the description of *Dermatophilaceae.*

Differentiation of the species of the genus *Dermatophilus*

The salient differentiating features are listed in Table 123. In addition *Dermatophilus chelonae* differs from *Dermatophilus congolensis* in a number of cultural characteristics including faster growth at 27°C than at 37°C and production of a distinctive odor. The DNA restriction enzyme digestion and protein electrophoresis patterns are distinct (Masters et al., 1995). The electrophoretic mobilities of enzymes differ from the mobilities observed with *Dermatophilus congolensis* strains. Biochemical differences between *Dermatophilus chelonae* and *Dermatophilus congolensis* include the ability of the chelonid isolates to reduce nitrate to nitrite and the fact that the chelonid isolates exhibit collagenase activity *in vitro*. Several studies identify *Dermatophilus congolensis* strains by molecular methods including random amplified polymorphic DNA (RAPD) and oligonucleotide probing (Garcia-Sanchez et al., 2004a, 2004b; Larrasa et al., 2002) as well as restriction length polymorphism (Razafindraibe et al., 2006) and pulsed-field gel electrophoresis of PCR products (Larrasa et al., 2004).

The type strains of the two *Dermatophilus* species share a moderate 16S rRNA gene sequence similarity of 93.9%. As a higher value of 95.4% similarity has been determined for the type strain of *Kineophaera limicola* DSM 14548^T and *Dermatophilus chelonae* DSM 44178^T than for strain DSM 14548^T and *Dermatophilus congolensis* DSM 44180^T (93.7%), the genus *Kineosphaera* appear to be phylogenetically placed within the radiation of *Dermatophilus* species (Stackebrandt, 2003).

TABLE 123. Diagnostic properties of the species of the genus *Dermatophilus*[a,b]

Characteristic	*Dermatophilus congolensis*	*Dermatophilus chelonae*
Colony morphology	On blood agar colonies rough, often becoming viscous, white to gray at first, becoming orange to yellow. On brain-heart-infusion medium, strains have a gray-yellow tint, a wrinkled and shiny surface, and either a rough or smooth consistency, depending on the number of filaments and cocci. Convex colonies with crateriform center may occur.	On bovine blood agar colonies initially dry and adherent, gray-white. After transfer to room temperature, growth continues, colonies are adherent, white, raised, and umbonate or annilliform, becoming sticky after several days.
Motility of zoospores	High	Low
Hemolysis	Hemolytic on media containing sheep blood but not horse blood	Beta-hemolytic on media containing ovine blood; on horse blood nonhemolytic at 37°C, and weakly beta-hemolytic at 27°C. Forms two hemolysis zones around colonies on blood agar at 37°C in the presence of 10% CO_2.
Urease	+	v
Antibody $2F_4$ reaction	+	−

[a]Symbols: +, >85% positive; −, 0–15% positive; v, variable.

[b]Masters et al. (1995).

List of species of the genus *Dermatophilus*

1. **Dermatophilus congolensis** Van Saceghem 1915, 357 emend. mut. char. Gordon 1964, 521[AL]

con.go.len′sis. N.L. masc. adj. *congolensis* pertaining to the Congo (named for the Belgian Congo).

The description has been taken from Gordon (1989). Hyphae, 0.5–1.5 µm in diameter, develop from germ tubes. After several transverse and longitudinal divisions, hyphae may be up to 5 µm in diameter, with branches at right angles tapering to nonseptate apices. Become converted entirely into eight-ranked packets of isodiametric segments encased in a gelatinous sheath (Figure 158). Each segment is released as a motile spore bearing a tuft of five or more flagella. The spores subsequently lose motility and germinate. On blood agar, colonies are rough, often becoming viscous; they are adherent through invasion of substrate by hyphae; often white to gray at first, usually becoming orange to yellow; hemolytic on media containing sheep but not horse blood. Good growth on Loeffler's medium, light yellow; medium liquefied by most strains. No growth on Sabouraud glucose agar, Czapek agar, or tomato paste-oatmeal agar. Broth is clear with a flocculent or ropy sediment, sometimes with a surface ring of growth. Acid from glucose and fructose; transient acid (within 48 h) from galactose; often late production from maltose. Acid not produced from lactose, sucrose, xylose, dulcitol, mannitol, sorbitol, or salicin. Starch hydrolyzed. Gelatin and casein hydrolyzed. Tyrosine and xanthine not hydrolyzed. Indole not formed; methyl red and Voges–Proskauer tests negative. Nitrates not reduced. Aerobic, facultatively anaerobic. In an atmosphere of 10% carbon dioxide at 37°C, growth is accelerated and aerial hyphae are formed, while septation and spore formation are delayed. Susceptible to a wide range of antibacterial antibiotics including penicillin, streptomycin, chloramphenicol, erythromycin, and the tetracyclines. Resistant to the antifungal agents griseofulvin, nystatin, and tolnaftate.

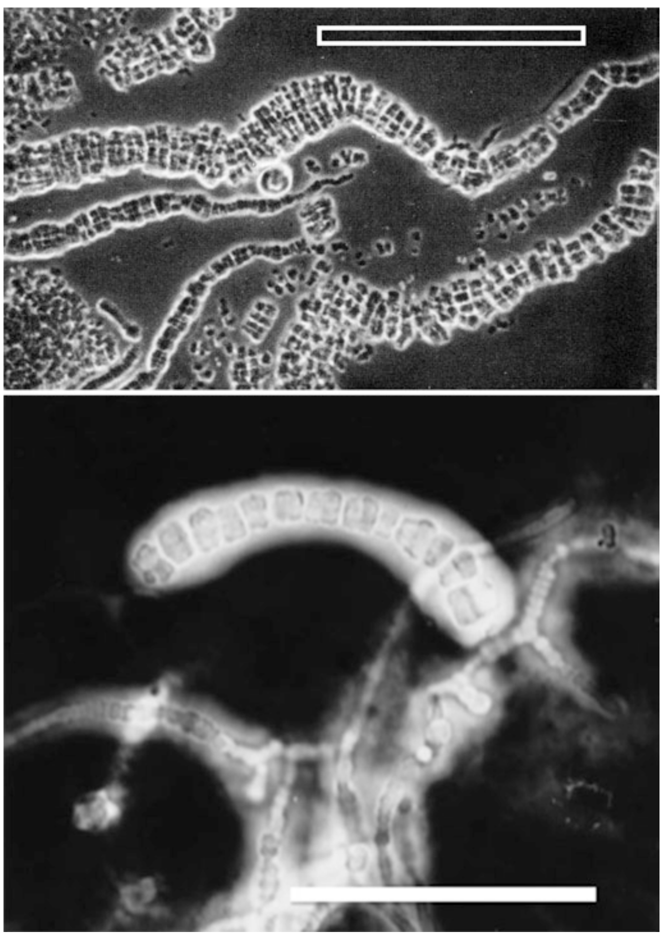

FIGURE 158. Morphology of *Dermatophilus congolensis.* (top) Wet mount of broth culture, showing fully segmented hyphae with cubical packets of coccoid spores. Scale bar = 20 µm. (Reprinted with permission from Gordon, 1964. J. Bacteriol. *88*: 509–522.) (bottom) Thick capsulate around mature filaments of mammalian strain W15. Scale bar = 30 µm. (Reprinted with permission from Masters et al., 1995. Int. J. Syst. Bacteriol. *45*: 50–56.)

Etiological agent of dermatophilosis, an exudative, often severe, dermatitis affecting large numbers of cattle, sheep, goats, and domesticated equines and causing important economic problems in many parts of the world. Occasional infections have been reported in many additional mammalian species, including humans.

DNA G+C content (mol%): not available.

Type strain: ATCC 14637, CCUG 47448, DSM 44180, JCM 8106, NCTC 13039, NRRL B-2350.

Sequence accession no. (16S rRNA gene): AJ243918.

2. **Dermatophilus chelonae** Masters, Ellis, Carson, Sutherland and Gregory 1995, 55[VP]

chel.lo′na.e. L. gen. n. *chelonae* of a turtle or tortoise, the source of the first isolates.

The description has been taken from Master et al. (1995). Coccoid zoospores that are 0.7 × 0.8 µm–1.2 × 1.6 µm. Produce germ tubes (diameter, ~1 µm) which elongate into filaments, eventually producing branching mycelia. Initially, septa form transversely, and there is a slight bulging of the filament on one side of the septum. Longitudinal septa are produced later, creating mature filaments with transverse and longitudinal divisions at regular intervals; the filaments are up to five cuboidal segments (~4 µm) in diameter and are surrounded by a thin capsule (thickness, 0.13–1.3 µm) (Figure 159). The segments separate, becoming zoospores with 0–6 flagella; aflagellate zoospores are the most common zoospores. All forms (zoospores, germ tubes, filaments, and segments) are Gram-stain-positive. Negative for fluorescent-antibody staining with monoclonal antibody 2F. Colonies on bovine blood agar after 3 d of growth are initially dry and adherent; the colonies are small, very slightly raised, and gray-white and have two hemolysis zones (beta and alpha) at 37°C; they are white, raised, and larger and have a beta-hemolysis zone at 27°C. After transfer to room temperature, growth continues, and colonies are adherent, white, raised, and umbonate or annelliform; the colonies become sticky after several days and caseous after prolonged storage. On ovine blood agar, colonies are beta-hemolytic; on equine blood agar, colonies are nonhemolytic at 37°C and weakly beta-hemolytic at 27°C. Good growth occurs on 1% tryptone-1.75% casein

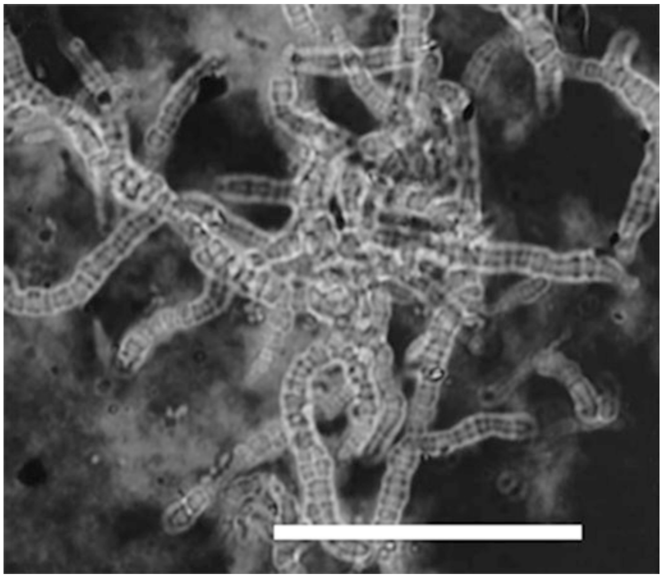

FIGURE 159. Morphology of *Dermatophilus chelonae.* Thin capsule (0.5 µm thick) around cells of strain W16[T]. Scale bar = 30 µm. (Reprinted with permission from Masters et al., 1995. Int. J. Syst. Bacteriol. *45*: 50–56.)

hydrolysate-0.5% NaCl agar, continuing for several weeks at room temperature. Cultures in tryptosephosphate-10% ovine serum broth produce a flocculent deposit and a clear supernatant, and no growth is suspended or occurs at the surface. Cultures produce a distinctive putrid odor. Acid is produced from glucose and is often produced from fructose and galactose (variable) as well as maltose. Acid is not produced from lactose, sucrose, xylose, dulcitol, mannitol, sorbitol, salicin, or trehalose. Gelatin and casein are hydrolyzed. Urease is not always produced. Weak reduction of nitrate to nitrite occurs. Indole is not formed; methyl red and Voges–Proskauer tests are negative. Chondroitinase activity occurs with chondroitin 4-sulfate but not with chondroitin 6-sulfate. Collagenase activity occurs with *in vitro*-assembled collagen.

Resistant to polymyxin B (1000 IU/ml), streptomycin (10 µg), and neomycin (30 µg). Susceptible to penicillin G (10 U), tetracycline (30 µg), chloramphenicol (30 µg), and sulfafurazole (100 µg).

Isolated from chelonids with skin lesions or abscesses at the Perth Zoo, in Perth, Western Australia. Low levels of infectivity on sheep, rabbits, and guinea pigs.

DNA G+C content (mol%): not available.

Type strain: W16, ATCC 51576, CCUG 47447, CIP 104541, DSM 44178, JCM 9706.

Sequence accession no. (16S rRNA gene): AJ243919.

Genus II. **Kineosphaera** Liu, Hanada, Marsh, Kamagata and Nakamura 2002, 1847[VP]

Erko Stackebrandt

Ki.ne.o.spha.e′ra. Gr. n. *kinesis* motion; L. fem. n. *sphaera* sphere, N.L. fem. n. *Kineosphaera* a motile sphere.

Cells are strictly aerobic, nonsporeforming, Gram-stain-positive, motile cocci (1–2 µm in diameter) which grow in pairs and packets. Catalase negative and oxidase positive. Cells do not use nitrite as an electron acceptor. The cell wall contains *meso*-A2pm as its characteristic diamino acid. The major menaquinone is MK-8(H4). The predominant cellular fatty acids are $C_{16:0}$; $C_{17:1}$, $C_{18:1}$, $C_{17:0}$, and $C_{16:1}$ occurs in smaller amounts. Phospholipids are phosphatidylglycerol, phosphatidylinositol, diphosphatidylglycerol, phosphatidylethanolamine, and phosphatidylcholine. The genus is a member of the family *Dermatophilaceae*, order *Micrococcales*, class *Actinobacteria*.

DNA G+Ccontent (mol%): 71.

Type species: **Kineosphaera limosa** Liu, Hanada, Marsh, Kamagata and Nakamura 2002, 1848[VP].

Further descriptive information

The spherical cells of strain Lpha5[T] have a rough surface (Figure 160A) and contain intracellular granules (Figure 160B) consisting of 3-hydroxybutyrate and 3-hydroxyvalerate as main components (Liu et al., 2002). Cells appear to divide by binary fission. The morphology resembles that of *Dermatophilus* strains grown in liquid growth media in which division is not confined so that cuboid packets of cells are formed.

Enrichment and isolation procedures

Kineosphaera limosa Lpha5[T] (DSM 14548[T]) and its closest relative, strain Lpha7 were isolated only once from an activated sludge reactor enriched with 2% phosphorous (Liu, 1995;

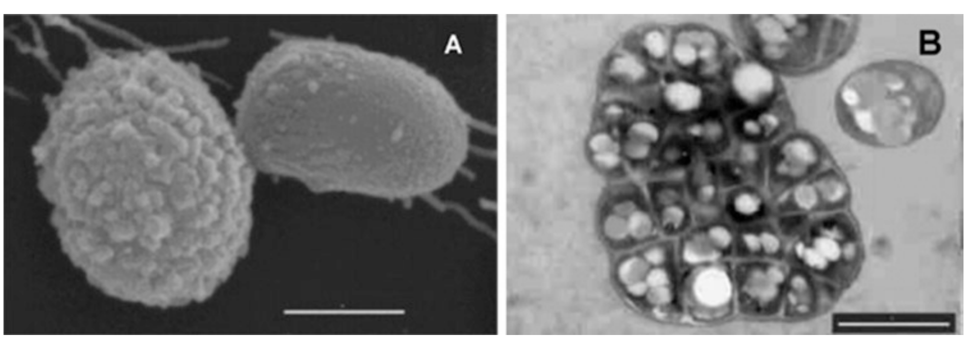

FIGURE 160. Morphology of *Kineosphaera limosa* strain Lpha5[T]. (A) Scanning electron micrograph. (B) Transmission electron micrograph, showing intracellular PHA granules. Bar = 1.0 µm. (Reprinted with permission from Liu et al., 2002. Int. J. Syst. Evol. Microbiol. *52*: 1845–1849.)

Liu et al., 2000, 2002). *Kineosphaera limosa* was isolated on medium GM1 (Liu et al., 1997) at 30°C at pH 7.0. On this medium strains require 1–2 weeks for colonies to appear. In liquid GM1 Medium, the doubling time is 1.7 d. Medium GM1 contains per liter at pH 7.0: glucose, 0.5 g; Na-acetate·$3H_2O$, 2 g; peptone, 0.5 g; yeast extract, 0.5 g; KH_2PO_4, 0.44 g; $MgSO_4$·$7H_2O$, 0.5 g; $(NH_4)_2SO_4$, 0.5 g; vitamin solution, 10 ml; sludge extract (autoclaved and filtered), 100 ml; and agar, 16 g.

Maintenance procedures

Kineosphaera limosa is maintained aerobically on DSM medium 776 (Nakamura et al., 1995) containing in grams per liter: glucose, 0.5 g; peptone, 0.5 g; yeast extract, 0.5 g; Na-glutamate, 0.5 g; KH_2PO_4, 0.5 g; $(NH_4)_2SO_4$, 0.1 g; $MgSO_4$·$7H_2O$, 0.1 g; and at pH 7.0, at 30°C. Cells also grow well on Bacto (Becton & Dickinson).

Differentiation of the genus *Kineosphaera* from other genera

Kineosphaera limosa Lpha5^T differs morphologically from dermatophili in the lack of formation of motile spores, a germ tube that extends at its growing tip to elongate into filaments, and a mycelium. Differences also occur in DNA base composition and in the composition of fatty acids and polar lipids (Table 122), while members of both genera are similar in peptidoglycan type and menaquinones; they share the same set of 16S rRNA gene signature nucleotides defined for members of the genus *Dermatophilus* (Stackebrandt, 2003; Stackebrandt and Schumann, 2000).

Taxonomic comments

The type strain of *Kineosphaera limosa* Lpha5^T was described for a coccoid organism from activated sludge that showed 94% 16S rRNA gene sequence similarity to *Dermatophilus congolensis* DSM44180^T. However, as only the 16S rRNA gene sequence of *Dermatophilus congolensis* ATCC 14637^T but not that of the second *Dermatophilus* species, *Dermatophilus chelonae* DSM 44178^T, was included in the phylogenetic analysis, the impression was given that the type strain Lpha5^T branched outside the radiation of the genus *Dermatophilus*. When sequences of the two type strains of *Dermatophilus*, *Kineosphaera limosa* Lpha5^T, and other *Dermatophilus* species were included in the phylogenetic analysis, it was obvious that *Kineosphaera limosa* branched within the radiation of the genus *Dermatophilus* (Stackebrandt, 2003).

The involvement of *Kineosphaera* species in the removal of phosphate is unknown. No information is available about pathogenicity of these organisms.

List of species of the genus *Kineosphaera*

1. **Kineosphaera limosa** Liu, Hanada, Marsh, Kamagata and Nakamura 2002, 1848^{VP}

li.mo′sa. L. fem. adj. *limosa* muddy, pertaining to sludge, the natural habitat of the species.

Colonies are light-yellow, irregular, and umbonate (2–3 µm in diameter) with undulating margins when the strain is grown on GM1 medium. Neisser-stain-negative and polyhydroxybutyrate-stain-positive. The optimum growth temperature is 30°C (temperature growth range 10–35°C), and the optimum growth pH is 7.0 (pH growth range is pH 6.0–10.2). Grows in the presence of up to 3.0% (w/v) NaCl. Utilizes dextrin, D-arabitol, fructose, α-D-glucose, maltose, 3-*O*-methylglucose, psicose, trehalose, turanose, xylitol, adenosine, Tween 40, Tween 80, *N*-acetyl-D-mannosamine, D-mannose, methyl-β-D-glucoside, palatinose, salicin, D-sorbitol, sucrose, D-trehalose, β-hydroxybutyric acid, methylpyruvate, propionic acid, succinamic acid, succinic acid, and glycerol. Cells accumulate PHA. The major cellular fatty acids are $C_{16:0}$, $C_{17:1}$, $C_{18:1}$, $C_{17:0}$, and $C_{16:1}$; $C_{15:0}$ and $C_{14:0}$ occur in smaller amounts.

Source: activated sludge.

DNA G+C content (mol%): 71.3 (HPLC).

Type strain: Lpha5, DSM 14548, JCM 11399, NBRC 100340.

Sequence accession no. (16S rRNA gene): AF109792.

Peter Kämpfer and Ingrid Groth

In.tra.spo.ran.gi.a.ce′a.e. N.L. neut. n. *Intrasporangium* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Intrasporangiaceae* the family of *Intrasporangium*.

Cell morphology comprises **branching mycelium and filaments**, but **typically irregular short rods and cocci**. In some genera, a rod–coccus growth cycle occurs (*Knoellia*, *Terrabacter*). Gram-stain-positive. **Nonsporeforming. Generally nonmotile** with the **exception of some strains of *Terrabacter*. Aerobic and facultatively anaerobic**. Colonies are smooth, circular, and vary from white to yellow. Growth usually between 20 and 37°C, but may also occur at 40 or 42°C. **Oxidase-negative and in a few genera variable; catalase-positive**. The characteristic diamino acids in the peptidoglycan are LL- and *meso*-diaminopimelic acid (LL-A_2pm, *meso*-A_2pm,) and L-ornithine which is consistent with the **peptidoglycan types A1γ, A3γ, and A4β**, respectively. The major menaquinone is typically **MK-8(H_4)**, but **MK-8** may occur as main component, too. Common phospholipids are **phosphatidylglycerol**, **diphosphatidylglycerol**, and **phosphatidylinositol;** phosphatidylethanolamine and unidentified phospho- and glycolipids may additionally be present in some genera. The **cellular fatty acid profiles are complex** with **major amounts of iso- and anteiso-branched-chain acids together with saturated and monounsaturated straight-chain acids. Mycolic acids are absent**.

The family is a member of the order *Micrococcales* and currently accommodates 16 genera, among them *Intrasporangium* (Kalakoutskii et al., 1967), *Arsenicicoccus* (Collins et al., 2004), *Humihabitans* (Kageyama et al., 2007a), *Janibacter* (Martin et al., 1997), *Knoellia* (Groth et al., 2002), *Kribbia* (Jung et al., 2006), *Lapillicoccus* (Lee and Lee, 2007), *Marihabitans* (Kageyama et al., 2008a), *Ornithinicoccus* (Groth et al., 1999), *Ornithinimicrobium* (Groth et al., 2001), *Oryzihumus* (Kageyama et al., 2005), *Phycicoccus* (Lee, 2006), *Serinicoccus* (Yi et al., 2004), *Terrabacter* (Collins et al., 1989), *Terracoccus* (Prauser et al., 1997), and *Tetrasphaera* (Maszenan et al., 2000). The 16S rRNA gene signature nucleotides that define all genera of the family are: position 30:553 (C–G), 660:745 (G–C), 838:848 (C–G), and 859 (C). The signatures that differentiate the genera from one another are listed in Table 124.

DNA G+C content (mol%): 68–74.

Type genus: **Intrasporangium** Kalakoutskii, Kirillova and Krassil'nikov 1967, 79[AL].

Further descriptive information

The genera of the family *Intrasporangiaceae* are rather heterogeneous concerning their phenotypic characteristics. This is obvious from the diagnostic morphological and

chemotaxonomic characteristics listed in Table 125. According to the isomer and the kind of the diagnostic diamino acid in the peptidoglycan, the members of the *Intrasporangiaceae* can be divided into three groups. The first group contains the genera having LL-A_2pm in the peptidoglycan, namely *Intrasporangium* (Kalakoutskii et al., 1967), *Arsenicicoccus* (Collins et al., 2004), *Humihabitans* (Kageyama et al., 2007a), *Lapillicoccus* (Lee and Lee, 2007), *Terrabacter* (Collins et al., 1989), and *Terracoccus* (Prauser et al., 1997). The second group accommodates the genera possessing *meso*-A_2pm, including *Janibacter* (Martin et al., 1997), *Knoellia* (Groth et al., 2002), *Kribbia* (Jung et al., 2006), *Marihabitans* (Kageyama et al., 2008a), *Oryzihumus* (Kageyama et al., 2005), *Phycicoccus* (Lee, 2006), and *Tetrasphaera* (Maszenan et al., 2000). The genera falling into the third group have L-ornithine in the peptidoglycan; these are *Ornithinicoccus* (Groth et al., 1999), *Ornithinimicrobium* (Groth et al., 2001), and *Serinicoccus* (Yi et al., 2004). Furthermore, a group of related strains comprises the L-lysine-containing genus *Sanguibacter* (Fernández-Garayzábal et al., 1995a, 1995b), now classified in the family *Sanguibacteraceae*, and the two genera *Actinotalea* (Yi et al., 2007) and *Demequina* (Yi et al., 2007), both with L-ornithine in the cell wall, and which are classified in this volume within the *Cellulomonadaceae*.

The genera *Intrasporangium, Terracoccus, Terrabacter*, and *Janibacter* share putrescine as the major polyamine (Busse and Schumann, 1999). The type genus *Intrasporangium* shares with its most closely related genus, *Humihabitans*, the occurrence of a branched vegetative mycelium with the tendency to fragmentation, but differs from this genus by possessing MK-8 as major menaquinone. Interestingly, MK-8 as main component of the menaquinones is also found in the pleomorphic species *Tetrasphaera vanveenii* (McKenzíe et al., 2006) which shows filamentous growth when grown on glucose sulfide (GS) medium under laboratory conditions (Williams and Unz., 1985). The filaments are similar to those observed in the biomass samples obtained from activated sludge plants. In contrast to *Intrasporangium*, minor amounts of MK-8(H_2) and MK-8(H_4) are additionally present in *Tetrasphaera vanveenii*, and the formation of a branched mycelium is not observed. The occurrence of spherical or lemon-shaped vesicles in cultures of *Intrasporangium calvum* caused controversial discussions about their function. While Kalakoutskii et al. (1967) believed that the vesicles are comparable to the sporangia of *Actinoplanes* and other sporangia-forming actinomycetes, Lechevalier and Lechevalier (1969) did not find evidence of any stage of sporangiospore formation in *Intrasporangium calvum* vesicles by electron microscopic studies. Furthermore, Lechevalier and Lechevalier observed similar swellings in different actinomycetes isolated from soil and grown on media which were nutritionally unsatisfactory and in older cultures such as those of *Intrasporangium calvum*. Based on these studies, the vesicles should not be considered as morphological structures of taxonomic importance (Lechevalier and Lechevalier, 1969; Prauser et al., 1997).

The majority of strains belonging to the family were isolated from activated sludge or soils from different geographic regions including agricultural fields, soil from caves, permafrost soil, and marine sediments. Some of the strains affiliated to the genera *Arsenicicoccus, Kribbia, Ornithinimicrobium*, and *Tetrasphaera* are involved in the degradation of different kinds of toxic chemical compounds in waste water treatment plants or in contaminated soils. Some of the strains belonging to the genus *Janibacter* are associated with insects, hard corals, or plants. The phylogenetic positions of the current members of the family *Intrasporangiaceae* are shown in the 16S rRNA gene sequence based phylogenetic tree (Figure 161).

Taxonomic comments

The family *Intrasporangiaceae* was established by Rainey et al. 1997 (in Stackebrandt et al., 1997) to accommodate the genera *Intrasporangium, Sanguibacter*, and *Terrabacter*. Because of their genomic relatedness and the correspondence in the signature nucleotides, the genera *Janibacter* and *Terracoccus* were later included in this family (Stackebrandt and Schumann, 2000). With the addition of these taxa into the *Intrasporangiaceae*, it became evident that *Sanguibacter* formed a separate line of descent within the suborder *Micrococcineae* (elevated to order *Micrococcales* in the present volume) and had to be excluded from the *Intrasporangiaceae*. Consequently the 16S rRNA gene signature nucleotides specific for the emended family *Intrasporangiaceae* had to be redefined and *Sanguibacter* was proposed as the type genus of a novel family (Stackebrandt and Schumann, 2000). The genus *Ornithinicoccus* was at that time considered not included into the *Intrasporangiaceae* as the 16S rRNA gene signatures showed significant deviations from this set. However, with the addition of further actinobacterial 16S rRNA gene sequences to the databases, it has become obvious that *Ornithinicoccus, Ornithinimicrobium, Knoellia, Tetrasphaera, Arsenicicoccus, Serinicoccus*, and *Oryzihumus* should also be affiliated to the *Intrasporangiaceae* together with "*Candidatus* Nostocoida limicola" Blackall et al. 2000 (Garrity et al., 2007). Based on the later finding that the isolates of "*Candidatus* Nostocoida limicola" are members of the genus *Tetrasphaera* and represent three novel species of this genus (McKenzíe et al., 2006), the term "*Candidatus* Nostocoida limicola" lost its standing in nomenclature for these organisms and consequently should no longer be used.

From the phylogenetic data, it is very likely that the recently described genera *Kribbia, Phycicoccus, Lapillicoccus, Humihabitans*, and *Marihabitans* belong to the family *Intrasporangiaceae*.

It should be noted that the genera *Lapillicoccus* and *Phycicoccus* show a close relationship to members of the genus *Tetrasphaera* (Figure 161). A tree on the basis of the maximum-likelihood algorithm revealed the separate position of these genera. The genus *Lapillicoccus* is chemotaxonomically clearly different from *Tetrasphaera*, in contrast to *Phycicoccus* (Table 125). The genus *Tetrasphaera* is heterogeneous and should perhaps be divided in future studies on the basis of more strains. The genera *Demequina* and *Actinotalea* are grouped more closely to *Sanguibacter* and *Cellulomonas*, which also show a closer relationship to *Rarobacter, Cellulosimicrobium*, and *Promicromonospora*.

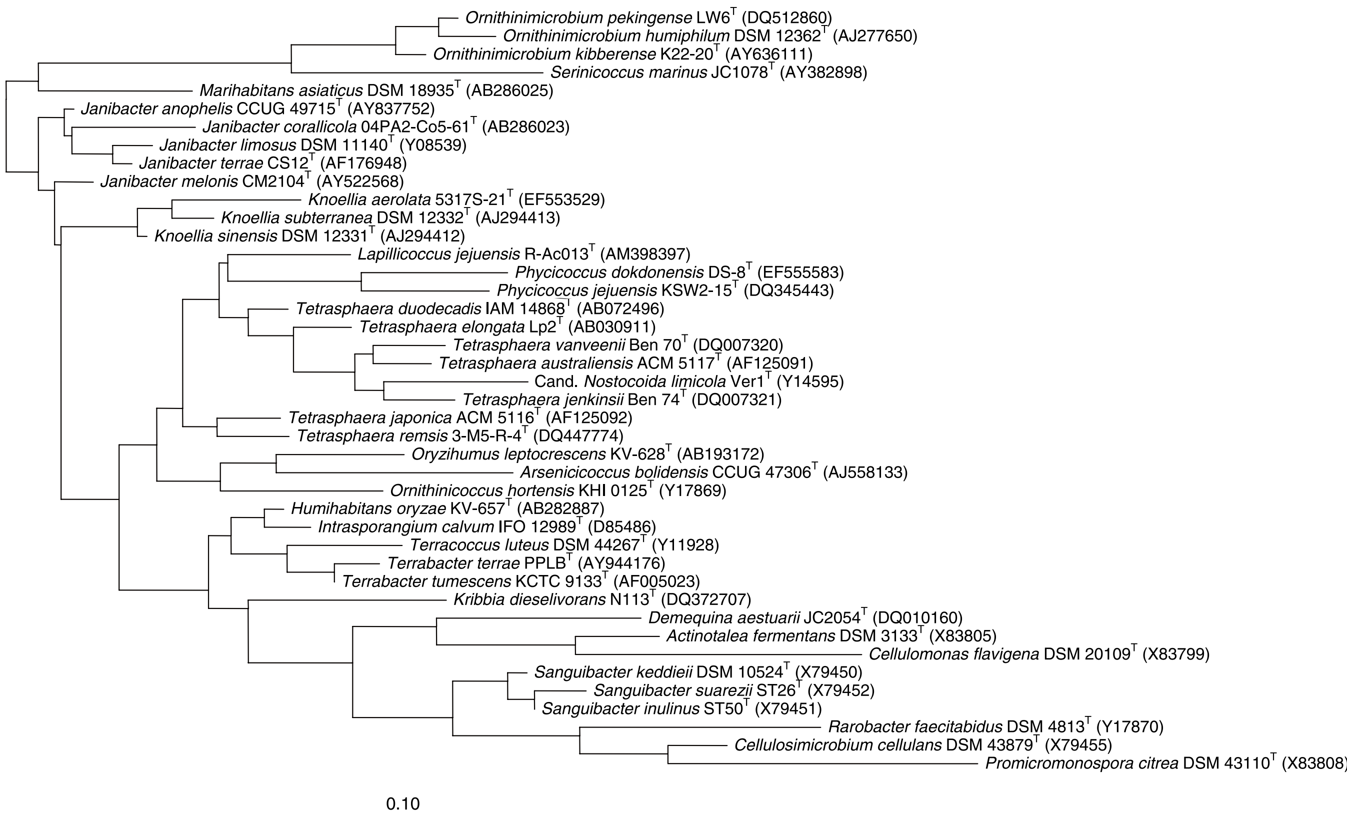

FIGURE 161. Phylogenetic tree showing the relationship of members of the family *Intrasporangiaceae* on the basis of 16S rRNA gene sequences available from the European Molecular Biology Laboratory databank (accession numbers are given in brackets). The tree was calculated with the maximum-likelihood method, using the software environment ARB (Ludwig et al., 2004). A filter defining positions which share identical residues in at least 50% of all included sequences from the family *Intrasporangiaceae*, was used for reconstructing the tree. Bar = 0.10 substitutions per site.

Genus I. **Intrasporangium** Kalakoutskii, Kirillova and Krassilnikov 1967, 79[AL]

INGRID GROTH

In.tra.spo.ran′gi.um. L. prep. *intra* within; Gr. n. *spora* a seed; Gr. n. *angeion* a vessel; N.L. neut. n. *Intrasporangium* a name coined to emphasize the possibility of intercalary formation of sporangia in mycelial filaments.

Branching mycelium, 0.4–1.2 µm in diameter, **with a tendency to break into fragments of various size and shape**. **No formation of aerial mycelium**. Gram-stain-positive, not acid-fast. Spherical and lemon-shaped vesicles (5–15 µm in diameter) are formed intercalary and/or at the hyphal apices depending on the age of the cultures. **Nonmotile**. **Aerobic**. Colonies are compact, 1–5 mm, circular, glistening and cream-whitish. Good growth on complex organic media containing peptone and meat extract and at temperatures of 28–37°C. No growth at 45°C and on the majority of mineral synthetic media routinely employed for actinomycetes. The **peptidoglycan type is A3γ** based on LL-A_2pm as the characteristic diamino acid. The predominant menaquinone is **MK-8**. The polar lipids consist of **phosphatidylinositol, phosphatidylinositol mannoside, phosphatidylglycerol, and diphosphatidylglycerol.** The cellular fatty acid profile is dominated by **iso- and anteiso-branched-chain acids** with major amounts of $C_{15:0}$ iso, $C_{15:0}$ anteiso, and $C_{16:0}$ iso. Mycolic acids are absent. Based on 16S rRNA gene sequence comparison, *Intrasporangium* is most closely related to the genera *Humihabitans* and *Terracoccus*. Further close relatives are the genera, *Terrabacter*, *Janibacter*, *Knoellia*, and *Lapillicoccus*. The 16S rRNA gene signature nucleotides that differentiate the genus from the other genera of the family *Intrasporangiaceae* are listed in Table 124.

DNA G+C content (mol%): 68.

Type species: **Intrasporangium calvum** Kalakoutskii, Kirillova and Krassilnikov 1967, 79[AL].

Further descriptive information

The genus is represented by the sole species *Intrasporangium calvum* (Kalakoutskii et al., 1967) and accommodates a single strain. A second strain is mentioned by Sukapure et al. (1970). However, this strain has not been deposited in any type culture collection, and a detailed description is missing. The closest phylogenetic neighbors of *Intrasporangium calvum* are *Terracoccus luteus* (Prauser et al., 1997) and *Humihabitans oryzae* (Kageyama

et al., 2007a). Both genera are currently represented by only a single strain, too. *Intrasporangium* shares with *Terracoccus* and *Humihabitans* 16S rRNA gene sequence similarities of 97.7% and 97.6%, respectively. Slightly less closely related are the genera *Terrabacter* (Collins et al., 1989), *Janibacter* (Martin et al., 1997), *Knoellia* (Groth et al., 2002)and *Lapillicoccus* (Lee and Lee, 2007) showing sequence similarities of 96.5–97.4%; 95.6–97.0%; 94.9–96.4% and 96.2%, respectively. The chemotaxonomic data referring to the composition of the interpeptide bridge, the pattern of the polar lipids, and the profile of cellular fatty acids for *Intrasporangium calvum* were obtained by Schumann et al. (1997) as a result of a comprehensive study with type strains of LL-A_2pm-containing taxa. The authors supplemented the data of the structure of the interpeptide bridge reported by Kalakoutskii et al. (1989) in the previous edition of this *Manual*. The interpeptide bridge of *Intrasporangium calvum* was found to consist of three glycine residues and a fourth glycine residue bound to the α-carboxyl group of the D-glutamic acid in position 2 of the peptide subunit (Prauser et al., 1997). The previously given data related to the fatty acid profile and the pattern of phospholipids could not be confirmed by Schumann et al. (1997) and had to be replaced. The characteristic vesicles occurring in old cultures of *Intrasporangium calvum* are not comparable to true sporangia, as was shown by electron microscopic studies (Lechevalier and Lechevalier, 1969). Prauser et al. (1997) confirmed that *Intrasporangium calvum* was mistakenly thought to form sporangia.

Enrichment and isolation procedures

Intrasporangium calvum grows only moderately and rather slowly even on peptone containing media. Subculturing of the organism on yeast peptone agar (g/l tap water: baker's yeast, 5.0; peptone, 5.0; glucose, 10.0 and agar, 15; pH 7.0) and in different variations of meat-extract-peptone broth or agar (g/l: peptone, 5.0; beef extract, 5.0; NaCl, 5.0 and agar 15.0–20.0, pH 7.2–7.4) supplemented with either 0.5% glycerol, 0.1% yeast extract, 0.5% glucose, 5% starch, 0.001% Na-thioglycollate, or 10% blood serum did not improve growth. Growth was sparse on oatmeal agar, rice agar, yeast glucose agar, and wheat meal agar. No growth was obtained on malt agar supplemented with 1% $CaCO_3$, potato agar, Czapek agar, glutamic acid glucose agar, glucose asparagine agar, soil extract- or water agar. Growth was also not enhanced on complex media upon enrichment of the atmosphere by H_2 and/or CO_2. The type strain was isolated under nonselective conditions on plates of meat-peptone agar exposed to the atmosphere of a school dining room (Kalakoutskii et al., 1967).

Maintenance procedures

Cultures of *Intrasporangium calvum* can be maintained by serial transfers on the above-mentioned complex media containing peptone and meat-extract. For long-term preservation, routine procedures of lyophilization or storage in the vapor phase of liquid nitrogen (−140°C) by adding 5% dimethylsulfoxide to the cultures can be applied.

Differentiation of the genus *Intrasporangium* from other genera

In the 16S rRNA gene tree of the *Intrasporangiaceae*, the genus *Intrasporangium* forms a common branch with the genus *Humihabitans* adjacent to the genera *Terracoccus* and *Terrabacter*. The phenotypic differences between *Intrasporangium* and the very closely related *Humihabitans* are mainly based on the menaquinone type. In contrast to *Humihabitans* and all other genera of the family *Intrasporangiaceae*, *Intrasporangium* has MK-8 as major menaquinone. However, one species of the genus *Tetrasphaera* (*Tetrasphaera vanveenii*) also possesses MK-8 as main menaquinone (McKenzíe et al., 2006). As both *Intrasporangium* and *Humihabitans* are represented by a single strain, the phylogenetic and phenotypic variability within the genus cannot currently be assessed. *Intrasporangium* shares with *Terracoccus* and *Terrabacter* the peptidoglycan type A3γ (Schleifer and Kandler, 1972), but it can be readily distinguished from these two genera by the menaquinone type, differences in the composition of fatty acids and polar lipids, and differences in morphological properties. The susceptibility of *Intrasporangium calvum* to genus-specific phages (Prauser and Falta, 1968; Wellington and Williams, 1981) and the results of extensive numerical taxonomic studies (Williams et al., 1983) additionally underline the differences from *Terracoccus*, *Terrabacter*, and equally from all other aerobic mycelium-forming actinomycetes. The slightly less closely related genera *Janibacter* and *Knoellia* can be readily distinguished from *Intrasporangium* by the presence of *meso*-A_2pm in their peptidoglycan, menaquinones of the MK-8(H_4) type, and morphological and further chemotaxonomic characteristics listed in Table 125.

Taxonomic comments

The given description is currently based on a single species with a single strain and therefore cannot reflect the phylogenetic depth and the phenotypic variability of the entire taxon. Ecological aspects cannot be considered as the real habitat of *Intrasporangium* is unknown. Comparative studies based on further isolates would also be useful to clarify the function of the intercalar vesicles (Figure 162), which should not be termed sporangia.

Acknowledgements

L.V. Kalakoutskii wrote the section on *Intrasporangium* in the previous edition of this *Manual* (1986 and 1989). Most of the data referring to morphological, physiological, and cultural characteristics have been retained from that version. I am grateful to H. Prauser for his helpful discussions and to B. Schütze for critical reading of this article.

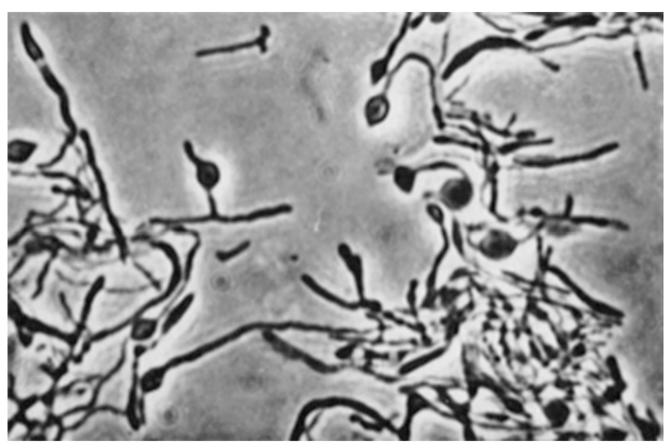

FIGURE 162. 6-d-old slide culture of *Intrasporangium calvum* on meat-peptone agar (4000×). Phase contrast. Branching mycelium and intramycelial vesicles in both terminal and intercalary positions (Reproduced with permission from Kalakoutskii et al., 1967. J. Gen. Microbiol. *48*: 79–85.).

List of species of the genus *Intrasporangium*

1. **Intrasporangium calvum** Kalakoutskii, Kirillova and Krassilnikov 1967, 79[AL]

cal′vum. L. neut. adj. *calvum* bald, referring to the absence of aerial mycelium.

The description is the same as for the genus. Macroscopically visible colonies appear on peptone containing media after 3–5 d of incubation at 28°C. Colonies are viscous, round, glistening, and whitish, becoming creamy on aging. The vesicles begin to appear following 5–6 d of cultivation on solid media, but are rare under conditions of submerged cultivation. Growth in liquid cultures usually occurs in a sedimented form. Vesicles are abundant in older cultures (about 12 d). The temperature range for growth is 10–42°C. Nitrate is reduced to nitrite. According to Williams et al. (1983) the organism is able to utilize L-arginine, L-cysteine, L-methionine, L-phenylalanine, and L-serine as sole nitrogen source (0.1%, w/v) in a basal medium containing glucose and mineral salts. On ISP medium 9 the following compounds are able to support growth if added as sole carbon sources (1.0%, w/v): D-glucose, cellobiose, D-fructose, mannitol, L-rhamnose, salicin, trehalose, D-xylose, and sodium pyruvate (0.1%, w/v). Degradation of esculin, arbutin, casein, gelatin, elastin, Tween 80, and DNA was noted on modified Bennett's agar and Bacto DNase test agar (Difco). On modified Bennett's agar, growth was possible in the presence of any of the following compounds: phenylethanol (0.1%, w/v), potassium tellurite (0.01%, w/v), thallous acetate (0.001%, w/v), cephaloridine (100 μg/ml), gentamicin (100 μg/ml), neomycin (50 μg/ml), or tobramycin (50 μg/ml).

DNA G+C content (mol%): 68 (T_m).

Type strain: ATCC 23552, DSM 43043, JCM 3097, KIP-7, NBRC 12989, NRRL B-3866, VKM Ac-701.

Sequence accession no. (16S rRNA gene): AJ566282, D85486.

Genus II. **Arsenicicoccus** Collins, Routh, Saraswathy, Lawson, Schumann, Welinder-Olsson and Falsen 2004, 607[VP]

Paul A. Lawson

Ar.se.ni.ci.coc′cus. L. n. *arsenicum* arsenic; N.L. masc. n. *coccus* berry (from Gr. masc. n. *kokkos* grain, seed), N.L. masc. n. *Arsenicicoccus* arsenic coccus, because the type species was recovered from an arsenic enrichment).

Cells are cocci that occur in clusters. Gram-stain-positive and nonsporeforming. **Facultatively anaerobic and catalase-positive.** Acid is formed from glucose and some other carbohydrates. Nitrate is reduced. Voges–Proskauer-negative. **The major long-chain cellular fatty acids are a complex mixture of straight-chain saturated, monounsaturated, iso- and anteiso-methyl-branched acids.** Hydroxy fatty acids are not present. **The major respiratory quinone is MK-8(H_4). Cell-wall murein is based on LL-diaminopimelic acid (type: LL-Dpm-glycine$_1$).** Isolated from arsenic enrichment from sediment containing mine waste (Adak, Boliden region, Sweden).

DNA G+C content (mol%): 72.2.

Type species: **Arsenicicoccus bolidensis** Collins, Routh, Saraswathy, Lawson, Schumann, Welinder-Olsson and Falsen 2004, 608[VP].

Further descriptive information

The genus contains only one species, *Arsenicicoccus bolidensis*, and therefore the characteristics provided below refer to this species. Using commercially available API kits, acid is formed from fructose, glucose, glycogen, mannitol, mannose, sucrose, and D-xylose. Depending on the test kit, acid may or may not be produced from cellobiose, lactose, maltose, and ribose. Using the API ZYM system, alkaline phosphatase, esterase C4, ester lipase C8, α- and β-galactosidase, and α- and β-glucosidase are positive; acid phosphatase and phosphoamidase are either weakly positive or negative. Chymotrypsin, cystine arlyamidase, α-fucosidase, β-glucuronidase, α-mannosidase, lipase C14, leucine arylamidase, *N*-acetyl-β-glucosaminidase, trypsin, and valine arylamidase are not detected. Using the API Coryne test kit, alkaline phosphatase, β-galactosidase, α-glucosidase, pyrazinamidase, and pyroydonyl arylamidase are detected, but not β-glucuronidase or *N*-acetyl-β-glucosaminidase. Esculin and gelatin are hydrolyzed, but urea is not. Chemotaxonomic characteristics are as given in the genus description. Possess As(V) reduction mechanisms that are coupled to respiration or impart resistance to As toxicity.

Isolation procedures

Arsenicicoccus bolidensis was isolated from sediment from a man-made lake near the town of Adak (Boliden region, Sweden) containing mine waste with high concentrations of As, Cu, and Zn present. The abandoned mine trailings are underlain by peat bogs and are mixed with glacial till (Routh and Saraswathy, 2005). Several 30–45 cm long undisturbed sediment cores were collected across the lake using a gravity corer, transported to the laboratory within 48 h, and immediately sliced for various geochemical and microbiological assays. During slicing, the outer surface of the cores was pared with a sterile knife and samples stored in zip lock plastic bags. Sediments were added to a basal salts medium (BSM) for enrichment. BSM contained the following constituents (in g/l): NH_4Cl, 0.25; K_2HPO_4, 0.14; KCl, 0.5; $CaCl_2·2H_2O$, 0.15; NaCl, 1.0: $MgCl_2·6H_2O$, 0.62; and 1 ml of trace elements solution containing $MnCl_2·4H_2O$, 0.1 mg; $FeCl_2·4H_2O$, 1.5 mg; $Co(NO_3)_2·6H_2O$, 0.12 mg; $ZnCl_2$, 0.07 mg; $CuCl_2·2H_2O$, 0.015 mg; H_3BO_3, 0.06 mg; $Na_2MoO_4·2H_2O$, 0.025 mg; $Ni(NO_3)_2·6H_2O$, 0.025 mg; and *para*-aminobenzoic acid, 0.05 mg. Lactate (0.089 mM) was used as the sole carbon source in the medium. The medium was later spiked with 0.435 mM As to facilitate the isolation of As resistant strains. The As enriched cultures were diluted 10-fold, and 0.1 ml aliquots of the extract were spread onto Tryptic Soy Agar (TSA) plates spiked with

0.435 mM As. After 72 h of incubation at 22°C, colonies were selected and replated on the same medium until pure cultures were obtained.

Maintenance procedures

Strains grow well on Soy Yeast Extract medium or Columbia agar base supplemented with 5% defibrinated sheep blood at 22–25°C. For long-term preservation, strains can be maintained in a medium containing 15–20% glycerol at −70°C or lyophilized.

Taxonomic comments

The genus *Arsenicicoccus* was proposed in 2004 to accommodate a phylogenetically distinct Gram-stain-positive, catalase-positive, facultatively anaerobic, nonsporeforming coccus-shaped organism originating from a manmade lake sediment (Collins et al., 2004). Phylogenetic analysis using 16S rRNA gene sequences shows that the genus is phylogenetically related to the order *Actinomycetales* of the class *Actinobacteria*. The taxon is monospecific and belongs to the family *Intrasporangiaceae* within the suborder *Micrococcineae* (Stackebrandt et al., 1997), which has been elevated to order *Micrococcales* in the taxonomic roadmap to the present volume. The family *Intrasporangiaceae* is a phenotypically heterogeneous taxon which contains actinomycetes that can be divided into three groups on the basis of the diagnostic diamino acid in the cell-wall peptidoglycan. The genera *Intrasporangium* (Kalakoutskii et al., 1967), *Terrabacter* (Collins et al., 1989), *Terracoccus* (Prauser et al., 1997), *Arsenicicoccus* (Collins et al., 2004), *Kribbia* (Jung et al., 2006), and *Lapillicoccus* (Lee and Lee, 2007) contain LL-diaminopimelic acid; the genera *Janibacter* (Martin et al., 1997), *Tetrasphaera* (Maszenan et al., 2000), *Knoellia* (Groth et al., 2002), *Oryzihumus* (Kageyama et al., 2005), and *Phycicoccus* (Lee, 2006) *meso*-diaminopimelic acid, and the genera *Ornithinicoccus* (Groth et al., 1999), *Ornithinimicrobium* (Groth et al., 2001), and *Serinicoccus* (Yi et al., 2004) contain L-ornithine.

Arsenicicoccus bolidensis forms a distinct lineage within this family of organisms, but does not display a particularly close affinity with any of the aforementioned taxa. Figure 163 depicts a phylogenetic reconstruction using the neighbor-joining method. *Arsenicicoccus bolidensis* clusters with *Oryzihumus leptocrescens*, *Ornithinicoccus hortensis*, and *Lapillicoccus jejuensis*. However, this grouping is not supported by significant bootstrap values nor is this cluster preserved when maximum-parsimony and maximum-likelihood tree-making algorithms are employed (data not shown).

Differentiation of the genus *Arsenicicoccus* from other genera

In addition to differentiation by 16S rRNA gene sequence analysis, *Arsenicicoccus bolidensis* can be readily distinguished from its closest phylogenetic relatives using a combination of biochemical, chemotaxonomic and morphological criteria (see Table 126).

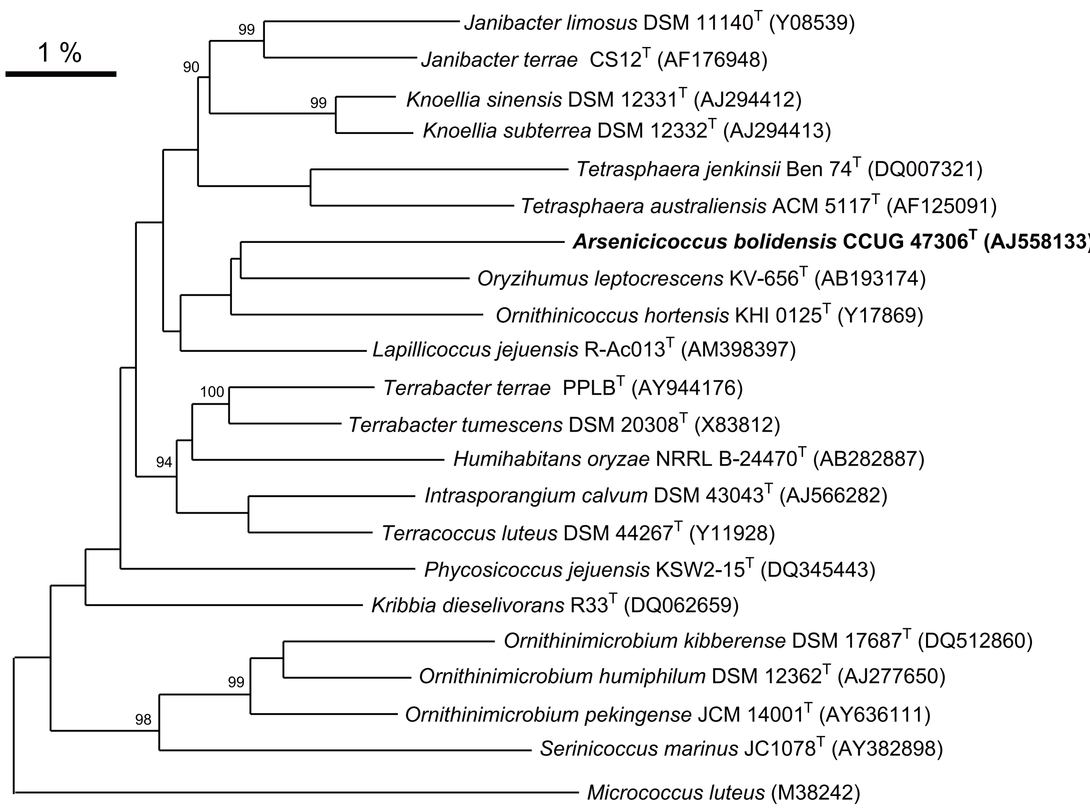

FIGURE 163. Unrooted neighbor-joining tree depicting the estimated phylogenetic relationships of members of the genus *Arsenicicoccus* and other members of the family *Intrasporangiaceae*; *Micrococcus luteus* was used as the outgroup. The numbers on the branches refer to bootstrap values determined from 1000 replications. Only values above 90% are shown. Bar = 1% sequence divergence.

TABLE 126. Characteristics distinguishing the genus *Arsenicicoccus* and genera in the family *Intrasporangiaceae*

List of species of the genus *Arsenicicoccus*

1. **Arsenicicoccus bolidensis** Collins, Routh, Saraswathy, Lawson, Schumann, Welinder-Olsson and Falsen 2004, 608[VP]

bo.li.den′sis. N.L. masc. adj. *bolidensis* pertaining to the Boliden region in Vasterbotten district of northern Sweden, where the type strain was isolated.

Characteristics are as given for the genus with the following information. Depending on the test kit, acid may or may not be produced from cellobiose, lactose, maltose, and ribose. Using the API ZYM system, alkaline phosphatase, esterase C4, ester lipase C8, α- and β-galactosidase, α- and β-glucosidase are positive; acid phosphatase and phosphoamidase are either weakly positive or negative. Chymotrypsin, cystine arlyamidase, α-fucosidase, β-glucuronidase, α-mannosidase, lipase C14, leucine arylamidase, *N*-acetyl-β-glucosaminidase, trypsin, and valine arylamidase are not detected. Using the API Coryne test kit, alkaline phosphatase, β-galactosidase, α-glucosidase, pyrazinamidase, and pyroydonyl arylamidase are detected but β-glucuronidase and *N*-acetyl-β-glucosaminidase are not. Esculin and gelatin are hydrolyzed, but urea is not. Chemotaxonomic characteristics are as given in the genus description. Possess As(V) reduction mechanisms that are coupled to respiration or impart resistance to As toxicity. Other characteristics are as given for the genus.

Source: arsenic enrichment from sediment containing mine waste (Boliden, Sweden).

DNA G+C content (mol%): 72.2 (HPLC).

Type strain: CCUG 47306, DSM 15745, IAM 15342, JCM 13385.

Sequence accession no. (16S rRNA gene): AJ558133.

Genus III. **Humihabitans** Kageyama, Takahashi and Ōmura 2007a, 2165[VP]

The Editorial Board

Hu.mi.ha′bi.tans. L. masc. n. *humus* soil; L. masc. n. *habitans* an inhabitant; N.L. masc. n. *Humihabitans* an inhabitant of soil.

Aerobes that form **branching hyphae** and fragmentary vegetative mycelium. Cell length is 1.0–2.2 µm with a mean diameter of 0.5 µm. **Stain Gram-positive. Catalase-positive.** The **major menaquinone is MK-8(H_4)**. The cell-wall peptidoglycan is type A3c and contains the diagnostic diamino acid, **LL-diaminopimelic acid**. Mycolic acids are absent. Phylogenetic analysis of the 16S rRNA gene sequence positions this genus within the family *Intrasporangiaceae*. Its closest relative is *Intrasporangium calvum*, from which it can be distinguished by the presence of the menquinone MK-8(H_4). The type strain was isolated from soil samples of a rice paddy field in Saitama Prefecture, Japan, using agar medium containing oxidant scavengers.

DNA G+C content (mol%): 70.

Type species: **Humihabitans oryzae** Kageyama, Takahashi and Ōmura 2007a, 2165[VP].

Enrichment and isolation procedures

Humihabitans type strain KV-657 was isolated from soil samples of rice paddies when grown on nutrient agar medium supplemented with superoxide dismutase. This technique was found to increase the number of colonies that appeared when isolating organisms from soil samples (Takahashi et al., 2003). Morphological and phenotypic studies were conducted on cells grown in GPM agar medium (1% D-glucose, 0.5% peptone, 0.5% meat extract, 0.3% NaCl and 1.2% agar; pH 7.0) and 1/5-strength GPM medium, respectively. Cells were isolated for studies after 2 d growth at 27°C.

Differentiation of the genus *Humihabitans* from other genera

Humihabitans can be distinguished from other members of the *Intrasporangiaceae* by phenotypic and chemotaxonomic properties. The major cellular fatty acids of isolates of this family are a complex mixture of straight-chain saturated, monounsaturated, iso- and anteiso-methyl-branched chains. *Humihabitans* contains a mixture of all these fatty acids, as well as the presence of the major menaquinone, MK-8(H_4), both characteristics of which distinguish it from the genera *Intrasporangium*. *Humihabitans* form branching and fragmentary hyphae, distinguishing the isolate from other genera including *Arsenicicoccus*, *Terrabacter*, and *Terracoccus*. Isolates of the genus *Arsenicicoccus* have a similar complex mixture of major fatty acids but differ from *Humihabitans* in cell morphology.

On the basis of 16S rRNA gene sequence, *Humihabitans* is related to *Intrasporangium calvum* with a similarity of 97.6%. The DNA–DNA hybridization with the same species is a relatively high 33–34%.

List of species of the genus *Humihabitans*

1. **Humihabitans oryzae** Kageyama, Takahashi and Ōmura 2007a, 2165[VP]

o.ry′za.e. L. gen. n. *oryzae* of rice, pertaining to the isolation of the type stain from rice paddy soil.

Cells form branching hyphae or fragmentary vegetative mycelium and range in length between 1.0 and 2.2 µm, with a mean diameter of 0.5 µm. Colonies are pale yellow in color. Growth occurs at pH 5–11 and at 8°C and 40°C. In 1/5-strength nutrient agar medium, NaCl is tolerated up to 3%. Utilizes D-fructose, D-glucose, maltose, D-mannitol, D-mannose, sucrose, trehalose and D-xylose but not L-arabinose, D-galactose, raffinose and L-rhamnose. Enzymic

activities present include esterase (C4), esterase lipase (C8), valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, acid phospatase, α-galactosidase, β-galactosidase and α-glucosidase. Weak reactions for lipase (C14), leucine arylamidase, naphthol-AS-BI-phosphohydrolase and β-glucosidase were detected. The cellular fatty acid components include $C_{14:0}$ iso (7.3%), $C_{15:0}$ iso (39.6%), $C_{15:0}$ anteiso (5.8%), $C_{15:0}$ (4.8%), $C_{16:0}$ iso (13.3%), $C_{17:0}$ iso (2.0%), $C_{17:0}$ anteiso (2.0%), $C_{17:0}$ ω8*c* (6.4%) and $C_{17:0}$ (5.8%).

DNA G+C content (mol%): 70 (HPLC).

Type strain: KV-657.

Sequence accession no. (16S rRNA gene): AB282887.

Genus IV. **Janibacter** Martin, Schumann, Rainey, Schuetze and Groth 1997, 533[VP]

Ingrid Groth

Ja.ni.bac′ter L. n. *Janus* a god in Roman mythology, who is said to have had two faces; N.L. masc. n. *bacter* a rod; N.L. masc. n. *Janibacter* referring to the changing morphology of the microorganisms.

Cells are typically **cocci**; in young cultures **irregular short rods or rod-like cells** may occur. Cells occur singly, in pairs, short chains, or irregular clumps. Gram-stain-positive. Not acid-fast. **Nonsporeforming. Nonmotile. Aerobic**. Colonies are smooth, circular, convex, and vary in color from white to yellow. Good growth on complex organic media. Optimal temperatures for growth 23–35°C. NaCl in the culture medium may be tolerated up to 10%. **Oxidase variable**; **catalase-positive**. The **peptidoglycan type** is **A1γ**, *meso*-A_2pm directly cross-linked, which is in accordance with type A31. The **acyl type is acetyl**. **Whole-cell sugars** so far analyzed are **glucose, mannose, and ribose**. The **predominant menaquinone is MK-8(H_4)**. The **polar lipids** consist of **phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol**. The **cellular fatty acid profiles are complex with major amounts of iso-branched-chain acids together with straight-chain saturated and monounsaturated acids** ($C_{16:0}$ iso, $C_{17:0}$, $C_{17:1}$ ω8*c*, $C_{18:1}$ ω9*c*). **Mycolic acids are absent**. 16S rRNA gene sequence analysis reveals that members of *Janibacter* are closely related to strains of *Knoellia*, *Tetrasphaera*, *Terrabacter*, *Intrasporangium*, *Lapillicoccus*, and *Terracoccus* with which they share 16S rRNA gene sequence similarities of 95.0–98.2%, 94.1–97.1%, 95.2–97.0%, 95.6–97.0%, 96.1–96.4%, and 95.0–96.4%, respectively. The 16S rRNA gene signature nucleotides that differentiate the genus from the other genera of the family *Intrasporangiaceae* are listed in Table 124, chapter *Intrasporangiaceae*.

DNA G+C content (mol%): 69–73.

Type species: **Janibacter limosus** Martin, Schumann, Rainey, Schuetze and Groth 1997, 533[VP].

Further descriptive information

The genus *Janibacter* currently accommodates six species, *Janibacter limosus* (Martin et al., 1997), *Janibacter anophelis* (Kämpfer et al., 2006), *Janibacter corallicola* (Kageyama et al., 2007b, 2007c), *Janibacter hoylei* (Shivaji et al., 2009), *Janibacter melonis* (Yoon et al., 2004), and *Janibacter terrae* (Yoon et al., 2000; emend. Lang et al., 2003). While strains of *Janibacter limosus* and *Janibacter terrae* were isolated from wastewater contaminated soils *Janibacter anophelis*, *Janibacter corallicola*, and *Janibacter melonis* were associated with insects, a hard coral, or plants, respectively. *Janibacter hoylei* was isolated from air.

The 16S rRNA gene sequence similarity values between the type strains of the *Janibacter* species range from 97.0–98.9%. The low levels of DNA–DNA relatedness obtained in DNA–DNA hybridization studies with different combinations of the type strains clearly separate these strains at the species level from one another (Kämpfer et al., 2006; Lang et al., 2003; Shivaji et al., 2009; Yoon et al., 2000, 2004). The same is true for the cellular fatty acid profiles which are useful in the differentiation of *Janibacter* species.

Cell morphology of *Janibacter* species comprises cocci together with short rods or rod-like cells. While young cultures either consist of cocci or short rods (Figure 164), stationary cells are always coccoid. A marked rod–coccus growth cycle is not reported. Neither substrate nor primary mycelium is formed. Growth occurs up to a temperature of 38°C, but 40°C may be also tolerated by some strains depending on the composition of the culture medium (Lang et al., 2003; Shivaji et al., 2009; Yoon et al., 2004). NaCl in the culture medium is tolerated up to a concentration of 7% and, in some cases, up to 10%. No growth occurs under anaerobic conditions.

The type strains of *Janibacter limosus*, *Janibacter hoylei*, *Janibacter melonis*, and *Janibacter terrae* are able to reduce nitrate to nitrite (data for *Janibacter anophelis* and *Janibacter corallicola* are not reported).The type strains of *Janibacter limosus*, *Janibacter anophelis*, *Janibacter corallicola*, *Janibacter melonis* and *Janibacter terrae* utilize D-glucose, D-maltose, D-mannose, and D-trehalose, in some cases at least in weak or delayed reactions (Kageyama et al., 2007b; Kämpfer et al., 2006). *Janibacter hoylei* does not utilize these carbon sources. The following physiological properties given for *Janibacter limosus* DSM 11140[T] in the original description (Martin et al., 1997) should be considered to be variable: decomposition of gelatin, starch, and Tween 80; utilization of acetate, benzoate, and citrate. Yoon et al. (2000) and Lang et al. (2003) obtained conflicting results when they used this strain as a reference in these tests. Acid production from various carbon sources was not observed in all currently described *Janibacter* species, both when tests based on the method of Hugh and Leifson (1953) or Kämpfer et al. (1991) were applied (Kämpfer et al., 2006; Martin et al., 1997; Shivaji et al., 2009; Yoon et al., 2000, 2004) and when commercially available test systems like the API 50CH galleries (bioMérieux) were used (Lang et al., 2003).

Susceptibility to antibiotics is only reported for two strains of *Janibacter limosus* (Martin et al., 1997). Some of the strains belonging to *Janibacter terrae* were found to be able to degrade environmental pollutants like dibenzofuran (Engesser et al., 1989; Strubel et al., 1989) or trichloroethylene (Imamura

et al., 2000). The two strains of *Janibacter melonis* are endophytic and are considered to cause abnormal spoilage in oriental melons (Yoon et al., 2004). The recently described type strain of *Janibacter anophelis* was isolated from the midgut of *Anopheles arabiensis* which may indicate an endosymbiontic life cycle (Kämpfer et al., 2006). The two strains of *Janibacter corallicola* (Kageyama et al., 2007b) derived from the hard coral *Acropora gemmifera* collected in the Angauru Coral Garden in Palau, a marine habitat. The type strain of *Janibacter hoylei* was isolated from an air sample collected at an altitude of 40–41.4 km.

Enrichment and isolation procedures

Strains of *Janibacter* grow readily in liquid or on solidified complex media, i.e. Bacto nutrient agar (Difco, g/l: Bacto beef extract, 3.0; Bacto peptone, 5.0; and Bacto agar, 15.0; pH 6.8), rich (R) medium (Yamada and Komagata, 1972) which is composed of (g/l): Bacto peptone (Difco), 10.0; yeast extract (Difco), 5.0; Casamino acids (Difco), 5.0; beef extract (Difco), 2.0; malt extract (Difco), 5.0; glycerol, 2.0; $MgSO_4 \cdot 7H_2O$, 1.0; Tween 80, 0.05; and agar, 20.0; pH 7.2, Bacto tryptic soy broth (Difco, g/l: Bacto tryptone, 17.0; Bacto soytone, 3.0; glucose, 2.5; NaCl, 5.0; and K_2HPO_4, 2.5; pH 7.3), and peptone-yeast extract-brain heart infusion medium (Yokota et al., 1993) containing (g/l): peptone, 10.0; yeast extract, 2.0; Bacto brain heart infusion (Difco), 2.0; NaCl, 2.0; and glucose, 2.0; pH 7.0, and GPM agar (Kageyama et al., 2007b) containing (g/l): glucose, 10.0; peptone, 5.0; meat extract, 5.0; NaCl, 3.0; and agar, 12.0; pH 7.0. The strains of *Janibacter limosus* were isolated from their special habitat on plate count agar (Difco, g/l: Bacto tryptone, 5.0; Bacto yeast extract, 2.5; Bacto glucose, 1.0; and Bacto agar, 15.0; pH 7.0) and those of *Janibacter melonis* on Bacto nutrient agar using standard dilution plate procedures. *Janibacter anophelis* was isolated by streaking the midgut suspension of the mosquito on agar plates containing LB agar (g/l: tryptone, 10; yeast extract, 5.0; NaCl, 10.0; glucose, 1.0; pH 7.0; and agar supplemented with $CaCl_2$ to a final concentration of 2.5 mM before pouring) (Lindh et al., 2005). In case of some strains of *Janibacter terrae*, special enrichment methods were applied using either dibenzofuran as sole source of carbon and energy (Lang et al., 2003) or incubating the isolation plates in a trichloroethylene enriched atmosphere (Imamura et al., 2000). The two strains of *Janibacter corallicola* were isolated from homogenized corals, suspended and diluted in sterile seawater, on MA + Ca medium which consists of Difco Marine Broth 2216 (Becton Dickinson), 3.74 g/l; filtrated seawater, 750 ml; distilled water with 1% $CaCO_3$, 250 ml; and agar, 15 g/l (Kageyama et al., 2007b). The type strain of *Janibacter hoylei* was isolated from an air sample collected at an altitude of 40–41.4 km using a balloon with a cryosampler. Under sterile laboratory conditions the air sample from the cryotube was sequentially filtered through a 0.45 μm filter and a 0.22 μm filter using a milipore filtration unit. The filters were cut into pieces and placed on agar plates containing nutrient agar, LB agar and minimal salt agar. Growth of strain PVAS[T] (*Janibacter hoylei*) was observed after 24 d of incubation at 30°C as a single colony on a minimal salt agar plate, which consisted of (per 100 ml) 20 ml of a 3.39% (w/v) sodium dihydrogen phosphate solution, 20 ml 1.5% (w/v) potassium phosphate, 20 ml 0.25% (w/v) NaCl, 20 ml 0.5% (w/v) ammonium chloride and 18 ml Millipore water. The final agar concentration was 2%. The medium was supplemented with 2 ml sterile 20% glucose and 0.2 ml sterile 0.1 M $MgSO_4$ solution; pH 7 (Shivaji et al., 2009).

Maintenance procedures

Cultures of *Janibacter* strains can be maintained by serial transfers on the complex organic media mentioned above. For long-term preservation, storage of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

Differentiation of the genus *Janibacter* from other genera

The genus *Janibacter* shares with the genera *Knoellia* (Groth et al., 2002), *Kribbia* (Jung et al., 2006), *Marihabitans* (Kageyama et al., 2008a), *Oryzihumus* (Kageyama et al., 2005), *Phycicoccus* (Lee, 2006), and *Tetrasphaera* (Maszenan et al., 2000) the peptidoglycan type A1γ (Schleifer and Kandler, 1972), based on *meso*-A_2pm, and the menaquinone type MK-8(H_4). However, *Janibacter* can be distinguished from these genera by the compositions of cellular fatty acids and phospholipids together with differences in morphological, cultural, and physiological characteristics. Among the *Actinobacteria*, the common occurrence of the peptidoglycan type A1γ and the menaquinone type MK-8(H_4) is also reported for some other genera which do not possess mycolic acids. These are the genera *Nakamurella* (*ex* Yoshimi et al. 1996) Tao et al. 2004, *Dermatophilus* Van Saceghem 1915, *Kineosphaera* Liu et al. 2002, and *Pseudonocardia* (Henssen 1957) emend. Warwick et al. 1994 emend. Reichert et al. 1998 emend. Huang et al. 2002. While *Nakamurella* and *Pseudonocardia* are the type genera of their own families; *Nakamurellaceae* (*ex* Yoshimi et al. 1996) Tao et al. 2004 emend. Zhi et al. 2009 and *Pseudonocardiaceae* (Embley et al. 1988, 1989) emend. Stackebrandt et al. 1997 emend. Zhi et al. 2009, respectively, the genera *Dermatophilus* and *Kineosphaera* are members of the *Dermatophilaceae* (Austwick 1958) emend. Stackebrandt et al. 1997 emend. Stackebrandt and Schumann 2000 emend. Zhi et al. 2009. The phylogenetic separateness of these genera from *Janibacter* is supported by a broad spectrum of different phenotypic characteristics. The above-mentioned close phylogenetic neighbors *Terrabacter*, *Intrasporangium*, *Lapillicoccus*, and *Terracoccus* have LL-A_2pm as the diagnostic diamino acid in their peptidoglycan

and can additionally be distinguished from *Janibacter* by morphological and further chemotaxonomic characteristics listed in Table 125 (chapter *Intrasporangiaceae*).

Taxonomic comments

An emended description of the species *Janibacter terrae* (Yoon et al., 2000) was given by Lang et al. (2003) due to the inclusion of ten dibenzofuran-degrading strains and *Janibacter brevis* as its later heterotypic synonym. Both species *Janibacter terrae* and *Janibacter brevis* were independently described by two research groups (Yoon et al., 2000; Imamura et al., 2000). Lang et al. (2003) carried out DNA–DNA hybridization with the type strains of *Janibacter brevis* DSM 13953^T and *Janibacter terrae* DSM 13876^T. As the DNA–DNA similarity between these strains was about 80% and the 16S rRNA gene sequence similarity was found to be 99.9%, it became obvious that *Janibacter brevis* and *Janibacter terrae* should be considered as synonyms of one species. According to Rule 24b of the Bacteriological Code the name *Janibacter terrae* has priority (Lang et al., 2003; Lapage et al., 1992).

List of species of the genus *Janibacter*

1. **Janibacter limosus** Martin, Schumann, Rainey, Schuetze and Groth 1997, 533^{VP}

li.mo′sus. L. masc. adj. *limosus* muddy, pertaining to sludge, the natural habitat of the species.

See Table 127 and the generic description. Cells are coccoid (0.3–1.2 μm) or short rods (0.4 × 1.4 μm). Optimum growth temperature is 28°C. Tolerates up to 10% NaCl in the culture medium. Utilizes formate and malate. Hippurate, succinate, and DL-tartrate are not utilized. Casein and tyrosine are hydrolyzed; adenine, esculin, hypoxanthine, urea, and xanthine are not hydrolyzed. H_2S is produced; indole and acetoin are not produced. The strains are susceptible to the following antibiotics (μg/disc): chloramphenicol (30), ciprofloxacin (5), erythromycin (15), gentamicin (10), kanamycin (30), lincomycin (2), neomycin (30), nitrofuran (300), oxytetracycline (30), and polymyxin B (300 IU/disc); but are not susceptible to penicillin G (2 IU/disc), rifampin (2), and sulfonamide (300). The predominant cellular fatty acids are $C_{17:1}$ ω8*c*, $C_{17:0}$, $C_{18:1}$ ω9*c*, and $C_{16:0}$ iso.

DNA G+C content (mol%): 70 (HPLC).

Type strain: HKI 83, ATCC 700321, CCUG 37980, CIP 105276, DSM 11140, NBRC 16128, JCM 10980.

Sequence accession no. (16S rRNA gene): Y08539.

2. **Janibacter anophelis** Kämpfer, Terenius, Lindh and Faye 2006, 391^{VP}

a.no.phe′lis. N.L. gen. n. *anophelis* of a mosquito of the genus *Anopheles*; the strain was isolated from the midgut of *Anopheles arabiensis.*

See Table 127 and the generic description. Optimum growth temperature in Luria–Bertani (LB) broth is 35°C with a generation time of 44 min. Utilizes propionate, fumarate, glutarate, 3-hydroybutyrate, DL-lactate, L-malate, pyruvate, L-alanine, L-aspartate, L-histidine, L-leucine, and L-serine as sole carbon sources; the following carbon sources are not utilized: *N*-acetyl-D-galactosamine, L-arabinose, *p*-arbutin, D-cellobiose, D-galactose, melibiose, L-rhamnose, D-ribose, salicin, D-xylose, adonitol, maltitol, D-mannitol, sorbitol, *trans*-aconitate, citrate, itaconate, mesaconate, β-alanine, L-ornithine, L-phenylalanine, L-tryptophan, DL-3-hydroxybenzoate, DL-4-hydroxybenzoate, and L-phenylacetate. The predominant cellular fatty acids are $C_{16:0}$ iso, $C_{17:0}$, and $C_{17:1}$ ω8*c*.

DNA G+C content (mol%): not available.

Type strain: H2.16B, CCUG 49715, CIP 108728, JCM 21813.

Sequence accession no. (16S rRNA gene): AY837752.

3. **Janibacter corallicola** Kageyama, Takahashi, Yasumoto-Hirose, Kasai, Shizuri and Ōmura 2007c, 2449^{VP} (Effective publication: Kageyama, Takahashi, Yasumoto-Hirose, Kasai, Shizuri and Ōmura 2007b, 187.)

co.ral.li′co.la. L. n. *corallum* coral; L. suff. *-cola* inhabitant, dweller, N.L. n. *corallicola* coral-dweller.

See Table 127 and the generic description. Cells are cocci and vary in their diameter from 0.6–1.1 μm. Colonies are pale yellow. Growth occurs in a range of pH 5–9 and a temperature range of 16–38°C, optimum growth at pH 6–8 and temperatures 23–36°C. NaCl is tolerated up to 7% in the culture medium. D-Galactose and raffinose are used as sole carbon sources, but L-arabinose, D-mannitol, and xylose are not. Using the API ZYM system, activity is detected for esterase (C4), esterase lipase (C8), α-glucosidase, leucine arylamidase, and naphthol-AS-BI-phosphohydrolase. Weak reactions are displayed for lipase (C14), valine arylamidase, acid phosphatase, and β-glucosidase. Activities for cystine arylamidase and trypsin are variable. No activity is detected for alkaline phosphatase, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosamidase, α-mannosidase, and α-fucosidase. The predominant cellular fatty acids are $C_{16:0}$ iso, $C_{17:0}$, $C_{17:1}$ ω8*c*, and $C_{18:1}$ ω9*c*.

DNA G+C content (mol%): 70–71 (HPLC).

Type strain: 04PA2-Co5-61, MBIC 08265, DSM 18906, JCM 15571.

Sequence accession no. (16S rRNA gene): AB286023.

4. **Janibacter hoylei** Shivaji, Chaturvedi, Begum, Pindi, Manorama, Ananth Padmanaban, Shouche, Pawar, Vaishampayan, Dutt, Datta, Manchanda, Rao, Bhargava and Narlikar 2009, 2981^{VP}

hoy′le.i. N.L. gen. masc. n. *hoylei* of Hoyle, named after Sir Fred Hoyle, the famous English astronomer.

See Table 127 and the generic description. Cells are cocci, 0.4–0.7 in diameter. Colonies on LB agar are creamish in color, entire, circular and 2 mm in diameter. Good growth on nutrient agar at 25–30°C. Grows in LB broth at 20–40°C and at pH 5–10, optimum growth at 30°C and pH 9. Grows in the presence of 5% (w/v) NaCl in LB broth, weak growth in LB broth containing 10% (w/v) NaCl. Oxidase-positive. H_2S and indole are not produced. Voges–Proskauer reaction is negative. Casein is hydrolyzed, Tween 80 and esculin are not hydrolyzed. D-malate, sodium benzoate, sodium citrate, sodium formate, sodium succinate, D-gluconate, inositol,

putrescine, sucrose and D-galactose are not utilized, but monomethyl succinate is utilized. The predominant cellular fatty acids are: $C_{16:0}$ iso, $C_{17:0}$ 10 methyl, $C_{17:1}$ ω9*c* and $C_{18:1}$ ω9*c*.

DNA G+C content (mol%): 72.8 (HPLC)

Type strain: PVAS-1, MTCC 8307, DSM 21601, CCUG 56714.

Sequence accession no. (16S rRNA gene): DQ317608

5. **Janibacter melonis** Yoon, Lee, Yeo and Choi 2004, 1979[VP]

me.lo′nis. L. gen. n. *melonis* of melon (*Cucumis melo*), referring to the fruit from which the organisms were isolated.

See Table 127 and the generic description. Cells are cocci (0.8–1.0 µm). Colonies on rich (R) medium are cream-colored and 1.5–3.0 mm in diameter. Optimum growth temperature is 30°C. Growth occurs at 10°C, but not at 4°C. In liquid brain heart infusion medium, 40°C is tolerated for growth; in rich (R) medium, no growth at 40°C. Optimal pH value for growth is around pH 7.0; no growth at pH 5.0. Utilizes citrate and formate; benzoate and succinate are not utilized. Tween 20, 40, 60, 80, esculin, casein, starch, and tyrosine are hydrolyzed. Hypoxanthine, xanthine, gelatin and urea are not hydrolyzed. H_2S, acetoin, and indole are not produced. The predominant cellular fatty acids are $C_{16:0}$ iso, $C_{17:1}$ ω8*c*, $C_{18:1}$ ω9*c*, or $C_{17:0}$.

DNA G+C content (mol%): 73 (HPLC).

Type strain: CM2104, DSM 16063, JCM 12321, KCTC 9987.

Sequence accession no. (16S rRNA gene): AY522568.

6. **Janibacter terrae** Yoon, Lee, Kang, Kho, Kang and Park 2000, 1826[VP] emend. Lang, Kroppenstedt, Swiderski, Schumann, Ludwig, Schmid and Weiss 2003, 2003.

ter′ra.e. L. gen. n. *terrae* of the earth.

See Table 127 and the generic description. Optimum growth temperature is in the range of 25–30°C. Maximum growth temperature in liquid rich (R) medium is 40°C. Growth occurs in liquid brain heart infusion medium in the presence of 10% NaCl. Casein, gelatin, and starch are hydrolyzed. Tween 80 and esculin are not hydrolyzed. H_2S may be produced from cysteine. DL-Malate and turanose are utilized, but cellobiose, *m*- or *p*-hydroxybenzoate, citrate, succinate, DL-tartrate, ethanolamine, histamine, sarcosine, spermine, β alanine, L-arginine, L-leucine, L-ornithine, and L-valine are not utilized. Negative results are also obtained for production of acetoin, indol, arginine dihydrolase, urease, and β-galactosidase. The predominant cellular fatty acids are $C_{16:0}$ iso, $C_{17:1}$ ω8*c*, and $C_{18:1}$ ω9*c*.

DNA G+C content (mol%): 69–73 (HPLC).

Type strain: CS12, ATCC BAA-130, CCUG 45369, CIP 107018, DSM 13876, JCM 10705, KCCM 80001

Sequence accession no. (16S rRNA gene): AF176948.

Genus V. **Knoellia** Groth, Schumann, Schuetze, Augsten and Stackebrandt 2002, 81[VP]

INGRID GROTH

Kno.el′li.a. N.L. fem. n. *Knoellia* named after Hans Knöll (1913–1978), a German pioneer in antibiotic research.

Cells are irregular **rods** (1.5–6.0 × 0.4–1.2 µm) and **cocci** (0.6–1.5 µm) (Figure 165). They occur singly, in pairs, short chains, or clusters. A marked **rod–coccus growth cycle** may be expressed (Figure 166). Gram-stain-positive, **not acid-fast**, **nonsporeforming**. **Nonmotile**. **Aerobic to microaerobic**. Colonies are smooth, circular, convex, opaque with entire margins, and white to cream in color. Good growth occurs on complex organic media between pH 5–9 and at temperatures of 28–35°C; no growth at 42°C. NaCl in the culture medium is tolerated up to 2 or 4%. **Oxidase-negative; catalase-positive**. The **peptidoglycan** is of the **A1γ type** based on *meso*-A_2pm, direct cross-linkage, which is in accordance with type A31. **The acyl type is acetyl**. No diagnostic whole cell sugars are found. The major menaquinone is **MK-8(H_4);** MK-7(H_4) and MK-6(H_4) may occur in traces. The **polar lipids** are mainly composed of **phosphatidylethanolamine, phosphatidylinositol, diphosphatidylglycerol;** phosphatidylglycerol may occur in minor amounts. The cellular **fatty acid profile** is characterized by the predominance of **iso-branched-chain acids** ($C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$ iso, $C_{17:1}$ iso). Anteiso-branched ($C_{17:0}$ anteiso) and straight-chain saturated or monounsaturated acids may also occur in higher amounts ($C_{17:0}$, $C_{17:1}$ ω8*c*). **Mycolic acids are absent**. Based on 16S rRNA gene sequence comparison strains of *Knoellia* are most closely related to members of the genera *Janibacter*, *Lapillicoccus*, and *Tetrasphaera*. The 16S rRNA gene signature nucleotides that differentiate the genus from the other genera of the family *Intrasporangiaceae* are listed in Table 124, chapter *Intrasporangiaceae*.

DNA G+C content (mol%): 68–73.

Type species: **Knoellia sinensis** Groth, Schumann, Schuetze, Augsten and Stackebrandt 2002, 82[VP].

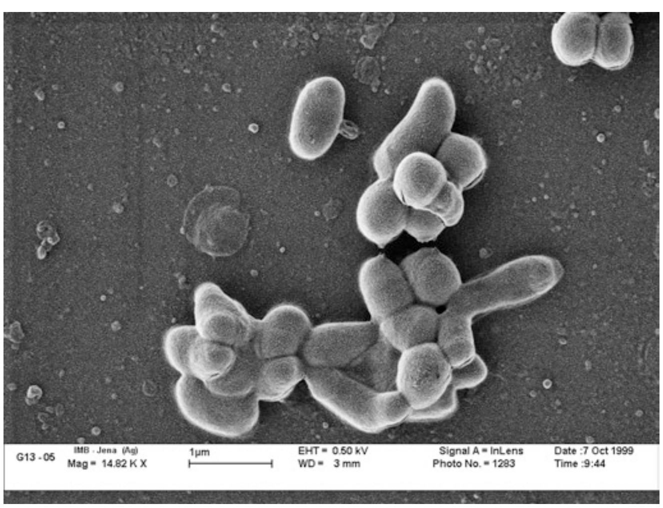

FIGURE 165. Scanning electron micrograph of cells from a 3-d-old culture of *Knoellia sinensis* DSM 12331[T] grown on rich (R) agar at 28°C. Bar = 1 µm.

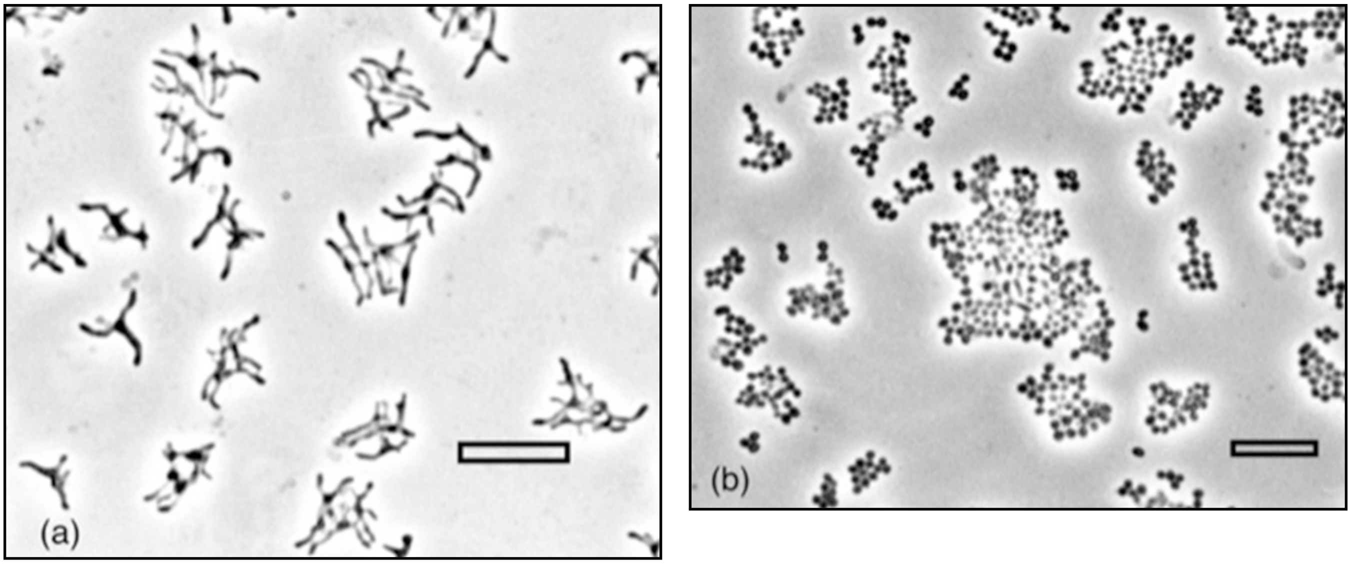

FIGURE 166. Micrographs of *Knoellia sinensis* DSM 12331[T] grown (a) on rich (R) agar at 28°C for 24 h and (b) in liquid rich (R) medium for 72 h. Bars = 10 μm.

Further descriptive information

In the 16S rRNA gene sequence tree of the *Intrasporangiaceae* (Figure 161), the strains of *Knoellia* form a common cluster with the species of *Janibacter* (Martin et al., 1997) and *Tetrasphaera* (Maszenan et al., 2000) with which they share 95.0–98.2% and 94.9–97.8% sequence similarities, respectively. The monospecific genus *Lapillicoccus* (Lee and Lee, 2007) forms a separate lineage adjacent to the *Janibacter-Knoellia-Tetrasphaera* cluster and is similar closely related (96.4%). Furthermore, the type strains of *Knoellia sinensis* and *Knoellia subterranea* possess a deviation from the 16S rRNA gene signature of members of the suborder *Micrococcineae* (elevated in this volume to order *Micrococcales*) that is shared with members of the genus *Tetrasphaera* (nt 952:1229, T–A base pair instead of C–G; Maszenan et al., 2000). The genus *Knoellia* currently accommodates three species, *Knoellia sinensis* (Groth et al., 2002), *Knoellia aerolata* (Weon et al., 2007a), and *Knoellia subterranea* (Groth et al., 2002). Each species is represented by a single strain. While *Knoellia sinensis* and *Knoellia subterranea* were isolated from soil samples collected at different sites of a cave, *Knoellia aerolata* was obtained from an air sample collected in Korea. The type strain of *Knoellia sinensis* shares 16S rRNA gene sequence similarities of 97.8 and 98.8%, respectively, with the type strains of *Knoellia aerolata* and *Knoellia subterranea*. Low levels of DNA–DNA relatedness (29.2, 37.0, and 41.0%) and numerous differences in physiological characteristics (Table 128) between the three organisms clearly indicate that they represent separate species.

The type strains of *Knoellia sinensis* and *Knoellia subterranea* are morphologically very similar. Their colonies grown on rich (R) medium (Yamada and Komagata, 1972) vary in size from 0.4–1.7 mm. The coccoid cells of the stationary growth phase grow out with several germ tubes (up to 6) to irregular rods after transfer to fresh medium. As the cocci remain in their positions within the chains or clusters during the outgrowth, the impression of a rudimentary mycelium is given. The occurrence of a comparable rod–coccus growth cycle is not reported in the description of *Knoellia aerolata* (Weon et al., 2007a).

The type strains of the three species share the following physiological properties. They are positive for reduction of nitrate, hydrolysis of esculin, starch and Tween 80, but negative for hydrolysis of hypoxanthine and xanthine and for the production of indole. By using the API 20NE and API ID 32GN test strips (bioMérieux), the three strains show positive reactions for the utilization of sodium acetate, D-glucose, maltose, sucrose, glycogen, salicin, valeric acid, 3-hydroxy-butyric acid, propionic acid, and L-proline as sole carbon sources, while fermentation of glucose, production of arginine dihydrolase, and utilization of L-arabinose, capric acid, trisodium citrate, phenylacetic acid, L-rhamnose, itaconic acid, suberic acid, sodium malonate, potassium 5-ketogluconate, 3-hydroxybenzoic acid, D-melibiose, L-fucose, potassium 2-ketogluconate, and 4-hydroxybenzoic acid are negative (Weon et al., 2007a). By using the API ZYM system (bioMérieux), positive reactions are obtained for the production of alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, α-glucosidase, and β-glucosidase, but negative results for the production of trypsin, chymotrypsin, α-galactosidase, *N*-acetyl-β-glucosamidase, α-mannosidase, and α-fucosidase. The production of β-galactosidase seems to be variable. Weon et al. (2007a) obtained positive results for the type strains of the three species using API 20NE test strips, while Groth et al. (2002) obtained negative results for *Knoellia sinensis* and *Knoellia subterranea* by using the API ZYM assay. The type strains of *Knoellia sinensis* and *Knoellia subterranea* produce H_2S, but not acetoin; they hydrolyze hippurate (weakly), but not adenine. They produce acid from D-cellobiose, D-fructose, D-galactose, D-glucose, maltose, D-mannose, and D-ribose, but not from L-arabinose, D-glucitol, glycerol, inulin, lactose, D-mannitol, D-raffinose, L-rhamnose, salicin, or D-xylose. They utilize succinate as sole carbon source, but not aconitate, benzoate, citrate, and DL-tartrate. Both strains are susceptible to the following

antibiotics (µg/disc): chloramphenicol (30), ciprofloxacin (5), erythromycin (15), gentamicin (10), kanamycin (30), lincomycin (2), neomycin (30), nitrofuran (300), oxytetracycline (30), penicillin G (2 IU/disc), polymyxin B (300 IU/disc), rifampin (2), streptomycin (10), and sulfonamide (300).

Enrichment and isolation procedures

The strains of *Knoellia sinensis* and *Knoellia subterranea* grow readily in liquid or on solidified complex media, i.e. Bacto nutrient agar (Difco, g/l: Bacto beef extract, 3.0; Bacto peptone, 5.0; and Bacto agar, 15.0; pH 6.8), rich (R) medium (Yamada and Komagata, 1972) which is composed of (g/l): Bacto peptone (Difco), 10.0; yeast extract (Difco), 5.0; Casamino acids (Difco), 5.0; beef extract (Difco), 2.0; malt extract (Difco), 5.0; glycerol, 2.0; $MgSO_4 \cdot 7H_2O$, 1.0; Tween 80, 0.05; and agar, 20.0; pH 7.2, Bacto tryptic soy broth (Difco, g/l: Bacto tryptone, 17.0; Bacto soytone, 3.0; glucose, 2.5; NaCl, 5.0; and K_2HPO_4, 2.5; pH 7.3,) and peptone-yeast extract-brain heart infusion medium (Yokota et al., 1993) containing (g/l): peptone, 10.0; yeast extract, 2.0; Bacto brain heart infusion (Difco), 2.0; NaCl, 2.0; and glucose, 2.0; pH 7.0. The type strain of *Knoellia sinensis* was isolated on casein mineral medium (Altenburger et al., 1996) containing (g/l): K_2HPO_4, 0.6; $Na_2HPO_4 \cdot 2H_2O$, 0.5; $MgSO_4 \cdot 7H_2O$, 0.05; $MgCl_2 \cdot 7H_2O$, 0.1; KNO_3, 0.2; $FeCl_3 \cdot 6H_2O$, 0.01; casein, 0.8 and yeast extract 0.4; pH 7.0, and that of *Knoellia subterranea* on peptone-yeast extract-brain heart infusion medium using standard dilution plate procedures. The type strain of *Knoellia aerolata* was isolated on R2A agar (Difco, g/l: Bacto yeast

extract, 0.5; Bacto proteose peptone no. 3, 0.5; Bacto Casamino acids, 0.5; glucose, 0.5; soluble starch, 0.5; sodium pyruvate 0.3; potassium phosphate dibasic, 0.3; magnesium sulfate, 0.05; and Bacto agar, 15.0; pH 7.2) by using an air sampler. For subculturing of *Knoellia aerolata*, R2A agar is recommended, but the strain grows also well on Bacto nutrient agar and Bacto tryptic soy agar.

Maintenance procedures

Cultures of *Knoellia* strains can be maintained by serial transfers on the complex organic media mentioned above. For long-term preservation, storage of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

Differentiation of the genus *Knoellia* from other genera

The genus *Knoellia* has in common with the genera *Janibacter* (Martin et al., 1997), *Kribbia* (Jung et al., 2006), *Marihabitans* (Kageyama et al., 2008a), *Oryzihumus* (Kageyama et al., 2005), *Phycicoccus* (Lee, 2006), and *Tetrasphaera* (Maszenan et al., 2000) the presence of *meso*-A_2pm, in the cell-wall peptidoglycan and MK-8(H_4) as main menaquinone, while the other members of the *Intrasporangiaceae* possess either LL-A_2pm, or L-ornithine, as diagnostic diamino acids. However, the genus *Knoellia* can be readily distinguished from the phylogenetically closest genus *Janibacter* by differences in the cellular fatty acid profiles and in the composition of polar lipids (Table 125, chapter *Intrasporangiaceae*). Furthermore, a rod–coccus growth cycle similar to that of *Knoellia* is not observed in *Janibacter* species. Physiological characteristics like acid production from selected carbon sources and tolerance to NaCl additionally contribute to differentiate these two genera from one another. The slightly less closely related genus *Tetrasphaera* can be distinguished from *Knoellia* by the occurrence of *meso*- or 3-hydroxy-A_2pm in the peptidoglycan and by differences in the fatty acid profiles. Morphological characteristics which referred to the coccoid cells in tetrads of the originally described *Tetrasphaera* species, *Tetrasphaera japonica* and *Tetrasphaera australiensis* (Maszenan et al., 2000), can generally no longer be used to distinguish these two genera from one another. With the description of further *Tetrasphaera* species, the variability in cell morphology within this genus has become obvious (Hanada et al., 2002; Ishikawa and Yokota, 2006; McKenzíe et al., 2006). The remaining genera of the *meso*-A_2pm containing group, *Kribbia*, *Marihabitans*, *Oryzihumus*, and *Phycicoccus* can also be well separated from *Knoellia* by their phylogenetic distinctiveness (16S rRNA gene sequence similarities below 96% and differences in the 16S rRNA gene signature nucleotides) together with the phenotypic characteristics listed in Table 125 (chapter *Intrasporangiaceae*). Interestingly, the genus *Lapillicoccus* (Lee and Lee, 2007), which shares with *Knoellia* a 16S rRNA gene sequence similarity of 96.4%, a value similar to that of *Janibacter* species, possesses LL-A_2pm as diagnostic diamino acid in the peptidoglycan. This characteristic, together with the missing phosphatidylethanolamine in the polar lipid pattern and the typical coccoid cell morphology, clearly distinguish *Lapillicoccus* from *Knoellia*. As the genera *Kribbia*, *Lapillicoccus*, *Marihabitans*, and *Oryzihumus*, are represented by only one species, the variability of the phenotypic markers within the genus cannot be reflected by the current descriptions. The availability of further strains of these genera will make the differentiation between the genera more efficient.

List of species of the genus *Knoellia*

1. **Knoellia sinensis** Groth, Schumann, Schütze, Augsten and Stackebrandt 2002, 82[VP]

si.nen′sis. N.L. fem. adj. *sinensis* of China, the origin of the type strain.

See Table 128 and the generic description. Rod-shaped cells vary in their dimensions from 1.7–4.5 × 0.4–0.9 µm and the cocci from 0.6–0.9 µm. By using the API ZYM system, activity is detected for valine arylamidase and cystine arylamidase. No activity is detected for β-glucuronidase. Weak reactions are displayed for lipase (C14), naphthol-AS-BI-phosphohydrolase, and acid phosphatase. The predominant cellular fatty acids are $C_{17:1}$ iso, $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$ iso, and $C_{17:0}$ anteiso.

DNA G+C content (mol%): 68 (HPLC).

Type strain: HKI 0119, CCUG 47139, CIP 106775, DSM 12331, JCM 11536, NBRC 100350.

Sequence accession no. (16S rRNA gene): AJ294412.

2. **Knoellia aerolata** Weon, Kim, Schumann, Kroppenstedt, Noh, Park and Kwon 2007a, 2863[VP]

a.e.ro.la′ta. Gr. n. *aer* air; L. part. adj. *latus*, *-a*, *-um* carried; N.L. fem. part. adj. *aerolata* airborne.

See Table 128 and the generic description. Rod-shaped cells vary in their dimensions from 1.0 × 1.5–2.0 µm and the cocci from 1.0–1.5 µm. Optimal growth at 30°C, pH 6.0–7.0 and up to1% NaCl. Chitin from crab shells, pectin, carboxymethylcellulose, and DNA are not hydrolyzed. By using the API ZYM system, activity is detected for β-glucuronidase. No activity is detected for cystine arylamidase, lipase (C14), naphthol-AS-BI-phospho-hydrolase, valine arylamidase, and acid phosphatase. The predominant cellular fatty acids are: $C_{16:0}$ iso, $C_{17:1}$ ω8*c*, and $C_{15:0}$ iso.

DNA G+C content (mol%): 73 (HPLC).

Type strain: 5317S-21, DSM 18566, KACC 20583.

Sequence accession no. (16S rRNA gene): EF553529.

3. **Knoellia subterranea** Groth, Schumann, Schütze, Augsten and Stackebrandt 2002, 82[VP]

sub.ter.ra′ne.a. L. fem. adj. *subterranea* under the earth, referring to the place of isolation.

See Table 128 and the generic description. Rod-shaped cells vary in their dimensions from 1.9–6.0 × 0.5–1.2 µm and the cocci from 0.8–1.4 µm. By using the API ZYM system, activity is detected for valine arylamidase, cystine arylamidase, and naphthol-AS-BI-phosphohydrolase. No activity is detected for β-glucuronidase. Weak reactions are displayed for lipase (C14) and acid phosphatase. The predominant cellular fatty acids are: $C_{15:0}$ iso, $C_{17:0}$ iso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

DNA G+C content (mol%): 69 (HPLC).

Type strain: HKI 0120, CCUG 48178, CIP 106776, DSM 12332, JCM 11537, NBRC 100351.

Sequence accession no. (16S rRNA gene): AJ294413.

Genus VI. **Kribbia** Jung, Kim, Song, Lee, Oh and Yoon 2006, 2430[VP]

Jung Hoon Yoon

Krib.bi′a. N.L. fem. n. *Kribbia* arbitrary name formed from the acronym of the Korea Research Institute of Bioscience and Biotechnology, KRIBB, where taxonomic studies of this taxon were performed.

Cells are irregular short rods or cocci, 0.4–0.6 µ × 1.0–1.5 µm. Gram-stain-positive. **Nonmotile**. **Facultatively anaerobic**. Catalase-positive. Oxidase-negative. Nitrate is reduced to nitrite. **The cell-wall peptidoglycan contains *meso*-diaminopimelic acid**. **The predominant menaquinone is MK-8(H_4)**. The cellular fatty acid profile consists of straight-chain, branched, unsaturated, and 10-methyl fatty acids.

DNA G+C content (mol%): 69–70.

Type species: **Kribbia dieselivorans** Jung, Kim, Song, Lee, Oh and Yoon 2006, 2430[VP].

Further descriptive information

Kribbia dieselivorans is the sole species of this genus. *Kribbia dieselivorans* was isolated from an enrichment culture with diesel oil-degradation activity. Two strains of *Kribbia dieselivorans* were isolated by plating the enrichment culture on 10× diluted nutrient agar and R2A agar, respectively. *Kribbia dieselivorans* was found to have the ability to degrade diesel oil. *Kribbia dieselivorans* grows well on a wide range of media including nutrient agar, trypticase soy agar, and R2A agar. Characteristics are given in detail in the species description or are shown in Table 129. Phylogenetically, the genus *Kribbia* is a member of the family *Intrasporangiaceae* (Jung et al., 2006) within the order *Micrococcales*, class *Actinobacteria*. In the phylogenetic trees constructed using the neighbor-joining, maximum-likelihood, and maximum-parsimony algorithms, the genus *Kribbia* forms an independent lineage within the clade comprising members of the family *Intrasporangiaceae*. The 16S rRNA gene sequence similarity values between the genus *Kribbia* and phylogenetically related genera (for type strains of species) are as follows: *Arsenicicoccus* (95.5%), *Humibacillus* (95.6%), *Humihabitans* (95.8%), *Intrasporangium* (95.6%), *Janibacter* (95.4–96.1%), *Knoellia* (94.9–95.0%), *Lapillicoccus* (95.3%), *Ornithinicoccus* (94.8%), *Ornithinimicrobium* (94.3–94.8%), *Oryzihumus* (94.2%), *Phycicoccus* (93.6–94.2%), *Sanguibacter* (93.2–94.0%), *Serinicoccus* (94.2%), *Terrabacter* (95.7–96.0%), *Terracoccus* (95.6%), and *Tetrasphaera* (93.8–94.5%).

Enrichment and isolation procedures

The genus *Kribbia* was isolated from oil-contaminated tidal flat sediment collected from Kwangyang in Korea. The sediment samples (each 0.5 mg) were inoculated in 100 ml of Bushnell-Haas broth (Difco) that contained 2% (w/v) diesel oil as a single carbon source. These media were incubated at 30°C on a horizontal shaker at 150 rpm. The enrichment culture **with diesel oil-degradation activity** was diluted serially, spread on 10× diluted nutrient agar and R2A agar, and **incubated at 30°C**. No selective media or enrichment procedures have yet been described which are specific for organisms of this genus. The genus *Kribbia* may grow on a wide range of media. If similar samples are available, isolation of the genus *Kribbia* may be achieved by the oil-enrichment and the dilution plating methods using a wide range of media.

Maintenance procedures

For short-term preservation, serial transfer from agar slants of appropriate media is recommended. Agar slants can be kept at 4°C for at least 2 months. For long-term preservation, lyophilization and storage in liquid nitrogen or in frozen glycerol suspensions are suitable. For lyophilization, the cell mass is suspended in an appropriate fluid such as 20% (w/v) skim milk. For storage in liquid nitrogen, cell mass is inoculated into cryo-tubes containing an appropriate fluid such as 20% (w/v) glycerol. Glycerol suspension is prepared by making suspension with cell mass in aqueous glycerol in appropriate vial or tube. The vial or tube is stored at −20°C or −70°C.

Differentiation of the genus *Kribbia* from other genera

The genus *Kribbia* and most genera belonging to the family *Intrasporangiaceae* have MK-8(H_4) as the predominant menaquinone, but the genus *Intrasporangium* has MK-8 as the predominant menaquinone (Jung et al., 2006; Kageyama et al., 2007a, 2008b; Lee and Lee, 2007). The genus *Kribbia* is distinguishable from members of the family *Intrasporangiaceae* by differences in the diamino acid type in position 3 of the peptidoglycan and the fatty acid profile (Table 129). The genus *Kribbia* contains *meso*-diaminopimelic acid as the diamino acid in the position 3 of the peptidoglycan, whereas the genera *Arsenicicoccus*, *Humihabitans*, *Humibacillus*, *Intrasporangium*, *Lapillicoccus*, *Terrabacter*, and *Terracoccus* and the genera *Ornithinicoccus*, *Ornithinimicrobium*, and *Serinicoccus* contain LL-diaminopimelic acid and L-ornithine, respectively, as the diamino acid in the

TABLE 129. Characteristics differentiating the genus *Kribbia* from the other meso-A_2pm-containing genera of the family *Intrasporangiaceae*[a]

Characteristics[b]	*Kribbia*	*Janibacter*	*Knoellia*	*Oryzihumus*	*Phycicoccus*

[a]Abbreviation: *meso*-A_2pm, *meso*-diaminopimelic acid.

[b]Data taken from Martin et al. (1997), Imamura et al. (2000), Yoon et al. (2000, 2004, 2008), Groth et al. (2002), Kageyama et al. (2005), Jung et al. (2006), Kämpfer et al. (2006), Lee (2006), and Weon et al. (2007a).

position 3 of the peptidoglycan (Jung et al., 2006; Kageyama et al., 2008b, 2007a; Lee and Lee, 2007). The fatty acid profiles, particularly major fatty acids, distinguish the genus *Kribbia* from *meso*-diaminopimelic acid-containing genera of the family *Intrasporangiaceae* (Table 129). The genus *Kribbia* is also distinguishable from members of the genus *Tetrasphaera* by differences in the predominant menaquinone type and/or the fatty acid profile (McKenzíe et al., 2006).

List of species of the genus *Kribbia*

1. **Kribbia dieselivorans** Jung, Kim, Song, Lee, Oh and Yoon 2006, 2430[VP]

die.se.li.vo′rans. N.L. n. *dieselum* diesel; L. v. *vorare* to devour; N.L. part. adj. *dieselivorans* diesel oil-devouring.

Cells are irregular short rods or cocci, 0.4–0.6 μm × 1.0–1.5 μm. Gram-stain-positive. Nonmotile. Facultatively anaerobic. Catalase-positive. Oxidase-negative. Urease-negative. Growth occurs between 8 and 42°C with an optimum temperature of 30°C. Optimal pH for growth is 6.5–7.5. Anaerobic growth occurs on TSA and on TSA with nitrate. Casein, gelatin, esculin, Tween 20, Tween 40, Tween 60, and Tween 80 are hydrolyzed. Starch, hypoxanthine, xanthine, and tyrosine are not hydrolyzed. Arginine dihydrolase, lysine decarboxylase, and ornithine decarboxylase are absent. H_2S and indole are not produced. Nitrate is reduced to nitrite. Acetate, benzoate, D-cellobiose, and pyruvate are utilized as sole carbon and energy sources. D-Glucose, D-trehalose, sucrose, and maltose are weakly utilized. D-Fructose, D-galactose, D-mannose, D-xylose, L-arabinose, citrate, formate, salicin, succinate, L-glutamate, and L-malate are not utilized as sole carbon and energy sources. Acid is produced from D-glucose, D-cellobiose, sucrose, maltose, and D-trehalose. Acid is not produced from D-sorbitol, *myo*-inositol, D-ribose, D-fructose, D-mannitol, melibiose, L-arabinose, D-melezitose, D-galactose, L-rhamnose, lactose, and D-raffinose. Susceptible to streptomycin, penicillin G, chloramphenicol, ampicillin, cephalothin, gentamicin, novobiocin, tetracycline, lincomycin, oleandomycin, neomycin, and carbenicillin, but not to polymyxin B and kanamycin. In assays with the API ZYM system (bioMérieux), esterase (C4), esterase lipase (C8), leucine arylamidase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase, and β-glucosidase are present, but alkaline phosphatase, lipase (C14), valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsine, acid phosphatase, α-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are absent. The major fatty acids (> 10% of total fatty acids) are $C_{18:0}$ 10 methyl, $C_{16:0}$ iso, $C_{18:1}$ ω9*c*, $C_{16:0}$, and $C_{18:0}$.

Source: a tidal flat sediment.

DNA G+C content (mol%): 69.6–69.9 (HPLC).

Type strain: N113, JCM 13585, KCTC 19143.

Sequence accession no. (16S rRNA gene): DQ372707.

Genus VII. **Lapillicoccus** Lee and Lee 2007, 2796[VP]

The Editorial Board

La.pil.li.coc′cus. L. masc. n. *lapillus* a little stone; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; N.L. masc. n. *Lapillicoccus* a coccus attached to a little stone, referring to the isolation source.

Nonsporeforming cocci (0.2–0.3 μm) that occur singly or in pairs. **Gram-stain-positive.** Nonmotile. **Aerobic**. Temperature range for growth 10–37°C, pH range 4.1–11.1, NaCl tolerance 0–2%. Cell wall contains LL-diaminopimelic acid as the diagnostic diamino acid. The acyl type of the muramic acid is acetylated. Mycolic acids are not present. MK-8(H_4) is the major menaquinone. Polar lipid profile comprises diphosphatidylglycerol and phosphatidylinositol.

DNA G+C content (mol%): 74.1.

Type species: **Lapillicoccus jejuensis** Lee and Lee 2007, 2796[VP].

Further descriptive information

Major fatty acids are $C_{16:0}$ iso (21.2%), $C_{17:1}$ ω8*c* (15.5%) and $C_{15:0}$ iso (13.7%).

Phylogenetic analysis of the 16S rRNA gene positions the genus within family *Intrasporangiaceae*. The closest phylogenetic neighbor is *Tetrasphaera japonica* (97.1% sequence similarity) (Maszenan et al., 2000). Environmental clones with high 16S rRNA gene sequence similarity have been detected in siliceous sedimentary rock (99.1%, accession no. AB179506, unpublished) and Mn-oxidizing microbiota associated with Mn nodules in rice field soils (98.8%, accession no. AB354142, unpublished).

Enrichment and isolation procedures

Strain R-Ac013[T] was isolated from a small stone collected from an agricultural field in Jeju, Republic of Korea. A piece of the stone was crushed into a powder (using a pestle) and suspended in 10 ml sterilized, distilled water. Serial diluents of the sample are transferred onto starch-casein agar (Kuester and Williams, 1964), and the plates are incubated at 30°C for 14 d. Colony morphology and pigmentation is visible after 7 d incubation on trypticase soy agar (TSA; Difco) at 28°C.

Maintenance procedures

Stock cultures are maintained as a 20% glycerol suspension at −20 and −80°C.

Differentiation of the genus *Lapillicoccus* from closely related genera

Lapillicoccus contains the diamino acid LL-DAP, while other phylogenetically related genera (*Tetrasphaera*, *Janibacter*, *Knoellia*,

Oryzihumus, and *Fodinibacter*) contain *meso*-DAP. *Intrasporangium* contains LL-DAP, but hyphal growth and possession of MK-8 as the major menaquinone differentiates it from *Lapillicoccus*. *Terrabacter* has long rod-shaped cell morphology and a rod–coccus life cycle, while *Lapillicoccus* has coccoid shape. The presence of phosphatidylethanolamine as the diagnostic phospholipid and absence of $C_{17:1}$ ω8*c* as a major fatty acid further distinguishes both *Terrabacter* and *Terracoccus*.

List of species of the genus *Lapillicoccus*

1. **Lapillicoccus jejuensis** Lee and Lee 2007, 2797[VP]

je.ju.en′sis. N.L. masc. adj. *jejuensis* of Jeju, Republic of Korea, referring to the site from which the type strain was isolated.

Colonies are circular, flat, undulate and bright yellow in color. Growth occurs at mesophilic temperature and pH 4.1–11.1, with optima at 30°C and pH 7.1. β-Galactosidase is present, but urease and arginine dihydrolase are not. Nitrate is not reduced to nitrite. Esculin is degraded, but indole production, glucose fermentation and gelatin hydrolysis does not occur. API ZYM detects leucine arylamidase, acid phosphatase, aglucosidase, *N*-acetyl-β-glucosaminidase, esterase lipase (C8) and α-chymotrypsin, but not alkaline phosphatase, esterase (C4), lipase (C14), valine arylamidase, cystine arylamidase, trypsin, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-glucosidase, β-glucuronidase, α-mannosidase and α-fucosidase. D-Arabinose, D-mannitol and malate are assimilated. Growth is not affected by D-glucose, D-mannose, *N*-acetyl-D-glucosamine, maltose, gluconate, caprate, adipate, citrate and phenylacetate. Positive for protease, cellulase and amylase activity. DNA is hydrolyzed. Hypoxanthine, tyrosine and xanthine are degraded.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 74.1 (HPLC).

Type strain: R-Ac013, KCTC R-Ac013, DSM 18607.

Sequence accession no. (16S rRNA gene): AM398397.

Genus VIII. **Ornithinicoccus** Groth, Schumann, Martin, Schuetze, Augsten, Kramer and Stackebrandt 1999, 1722[VP]

Ingrid Groth

Or.ni.thi.ni.coc′cus. N.L. n. *ornithinum* ornithine (an amino acid named after the Gr. n. *ornithos*, bird); Gr. masc. n. *kokkos* a grain; N.L. masc. n. *Ornithinicoccus* a coccus with ornithine.

Cells are irregular **cocci** (0.8–1.3 μm) that occur singly, in pairs, short chains, and clusters (Figure 167). Gram-stain-positive, not acid-fast, nonsporeforming. **Nonmotile. Aerobic to microaerobic**. Colonies are smooth, circular, opaque with entire margins and white to cream in color when grown on rich (R) medium. Additionally, colonies may appear that have a depressed center which is surrounded by a uniform or radial structured wall and a wrinkled marginal zone. Colonies vary in size from 0.6–4.3 mm. Good growth occurs on complex organic media at temperatures 28–37°C; no growth at 42°C. NaCl in the culture medium is well tolerated up to 4%. **Oxidase-negative; catalase-positive**. The **peptidoglycan type is A4β** with an L-Orn–$Gly_{(1,2)}$–D-Glu interpeptide bridge which is in accordance with variation A21.13. **The acyl type is acetyl**. No diagnostic whole cell sugars are found. The major menaquinone is **MK-8(H_4);** MK-8(H_2) is present in minor amounts. The polar lipids are composed of **phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, phosphatidylserine**, and two unknown phospholipids. The cellular fatty acid profile is distinctly dominated by the occurrence of **iso- and anteiso-branched-chain acids**. Mycolic acids are absent. Based on 16S rRNA gene sequence comparison, the genus *Ornithinicoccus* is most closely related to members of the genera *Humihabitans* and *Oryzihumus*. The 16S rRNA gene signature nucleotides that differentiate the genus from the other genera of the family *Intrasporangiaceae* are listed in Table 124.

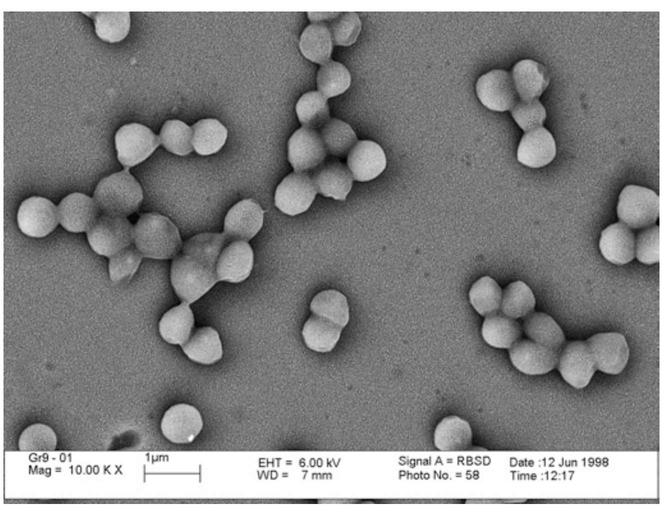

FIGURE 167. Scanning electron micrograph of cells from a 24-h-old culture of *Ornithinicoccus hortensis* DSM 12335[T] grown on rich (R) agar for 24 h.

DNA G+C content (mol%): 72.

Type species: **Ornithinicoccus hortensis** Groth, Schumann, Martin, Schuetze, Augsten, Kramer and Stackebrandt 1999, 1723[VP].

Further descriptive information

The genus *Ornithinicoccus* currently accommodates the sole species *Ornithinicoccus hortensis* (Groth et al., 1999). *Ornithinicoccus* forms a common branch with the monospecific genus

Oryzihumus (Kageyama et al., 2005) in the 16S rRNA gene tree of the *Intrasporangiaceae*, but the branching point is not supported by a high bootstrap value (Figure 161). The 16S rRNA gene sequence similarity between *Ornithinicoccus hortensis* and the strains of *Oryzihumus* is 95.6%. A slightly higher sequence similarity (95.8%) is found between *Ornithinicoccus* and the equally monospecific genus *Humihabitans* (Kageyama et al., 2007a). Furthermore, a comparable level of 16S rRNA gene sequence similarity (95.0–95.8%) is also present between *Ornithinicoccus hortensis* and *Intrasporangium calvum* (95.4%) (Kalakoutskii et al., 1967), two of the three species of *Ornithinimicrobium* (*Ornithinimicrobium kibberense*, 95.2%; *Ornithinimicrobium pekingense*, 95.1% (Liu et al., 2008; Mayilraj et al., 2006), two of the three species of *Knoellia* (*Knoellia sinensis*, 95.5%; *Knoellia subterranea*, 95.0%) (Groth et al., 2002), three of the five species of *Janibacter* (Martin et al., 1997) (*Janibacter anophelis*, 95.6%; *Janibacter melonis*, 95.4%; *Janibacter terrae*, 95.1%) (Kämpfer et al., 2006; Yoon et al., 2000, 2004), three of the eight species of *Tetrasphaera* (*Tetrasphaera remsis*, 95.8%; *Tetrasphaera japonica*, 95.6%; *Tetrasphaera duodecadis*, 95.4%) (Ishikawa and Yokota, 2006; Maszenan et al., 2000; Osman et al., 2007), and *Terrabacter tumescens* (95.0%) (Collins et al., 1989). Two strains of *Ornithinicoccus hortensis* (HKI 0125, DSM 12335) share a 16S rRNA gene sequence similarity of 100% between one another and exhibit a high similarity in all tested phenotypic characteristics. Both strains reduce nitrate to nitrite and produce H_2S. Indole is not produced. Aconitate, formate, malate, and succinate are utilized as sole carbon sources. While sodium malate is readily utilized, disodium succinate, sodium formate, and sodium aconitate are utilized after a prolonged incubation time (about 7 d). Benzoate and DL-tartrate are not utilized. The utilization of acetate and citrate is variable. Acid production from carbohydrates is generally weakly expressed: i.e. D-glucose, maltose, D-mannitol, D-glucitol, trehalose, starch, dextrin, sucrose. No acid production from L-arabinose, lactose, D-cellobiose, D-galactose, inulin, D-raffinose, L-rhamnose, D-ribose, salicin, and D-xylose. Variable results are obtained from D-fructose, glycerol, and D-mannose. Casein, gelatin, hippurate, hypoxanthine, xanthine, and Tween 80 are hydrolyzed; esculin and tyrosine are not hydrolyzed. On esculin-iron agar both strains produce a brown pigment after prolonged incubation (above 7 d). This pigment is different from the black staining of the agar in the case of positive esculin hydrolysis. It stains the colonies and penetrates into the agar. Methyl red and Voges–Proskauer reactions are negative. Urease activity is variable. Cells of *Ornithinicoccus hortensis* are susceptible to the antibiotics (µg/disc): ampicillin (10), chloramphenicol (30), ciprofloxacin (5), erythromycin (15), gentamicin (10), kanamycin (30), neomycin (30), nitrofuran (300), oxytetracycline (30), penicillin G (2 IU/disc), polymyxin B (300 IU/disc), rifampin (2), and streptomycin (10). Susceptibility to oxacillin (5) is unclear; no susceptibility to sulfonamid.

Enrichment and isolation procedures

Strains of *Ornithinicoccus hortensis* grow readily in liquid or on solidified complex organic media, i.e. rich (R) medium (Yamada and Komagata, 1972) which is composed of (g/l): Bacto peptone (Difco), 10.0; yeast extract (Difco), 5.0; Casamino acids (Difco), 5.0; beef extract (Difco), 2.0; malt extract (Difco), 5.0; glycerol, 2.0; $MgSO_4 \cdot 7H_2O$, 1.0; Tween 80, 0.05; and agar, 20.0; pH 7.2, peptone-yeast extract-brain heart infusion medium (Yokota et al., 1993) containing (g/l): peptone, 10.0; yeast extract, 2.0; Bacto brain heart infusion (Difco), 2.0; NaCl, 2.0; and D-glucose, 2.0; pH 7.0, Bacto tryptic soy broth (Difco, g/l: Bacto tryptone, 17.0; Bacto soytone, 3.0; glucose, 2.5; NaCl, 5.0 and K_2HPO_4, 2.5; pH 7.3), and Bacto nutrient agar (Difco, g/l: Bacto beef extract, 3.0; Bacto peptone, 5.0; and Bacto agar, 15.0; pH 6.8). Both strains of *Ornithinicoccus hortensis* were isolated from a soil sample (garden soil) on peptone-yeast extract-brain heart infusion agar by using a standard dilution plate procedure.

Maintenance procedures

Cultures of *Ornithinicoccus* strains can be maintained by serial transfers on the complex organic media mentioned above. For long-term preservation, storage of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

Differentiation of the genus *Ornithinicoccus* from other genera

Ornithinicoccus can be clearly distinguished from the closest phylogenetic neighbor *Humihabitans* (Kageyama et al., 2007a) which forms branching hyphae and has a peptidoglycan containing LL-A_2pm, Ala, Gly and Glu (type A3γ, Schleifer and Kandler, 1972). Similarly, morphological characteristics and the peptidoglycan type differentiate *Ornithinicoccus* from *Oryzihumus* (Kageyama et al., 2005). The strains of *Oryzihumus* are irregular slender rods and have *meso*-A_2pm together with Ala and Glu in their peptidoglycan (type A1γ; Schleifer and Kandler, 1972). *Ornithinimicrobium* (Groth et al., 2001) and *Ornithinicoccus* sharing 16S rRNA gene sequence similarities of 94.9–95.2% have in common the peptidoglycan type A4β (Schleifer and Kandler, 1972). However, *Ornithinimicrobium* has an interpeptide bridge that consists of L-Orn–L-Ala–Gly–D-Asp, while *Ornithinicoccus* is characterized by an L-Orn–$Gly_{(1,2)}$-D-Glu interpeptide bridge. The more distantly related genus *Serinicoccus* (Yi et al., 2004), which exhibits a 16S rRNA gene sequence similarity to *Ornithinicoccus* of only 92.8%, is also characterized by the peptidoglycan type A4β. However, the structure of the peptidoglycan has not yet been elucidated in all details. It seems that *Serinicoccus* represents a novel variation of the peptidoglycan type A4β containing ornithine and serine. The genera of the *Intrasporangiaceae* with a typical coccus morphology, e.g. *Arsenicicoccus* (Collins et al., 2004), *Lapillicoccus* (Lee and Lee, 2007), *Terracoccus* (Prauser et al., 1997), and *Phycicoccus* (Lee, 2006) share with *Ornithinicoccus* 16S rRNA gene sequence similarities below 95.0%. A low 16S rRNA gene sequence similarity (92.4–93.0%) is also present for the rod-shaped genera *Demequina* and *Actinotalea* (Yi et al., 2007) which share with *Ornithinicoccus* ornithine as the diagnostic diamino acid of the peptidoglycan. Both genera can be distinguished from *Ornithinicoccus* in that their interpeptide bridges consist of D-Glu and D-Asp, respectively. The degree of relationship between *Ornithinicoccus* and the other genera of the *Intrasporangiaceae* cannot currently be definitely determined as the closely related genera are represented by a low number of strains. The available phylogenetic data of genera with more than one or two species, *Janibacter* (Martin et al., 1997), *Knoellia* (Groth et al., 2002), *Tetrasphaera* (Maszenan et al., 2000), and *Terrabacter* (Collins et al., 1989), show that some species within the same genus may exhibit a similar level of relationship as the above-mentioned closest phylogenetic neighbors. These

genera can easily be differentiated from *Ornithinicoccus* by morphological and chemotaxonomic characteristics, especially by their peptidoglycan types (Table 125).

Taxonomic comments

The genus *Ornithinicoccus* was published in 1999. At that time, the family *Intrasporangiaceae* contained the genera *Intrasporangium* (Kalakoutskii et al., 1967), *Sanguibacter* (Fernández-Garayzábal et al., 1995a, 1995b), and *Terrabacter* (Collins et al., 1989; Stackebrandt et al., 1997). As in the 16S rRNA gene sequence of the type strain of *Ornithinicoccus hortensis*, only 12 of the 17 signature nucleotides were found that were described for the genera *Intrasporangium*, *Sanguibacter*, and *Terrabacter*, a family affiliation of *Ornithinicoccus* was postponed at that time until further strains would be available for analyses. The later exclusion of the genus *Sanguibacter* from the *Intrasporangiaceae* and the inclusion of *Terracoccus* and *Janibacter* into the emended family did not affect the affiliation of *Ornithinicoccus* to a higher taxonomic rank (Stackebrandt and Schumann, 2000). However, the descriptions of further novel actinobacteria required again a revision of the family *Intrasporangiaceae*. Based on new insights obtained from further 16S rRNA gene sequences, *Ornithinicoccus* was included in the *Intrasporangiaceae*, too (Garrity et al., 2007) Zhi et al. (2009) emended the description of the family *Intrasporangiaceae* and confirmed the affiliation of *Ornithinicoccus* to this family.

List of species of the genus *Ornithinicoccus*

1. **Ornithinicoccus hortensis** Groth, Schumann, Martin, Schuetze, Augsten, Kramer and Stackebrandt 1999, 1723[VP]

hor.ten′sis. L. masc. adj. *hortensis* of or belonging to a garden, referring to the place where the organism was isolated.

See generic description. By using the API ZYM system (bioMérieux), activity is detected for alkaline phosphatase, esterase (C 4), esterase lipase (C 8), lipase (C 14), leucine arylamidase, valine arylamidase, cystine arylamidase, chymotrypsin, phosphatase acid, naphthol-AS-BI-phosphohydrolase, and α-glucosidase. Negative results are obtained for trypsin, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosamidase, α-mannosidase, and α-fucosidase. The predominant cellular fatty acids are $C_{15:0}$ iso and $C_{15:0}$ anteiso. Minor amounts of $C_{15:0}$ and $C_{17:1}$ iso also are found.

DNA G+C content (mol%): 72 (HPLC).

Type strain: HKI 0125, ATCC BAA-9, CCUG 43142, CIP 106364, DSM 12335, NBRC 16434, JCM 11538.

Sequence accession no. (16S rRNA gene): Y17869.

Genus IX. **Ornithinimicrobium** Groth, Schumann, Weiss, Schuetze, Augsten and Stackebrandt 2001, 85[VP]

Ingrid Groth

Or′ni.thi.ni.mic.ro.bi.um. N.L. n. *ornithinum* ornithine (an amino acid named after the Gr. n. *ornithos*, bird); N.L. neut. n. *microbium* (from Gr. adj. *mikros* small and Gr. n. *bios* life) a microbe; N.L. neut. n. *Ornithinimicrobium* a microbe with ornithine.

Cells are irregular **short rods** (1.0–3.2 × 0.5–1.0 µm) and/or **cocci** (0.7–1.4 µm) that occur singly, in pairs, short chains, or clusters (Figure 168). Gram-stain-positive, not acid-fast, **nonsporeforming. Nonmotile. Aerobic to microaerobic**. Colonies are smooth, circular, opaque, convex with entire margins, and cream to yellow in color. Good growth on complex organic media between 25–38°C and pH 6–8. NaCl in the culture medium is tolerated up to 6–7%. **Oxidase-negative; catalase-positive**. The **peptidoglycan type is A4β** with L-Orn–L-Ala–Gly–D-Asp as interpeptide bridge which is in accordance with variation A21.14. **The acyl type is acetyl**. **Whole cell sugars** are glucose, **arabinose, rhamnose, and xylose**. The major menaquinone is **MK-8(H_4);** MK-8(H_2), MK-8 and MK-6 may occur in minor amounts. The **polar lipids** are composed of **phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol**, and unidentified phospho- and glycolipids. The cellular **fatty acid profile** is distinctly dominated by the occurrence of **iso-branched-chain acids;** anteiso-branched acids may also occur in a higher amount. Mycolic acids are absent. Based on 16S rRNA gene sequence comparison, strains of *Ornithinimicrobium* are most closely related to members of the genera *Serinicoccus* and *Ornithinicoccus*; slightly less closely related are the genera *Arsenicicoccus*, *Humihabitans*, *Oryzihumus*, and *Kribbia*. The 16S rRNA gene signature nucleotides that differentiate the genus from the other genera of the family *Intrasporangiaceae* are listed in Table 124.

DNA G+C content (mol%): 69–71.

Type species: **Ornithinimicrobium humiphilum** Groth, Schumann, Weiss, Schuetze, Augsten and Stackebrandt 2001, 85[VP].

Further descriptive information

Ornithinimicrobium shares with members of the most closely related genera *Serinicoccus* (Yi et al., 2004) and *Ornithinicoccus* (Groth et al., 1999) 16S rRNA gene sequence similarities of 95.0–95.8% and 94.9–95.2%, respectively. The sequence similarities between *Ornithinimicrobium* and *Arsenicicoccus* (Collins et al., 2004), *Humihabitans* (Kageyama et al., 2007a), *Oryzihumus* (Kageyama et al., 2005), and *Kribbia* (Jung et al., 2006) are 94.8–95.0%, 94.2–94.6%, 94.2–94.6%, and 93.8–94.3%, respectively. The genus *Ornithinimicrobium* currently accommodates three species, *Ornithinimicrobium humiphilum* (Groth et al., 2001), *Ornithinimicrobium kibberense* (Mayilraj et al., 2006), and *Ornithinimicrobium pekingense* (Liu et al., 2008). Each species is represented by a

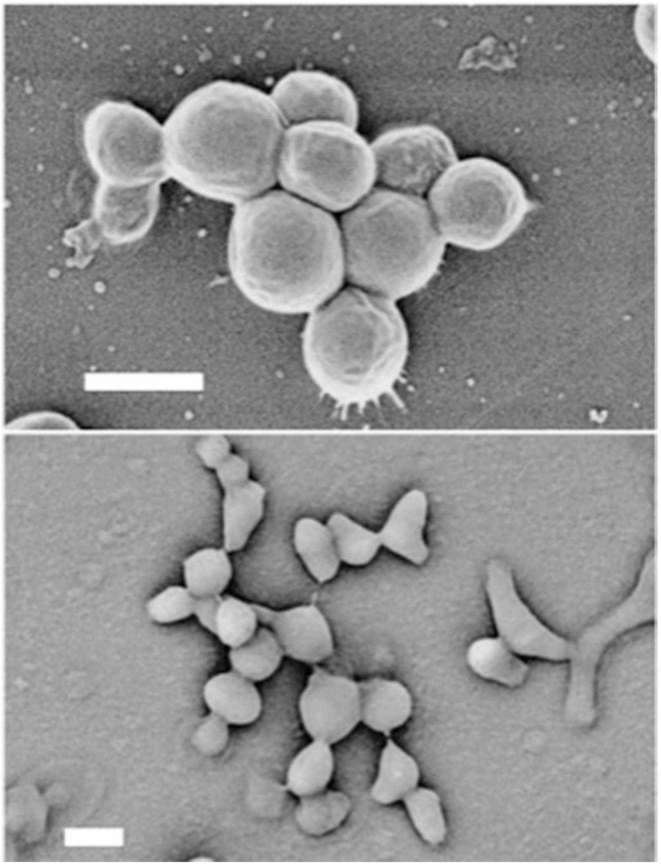

FIGURE 168. Scanning electron micrographs of cells from a 3-d-old culture of *Ornithinimicrobium humiphilum* DSM 12362^T grown on rich (R) agar at 28°C. Bars = 1 μm.

single strain. The 16S rRNA gene sequence similarities between the type strain of *Ornithinimicrobium humiphilum* and those of *Ornithinimicrobium kibberense*, and *Ornithinimicrobium pekingense* are 98.0 and 98.7%, respectively. DNA–DNA relatedness values of 64.5 and 31.5%, respectively, together with pronounced differences in phenotypic characteristics separate the three strains at the species level (Liu et al., 2008; Mayilraj et al., 2006).The type strains of *Ornithinimicrobium humiphilum*, *Ornithinimicrobium kibberense*, and *Ornithinimicrobium pekingense* have in common the following physiological characteristics: they are positive for hydrolysis of starch, but negative for Voges–Proskauer reaction and acid production from lactose, D-mannose, D-melibiose, L-rhamnose, and salicin. Some of the physiological properties reported for *Ornithinimicrobium humiphilum* seem to be variable depending on the applied cultural conditions. While Groth et al. (2001) obtained positive results for acid production from L-arabinose, D-cellobiose, D-glucose, maltose, trehalose (weakly positive), and xylose (weakly positive) using the oxidation-fermentation (O-F) medium described by Hugh and Leifson (1953), Mayilraj et al. (2006) obtained negative results for these characteristics by using the methods of Smith et al. (1952). The same is true for the reduction of nitrate to nitrite and the production of H_2S.

The phenotypic characteristics that differentiate the three species of *Ornithinimicrobium* are listed in Table 130.

Enrichment and isolation procedures

Strains of *Ornithinimicrobium* grow readily in liquid or on solidified complex organic media, i.e. rich (R) medium (Yamada and Komagata, 1972) which is composed of (g/l): Bacto peptone (Difco), 10.0; yeast extract (Difco), 5.0; Casamino acids (Difco), 5.0; beef extract (Difco), 2.0; malt extract (Difco), 5.0; glycerol, 2.0; $MgSO_4 \cdot 7H_2O$, 1.0; Tween 80, 0.05; and agar, 20.0; pH 7.2, peptone-yeast extract-brain heart infusion medium (Yokota et al., 1993) containing (g/l): peptone, 10.0; yeast extract, 2.0; Bacto brain heart infusion (Difco), 2.0; NaCl, 2.0 and D-glucose, 2.0; pH 7.0, and Bacto tryptic soy broth (Difco, g/l: Bacto tryptone, 17.0; Bacto soytone, 3.0; glucose, 2.5; NaCl, 5.0; and K_2HPO_4, 2.5; pH 7.3). The type strain of *Ornithinimicrobium humiphilum* was isolated from garden soil (Germany) on peptone-yeast extract-brain heart infusion medium and that of *Ornithinimicrobium kibberense* from soil, 45 cm below an ice glacier, 4200 m above sea level, in Kibber village of the Spiti valley, Himachal Pradesh (India), on tryptic soy agar using standard dilution plate procedures. The type strain of *Ornithinimicrobium pekingense* was isolated from activated sludge of a waste water treatment bioreactor. The waste water contained various nitroaromatic compounds (nitrobenzene, nitrophenol, 2, 4-dinitrophenol) and aniline. The reactor had been operated for one year. The sludge sample was suspended in sterile water and a portion of the suspension was directly spread on LB agar plates (g/l: tryptone, 10; yeast extract, 5.0; NaCl, 10.0; glucose, 1.0; and agar supplemented with $CaCl_2$ to a final concentration of 2.5 × 10 <MIN>3 M before pouring).

Maintenance procedures

Cultures of *Ornithinimicrobium* strains can be maintained by serial transfers on the complex organic media mentioned above. Stock cultures can be maintained at −80°C by adding 20% glycerol. For long-term preservation, storage of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

Differentiation of the genus *Ornithinimicrobium* from other genera

The genus *Ornithinimicrobium* has in common with members of the closely related genera *Serinicoccus* (Yi et al., 2004) and *Ornithinicoccus* (Groth et al., 1999) and with the distantly related genera *Actinotalea* and *Demequina* (Yi et al., 2007) L-ornithine as the diagnostic diamino acid in the peptidoglycan. However, there are pronounced differences in the structure of the interpeptide bridges between these genera. The interpeptide bridge of *Ornithinimicrobium* consists of L-Orn–L-Ala–Gly–D-Asp, while that of *Ornithinicoccus* consists of L-Orn–$Gly_{(1,2)}$–D-Glu. The structure of the peptidoglycan of *Serinicoccus* has not yet been elucidated in all details. It seems that *Serinicoccus* represents a novel variation of the peptidoglycan type A4β (Schleifer and Kandler, 1972) containing ornithine and serine (Yi et al., 2004). *Actinotalea* and *Demequina* are characterized by the presence of an L-Orn–D-Asp or an L-Orn–D-Glu interpeptide bridge, respectively, (Yi et al., 2007) and share with *Ornithinimicrobium* 16S rRNA gene

[b]Data from Groth et al. (2001).

[c]Data from Mayilraj et al. (2006).

[d]Data from Liu et al. (2008).

[e,f]Conflicting results reported by Mayilraj et al. (2006) or Liu et al. (2008), respectively.

[g]Data for *Ornithinimicrobium humiphilum* and *Ornithinimicrobium kibberense* from Mayilraj et al. (2006) using Biolog GP2 MicroPlates.

sequence similarities below 93% (91.6–92.0% and 90.8–91.2%, respectively). In addition to these differences in the structure of the peptidoglycan, further phenotypic characteristics contribute to distinguish all these genera from *Ornithinimicrobium* (Table 125). The less closely related genera *Arsenicicoccus*, *Humihabitans*, *Oryzihumus*, and *Kribbia* can also be readily differentiated from *Ornithinimicrobium* by phenotypic properties. Apart from other differentiating characteristics, *Arsenicicoccus* and *Humihabitans* possess LL-A_2pm as the diagnostic diamino acid in the peptidoglycan while *Oryzihumus* and *Kribbia* possess *meso*-A_2pm. Furthermore, the cells of *Arsenicicoccus* are typical cocci, and *Humihabitans* forms branched hyphae that undergo fragmentation.

Taxonomic comments

The genus *Ornithinimicrobium* could not be affiliated to any family of the suborder *Micrococcineae* at the time of the description in 2001. The highest 16S rRNA gene sequence similarity

values were found with *Ornithinicoccus* (Groth et al., 1999) and members of the family *Intrasporangiaceae* (Rainey et al., 1997 in Stackebrandt et al., 1997). According to Stackebrandt and Schumann (2000) the family contained the genera *Intrasporangium* (Kalakoutskii et al., 1967), *Terrabacter* (Collins et al., 1989; Stackebrandt et al., 1997), *Terracoccus* (Prauser et al., 1997) and *Janibacter* (Martin et al., 1997). Due to the lack of five of 17 family specific 16S rRNA gene signature nucleotides described for the *Intrasporangiaceae*, *Ornithinimicrobium* was not included in this family. However, the descriptions of further novel actinobacteria required again a revision of the family *Intrasporangiaceae*. Based on new insights obtained from further 16S rRNA gene sequences and signature nucleotides *Ornithinimicrobium* and *Ornithinicoccus* were now included in the *Intrasporangiaceae*, too (Garrity et al., 2007). Zhi et al. (2009) emended the description of the family *Intrasporangiaceae* and confirmed the affiliation of *Ornithinimicrobium* to this family.

List of species of the genus *Ornithinimicrobium*

1. **Ornithinimicrobium humiphilum** Groth, Schumann, Weiss, Schuetze, Augsten and Stackebrandt 2001, 85[VP]

hu.mi′phi.lum. L. n. *humus* soil; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*) friend, loving; N.L. neut. adj. *humiphilum* loving soil.

See Table 130 and the generic description. Subsequent to the isolation and later in few cultures, in addition to the typical rods and cocci both filamentous cells with swollen club shaped ends or a tendency to primary branching and single spherical cysts were observed. Colonies are circular, convex, glistening, and smooth with an entire margin (0.3–1.2 mm). Color varies within the yellow shade from whitish to bright yellow. Two colony types may be observed on rich (R) medium differing in size, color, and growth rate. While colonies of the pale yellow, opaque type grow rapidly after their transfer on a fresh medium, the growth of the smaller transparent yellow colonies is delayed and somewhat reduced. Optimum temperature for growth is 37–42°C; no growth at 50°C. Acids are produced from starch and, in a low amount, from dextrin. No acid production from D-glucitol, glycerol, and D-mannitol. Formate is used as sole carbon source. Utilization of malate and succinate is delayed and weakly expressed. Aconitate and DL-tartrate are not utilized. Gelatin, hypoxanthine, and xanthine are hydrolyzed; adenine, esculin, hippurate, tyrosine, and urea are not hydrolyzed. Indole is not produced. Cells are susceptible to (μg/disc): ampicillin (10), chloramphenicol (30), ciprofloxacin (5), erythromycin (15), gentamicin (10), kanamycin (30), lincomycin (2), neomycin (30), nitrofuran (300), oxytetracycline (30), penicillin G (2 IU/disc), polymyxin B (300 IU/disc), rifampin (2), and streptomycin (10); no susceptibility to oxacillin (5) and sulfonamide (300). By using the API ZYM system (bioMérieux), activity is detected for alkaline phosphatase, esterase (C 4), esterase lipase (C 8), leucine arylamidase, valine arylamidase, cystine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and α-glucosidase. No activity is detected for lipase (C 14), α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosamidase, α-mannosidase, and α-fucosidase. A weak reaction is observed for trypsin and chymotrypsin. The predominant cellular fatty acids are $C_{16:0}$ iso, $C_{15:0}$ iso, and $C_{15:0}$ anteiso.

DNA G+C content (mol%): 70 (HPLC).

Type strain: HKI 0124, CIP 106634, DSM 12362, JCM 11540.

Sequence accession no. (16S rRNA gene): AJ277650.

2. **Ornithinimicrobium kibberense** Mayilraj, Saha, Suresh and Saini 2006, 1660[VP]

kib.be.ren′se. N. L. neut. adj. *kibberense* pertaining to Kibber, a village in the Indian Himalayas, where the type strain was isolated.

See Table 130 and the generic description. Growth temperature ranges from 20–37°C; optimum temperature for growth is 28°C; no growth at 4 and 42°C. Colonies on TSA are buff-yellow and 1–3 mm in diameter. Acids are produced from trehalose. No acid production from inulin, D-mannitol, and D-xylose. Nitrate reductase is present. H_2S and indole are not produced. Cells are susceptible to (μg/disc): colistin (10), lincomycin (2), and polymyxin B (300). For detailed results of the utilization of carbon sources using the Biolog GP2 MicroPlate test, see Mayilraj et al. (2006).

The predominant cellular fatty acids are $C_{17:1}$ ω9*c*, $C_{17:0}$ iso, $C_{15:0}$ iso, and $C_{16:0}$ iso.

DNA G+C content (mol%): 71 (T_m).

Type strain: K22-20, DSM 17687, JCM 12763, MTCC 6545.

Sequence accession no. (16S rRNA gene): AY636111.

3. **Ornithinimicrobium pekingense** Liu, Wang, Jiang and Liu 2008, 118[VP]

pe.king.en′se. N.L.neut. adj. *pekingense* of Peking, the former name of Beijing city, the origin of the type strain.

See Table 130 and the generic description. Cells are short rods and cocci. The rods vary in dimensions from 1.0–1.6 × 0.5–0.8 μm. Colonies grown on TSA are light yellow and 0.2–1.0 mm in diameter. Optimal growth occurs between 33–37°C and pH 7.8–8.2. Nitrate reductase is present. Gelatin is hydrolyzed. Acid production is negative from melezitose, sorbitol, and xylose. The predominant cellular fatty acids are $C_{15:0}$ iso and $C_{17:1}$ ω9*c*.

DNA G+C content (mol%): 69 (T_m).

Type strain: LW6, CGMCC 1.5362, JCM 14001.

Sequence accession no. (16S rRNA gene): DQ512860.

Genus X. **Oryzihumus** Kageyama, Takahashi, Seki, Tomoda and Ōmura 2005, 2557$^{\mathrm{VP}}$

Akiko Kageyama and Yōko Takahashi

Ory.zi.hu′mus. L. fem. n. *oryza* rice; L. masc. n. *humus* soil; N.L. masc. n. *Oryzihumus* rice soil.

Gram-stain-positive, catalase-positive, aerobic, nonmotile irregular rods. The peptidoglycan is of the A type of direct cross-linkage and contains *meso*-diaminopimelic acid, alanine, and glutamic acid. The acyl type of the glycan chain of peptidoglycan is acetyl. Mycolic acids are absent. The major menaquinone is **MK-8(H$_4$)**. The fatty acid profile is dominated by **$C_{16:0}$ iso and $C_{15:0}$ iso**. Phylogenetically, this genus is a member of the family *Intrasporangiaceae*, order *Micrococcales*.

DNA G+C content (mol%): 72–73.

Type species: **Oryzihumus leptocrescens** Kageyama, Takahashi, Seki, Tomoda and Ōmura 2005, 2558$^{\mathrm{VP}}$.

Further descriptive information

The family *Intrasporangiaceae* was proposed by Rainey et al. (in Stackebrandt et al., 1997) and emended by Stackebrandt and Schuman (2000). The genera belonging to this family can be divided into three groups on the basis of the diagnostic diamino acid types in the cell-wall peptidoglycan: LL-diaminopimelic acid (DAP), *meso*- DAP acid, or L-ornithine. Genera belonging to the *meso*- DAP group are *Janibacter* (Martin et al., 1997), *Knoellia* (Groth et al., 2002), *Kribbia* (Jung et al., 2006), *Oryzihumus* (Kageyama et al., 2005), *Phycicoccus* (Lee, 2006), and *Tetrasphaera* (Maszenan et al., 2000).

16S rRNA gene sequence data show that the genus *Oryzihumus* is closely related to the genus *Ornithinicoccus* of the family *Intrasporangiaceae* (Figure 169). Almost complete 16S rRNA gene sequences have been determined for *Oryzihumus* strains. The sequence similarity values for three *Oryzihumus leptocrescens* strains were above 99.9%, whereas the sequence similarity values between these three strains and *Ornithinicoccus hortensis* were below 95.6%.

Enrichment and isolation procedures

Strains KV-628^T, KV-641, and KV-656 were isolated from soil samples collected from a paddy field in Saitama prefecture, Japan. Soil samples (2 g) were suspended in 18 ml sterile water and then mixed. Soil particles were allowed to sediment, the liquid phase was diluted by 10^5 times and 100 µl was spread onto the surface of four kinds of GPM agar (1.0% glucose, 0.5% peptone, 0.5% meat extract, 0.3% NaCl, and 1.2% agar, pH 7.0) plated (Takahashi et al., 2003), as follows: (1) unsupplemented, (2) supplemented with SOD (300 units/plate), (3) supplemented with catalase (2100 units/plate) or supplemented with SOD plus catalase. Each plate was cultured at 27°C. Biomass for biochemical and chemotaxonomic characteristics was prepared by culture in Todd–Hewitt broth (Difco™) or Nutrient broth (Difco™) at 27°C for 3–4 d.

Maintenance procedures

Oryzihumus strains can be maintained for several weeks on nutrient agar plates. Long-term storage can be achieved at −80°C in nutrient broth or by lyophilization in the presence of stabilizers such as skim milk.

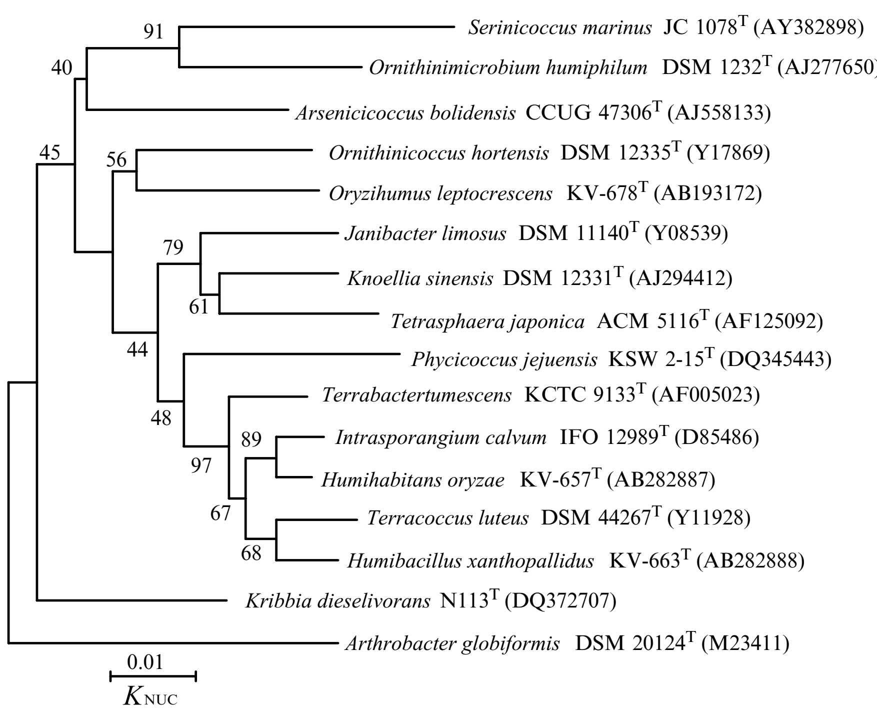

FIGURE 169. Phylogenetic tree derived from 16S rRNA gene sequences of the members of the family *Intrasporangiaceae* and constructed using the neighbor-joining method and K_{nuc} values. Numbers at branching points are bootstrap values (1000 resamplings). The tree was unrooted and *Arthrobacter globiformis* was used as an outgroup.

TABLE 131. Characteristics differentiating the genus *Oryzihumus* and *meso*-diaminopimelic acid-containing members of the family *Intrasporangiaceae*[a]

[f]Component detected in only some representatives of the genus.

Differentiation of the genus *Oryzihumus* from other genera

Characteristics that can be used to distinguish the genus *Oryzihumus* from other genera classified in *meso*-DAP acid group of family *Intrasporangiaceae* are shown in Table 131, these properties include cell morphology, major fatty acid, and polar lipids. The genus *Oryzihums* can be differentiated from other genera belong to the family *Intrasporangiaceae* on the basis of cell morphology and the pattern of phospholipids.

List of species of the genus *Oryzihumus*

1. **Oryzihumus leptocrescens** Kageyama, Takahashi, Seki, Tomoda and Ōmura 2005, 2558[VP]

lep.to.cres′cens. Gr.adj. *leptos* thin, fine, delicate, slender; L. part. adj. *crescens* growing; N.L. part. adj. *leptocrescens* slender growing.

Cells are irregular rods with diameters 0.4–0.9 × 0.9–1.9 µm. Colonies are pale yellow. Aerobic to microaerophilic. Growth occurs at pH 4–9; temperature range for growth is 15–37°C. In 1/5 Nutrient agar medium, NaCl is tolerated up to 5%. D-Glucose, maltose, sucrose, and trehalose are assimilated, but L-rhamnose and D-xylose are not. Susceptible to erythromycin (15 µg/ml), rifampin (30 µg/ml), novobiocin (30 µg/ml), streptomycin (10 µg/ml), and chloramphenicol (30 µg/ml). Not susceptible to aztreonam (100 µg/ml). Esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase, and β-glucosidase are detected by APIZYM enzyme assay; alkaline phosphatase, cystine arylamidase, trypsin, chymotrypsin, β-glucosidase, *N*-acetyl-β-glucosaminase, α-mannosidase, and α-fucosidase are negative. Weak reaction for lipase (C14) is detected. Variable reactions for α-galactosidase are detected.

Source: paddy soil.

DNA G+C content (mol%): 72–73 (HPLC).

Type strain: KV-628, JCM 12835, NBRC 100762, NRRL B-24347.

Sequence accession no. (16S rRNA gene): AB193172.

Genus XI. **Phycicoccus** Lee 2006, 2371[VP] emend. Zhang, Liu and Liu 2011, 74

Soon Dong Lee

Phy.ci.coc′cus. L. n. *phycos -i* from Gr. n. *phukos* seaweed; N.L. masc. n. *coccus* from Gr. n. *kokkos* a grain or berry; N.L. masc. n. *Phycicoccus* coccus from seaweed.

Cells are **spherical** (0.3–1.0 µm in diameter) or rod-shaped (0.5–0.9 × 1.1–2.0 µm). **Aerobic**. Gram-stain-positive. **Nonspore-forming. Nonmotile. Catalase-positive**. Colonies are circular, smooth, convex and white, cream, or yellow in color. Optimum growth temperature is 28–30°C. **Chemoorganotrophic.** Several carbohydrates are assimilated. Cell wall contains *N*-acetylated murein and *meso*-diaminopimelic acid (*meso*-DAP). The predominant menaquinone is tetrahydrogenated with eight

isoprene units [MK-8(H_4)]. The fatty acids are mainly of *iso*-methyl-branched, unsaturated and saturated types with substantial amount of *anteiso*-methyl-branched and 10-methyl fatty acids. Mycolic acids are not present. The phospholipids include diphosphatidylglycerol and phosphatidylinositol. The presence of phosphatidylethanolamine or phosphatidylglycerol is variable depending upon strains. Phylogenetically the genus belongs to the family *Intrasporangiaceae*.

DNA G+C content (mol%): 70.5–74.0.

Type species: **Phycicoccus jejuensis** Lee 2006, 2371[VP].

Further descriptive information

The cells of *Phycicoccus* are strictly aerobic, Gram-stain-positive cocci (0.3–1.0 µm in diameter) that occur singly, in pairs, in chains, or in clusters or rod-shaped (0.5–0.9 × 1.1–2.0 µm). All of the cells are nonmotile. Colonies are circular, smooth, convex and white, cream, or yellow in color.

No growth occurs on any medium under anaerobic conditions. The temperature range for growth is 5–37°C. Optimum growth occurs at pH 6.0–8.0. All strains give positive reactions in the following tests: catalase activity; hydrolysis of casein and Tween 80; assimilation of D-glucose, D-mannose, D-mannitol, *N*-acetyl-D-glucosamine, D-maltose, gluconate, and malate (API 20NE); esterase lipase (C8), leucine arylamidase, acid phosphatase, β-galactosidase, β-glucosidase, and naphthol-AS-BI-phosphohydrolase activities (API ZYM); and tolerance to 5% NaCl. They give negative reactions for indole production, urease and α-fucosidase activities, and assimilation of caprate and citrate.

The diagnostic diamino acid in the cell-wall peptidoglycan is *meso*-diaminopimelic acid, and the peptidoglycan is A1γ type. For those strains that have been examined, the glycan moiety of their cell walls is acetylated, indicating that the muramic acid occurs in the usual *N*-acetyl form. Weon et al. (2008) examined whole cell sugars in the type strain of *Phycicoccus aerophilus* and found glucose and ribose as diagnostic cell-wall sugars. The major menaquinone is the same in all species, tetrahydromenaquinone with eight isoprene units [MK-8(H_4)]. The polar lipid composition is variable. In the original description of the genus (Lee, 2006), the polar lipid profile comprised phosphatidylethanolamine (PE) as a characteristic phospholipid together with diphosphatidylglycerol and phosphatidylinositol. This profile is also found in *Phycicoccus aerophilus* (Weon et al., 2008). However, PE was not detected in *Phycicoccus dokdonensis* (Yoon et al., 2008) and *Phycicoccus bigeumensis* (Dastager et al., 2008). Instead, they contain phosphatidylglycerol in their polar lipid profiles. In addition, unknown glycolipids were reported in *Phycicoccus cremeus* (Zhang et al., 2011). All stains of *Phycicoccus* exhibit similar fatty acid profiles. The fatty acids consist mainly of *iso*-methyl-branched, unsaturated, and saturated components with substantial amounts of *anteiso*-methyl-branched and 10-methyl fatty acids. Small amounts of 3-hydroxyl fatty acid are present in some strains. The predominant fatty acids (>10% of a total) commonly detected in all strains examined are $C_{15:0}$ iso and $C_{16:0}$ iso. The other fatty acids present in substantial amounts are $C_{17:1}$ ω8*c*, $C_{17:0}$, $C_{15:0}$, $C_{15:0}$ anteiso, $C_{17:0}$ 10-methyl, and $C_{14:0}$ iso. Mycolic acids are not present. The DNA base ratios reported by members of the genus are 70.5–74.0 mol% G+C, as measured by HPLC or thermal renaturation.

Strains of *Phycicoccus* have been isolated from a variety of sources including dried seaweed, air, and soils (see list of species).

Enrichment and isolation procedures

Species have been isolated by plating. Nutrient agar (Difco), R2A (Difco) agar with or without 10-folded dilution, or chemically synthetic medium V2M (Zhang et al., 2010) have been used for air or soil samples with incubation times of 5–7 d. For isolation of *Phycicoccus jejuensis*, a piece of dried seaweed was directly applied onto plates of WAT agar, containing 0.05% $MgSO_4 \cdot 7H_2O$, 0.05% $CaCl_2 \cdot 2H_2O$, 1.5% agar, plus 60% (v/v) sterilized natural seawater (Lee, 2006).

Maintenance procedures

Phycicoccus strains can be preserved for several months in 20% glycerol suspension with or without the addition of 60% (v/v) natural seawater (−20°C). Lyophilization is recommended for longer preservation of several years.

Differentiation of the genus *Phycicoccus* from other genera

The genus *Phycicoccus* may be differentiated from genera which contain *meso*-DAP as cell-wall diamino acid and MK-8(H_4) as major menaquinone in the family *Intrasporangiaceae* by the characteristics given in Table 132.

Taxonomic comments

The genus *Phycicoccus* was established by Lee (2006) with the description of *Phycicoccus jejuensis* as the sole and type species. In the original description, the comparative analysis of 16S rRNA gene sequences indicated that *Phycicoccus* possesses about 96% sequence similarity to strains of "*Candidatus* Nostocoida limicola" which have been described as a filamentous bacterium isolated from activated sludge (Blackall et al., 2000) of the family *Intrasporangiaceae*. Because of the practical difficulty in obtaining biomass for polyphasic characterization, the description of this filamentous bacterium has not been not validated. *Phycicoccus* is readily differentiated from strains of "*Candidatus* Nostocoida limicola," based on the comparison of limited features, namely 16S rRNA gene sequence similarity and morphological characteristics (Blackall et al., 2000). At the same time when the *Phycicoccus* was proposed, strains of "*Candidatus* Nostocoida limicola," were assigned to the genus *Tetrasphaera* (McKenzíe et al., 2006). Among the *Intrasporangiaceae*, *Terrabacter* possesses high 16S rRNA gene sequence similarities to *Phycicoccus* but also LL-DAP instead of *meso*-DAP as the diagnostic cell-wall diamino acid and it lacks the unsaturated fatty acids common in *Phycicoccus* (Martin et al., 1997; Montero-Barrientos et al., 2005).

The genus *Phycicoccus* as presently defined exhibits a close chemotaxonomic relationship to bacteria of the family *Intrasporangiaceae* which contain *meso*-DAP as principal cell-wall diamino acid and MK-8(H_4) as major menaquinone. These include the genera *Janibacter*, *Knoellia*, *Kribbia*, *Oryzihumus*, and *Tetrasphaera*.

Differentiation and characteristics of the species of the genus *Phycicoccus*

Species of *Phycicoccus* can be differentiated using the characteristics described in Table 133.

TABLE 132. Characteristics differentiating *Phycicoccus* and genera which contain *meso*-DAP as cell-wall diamino acid and MK-8(H_4) as major menaquinone in the family *Intrasporangiaceae*[a]

List of species of the genus *Phycicoccus*

1. **Phycicoccus jejuensis** Lee 2006, 2371[VP]

je.ju.en′sis. N.L. masc. adj. *jejuensis* of Jeju, Republic of Korea, referring the site from which the type strain was isolated.

Cells are nonmotile cocci that occur singly, in pairs, or in clusters. Colonies are circular, smooth, translucent, and moderate yellow in color. Other characteristics are given in Table 133 and in *Further descriptive information*. The temperature range for growth is 4–37°C, with an optimum at 30°C. The pH for growth is pH 5.1–10.1, with an optimum at pH 7.1. Growth occurs up to 7% (w/v) NaCl. Hydrolyzes elastin. Negative for *N*-acetyl-β-glucosaminidase activity and glucose fermentation. Utilizes a variety of carbohydrates as sole carbon and energy sources. The major cellular fatty acids (>10% of total) are $C_{17:1}$ ω8*c*, $C_{16:0}$ iso, $C_{15:0}$ iso, $C_{15:0}$, and $C_{17:0}$. The polar lipids include phosphatidylethanolamine, phosphatidylinositol and diphosphatidylglycerol.

Source: dried seaweed.

DNA G+C content (mol%): 74 (HPLC).

Type strain: KSW2-15, JCM 15616, KCCM 42315, NRRL B-24460.

Sequence accession no. (16S rRNA gene): DQ345443.

2. **Phycicoccus aerophilus** Weon, Yoo, Kim, Schumann, Kroppenstedt, Hong and Kwon 2008, 2391[VP]

ae.ro.phi′lus. Gr. n. *aer aeros* air; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. masc. adj. *aerophilus* air-loving.

Cells are nonmotile, short rods (0.8–0.9 × 1.1–1.5 µm). Colonies on R2A medium are white, round, and convex with clear margins. Other characteristics are given in Table 133 and in *Further descriptive information*. The temperature range for growth is 5–37°C, with an optimum at 30°C. The pH for growth is pH 5.0–9.0, with an optimum at pH 6.0–7.0. Growth occurs at up to 7% (w/v) NaCl. Hydrolyzes tyrosine and xanthine, but not chitin, carboxymethyl-cellulose, hypoxanthine, or pectin. Positive for β-galactosidase, but negative for glucose fermentation and arginine dihydrolase. Utilizes sucrose, sodium acetate, L-alanine (weak), glycogen, salicin, melibiose, L-fucose, propionic acid, valeric acid, and 3-hydroxybutyric acid as sole carbon and energy sources. The major fatty acids (>10% of total) are $C_{17:1}$ ω8c, $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:0}$. The polar lipids include phosphatidylethanolamine, phosphatidylinositol, and diphosphatidylglycerol.

Source: air.

DNA G+C content (mol%): 70.5 (HPLC).

Type strain: 5516T-20, DSM 18548, KACC 20658.

Sequence accession no. (16S rRNA gene): EF493847.

3. **Phycicoccus bigeumensis** Dastager, Lee, Ju, Park and Kim 2008, 2427[VP]

bi.geu.men′sis. N.L. masc. adj. *bigeumensis* pertaining to Bigeum Island, Republic of Korea, the source of soil sample from where the type strain was isolated.

Cells are cocci with a warty appearance and occur singly or in short chains. Colonies are circular, small, smooth, and yellow in color. Other characteristics are given in Table 133 and in *Further descriptive information*. The temperature range for growth is 20–37°C, with an optimum at 28°C. The pH range for growth is 7.0–12.0, with an optimum at pH 7.4 ± 0.1. Growth occurs up to 5% (w/v) NaCl. Negative for *N*-acetyl-β-glucosaminidase activity. Utilizes L-arabinose, cellobiose, D-fructose, D-galactose, D-glucose, *myo*-inositol, D-lactose, D-mannose, D-mannitol, melibiose, raffinose, L-rhamnose, and trehalose as sole carbon and energy sources. Acid is not produced from any of the carbon sources. The major fatty acids (>10% of total) are $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$, and $C_{15:0}$ anteiso. The polar lipids include diphosphatidylglycerol and phosphatidylglycerol.

Source: soil.

DNA G+C content (mol%): 73.4 (HPLC).

Type strain: MSL-03, DSM 19264, KCTC 19266.

Sequence accession no. (16S rRNA gene): EF466128.

4. **Phycicoccus cremeus** Zhang, Liu and Liu 2011, 74[VP]

cre′me.us. N.L. masc. adj. *cremeus* cream-white.

Cells are nonmotile rods (0.5–0.8 × 1.5–2.0 µm). Colonies on R2A agar (after 2 d at 30°C) are 0.3–0.8 mm in diameter, circular, entire, smooth, circular, and cream in color. Other characters are given in Table 133 and in *Further descriptive information*. The temperature range for growth is 14–35°C, with an optimum at 29°C. The pH for growth is pH 4.1–10.0, with an optimum at pH 7.0–8.0. Growth occurs up to 7% (w/v) NaCl. Growth occurs on diluted TSB agar (1/10 and 1/20 strength of TSB) and on R2A agar. Does not hydrolyze Tween 20. Negative for arginine dihydrolase and *N*-acetyl-β-glucosaminidase activities, Voges–Proskauer reaction, and glucose fermentation. The major fatty acids (>10% of a total) are $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:1}$ ω8*c*, and $C_{17:0}$ 10-methyl. The polar lipids include diphosphatidylglycerol, phosphatidylinositol, and three unknown glycolipids.

Source: forest soil.

DNA G+C content (mol%): 72.0 (T_m).

Type strain: V2M29, CGMCC 1.6963, NBRC 104261.

Sequence accession no. (16S rRNA gene): FJ529696.

5. **Phycicoccus dokdonensis** Yoon, Lee, Kang and Oh 2008, 599[VP]

dok.do.nen′sis. N.L. masc. adj. *dokdonensis* of Dokdo, Republic of Korea, the source of the soil sample from which the type strain was isolated.

Cells are nonmotile cocci (0.3–0.7 µm in diameter). Colonies on Trypticase soy agar after 7 d of incubation at 30°C are 0.6–1.2 mm in diameter, circular, smooth, glistening, convex, and grayish yellow in color. Other characteristics are given in Table 133 and in *Further descriptive information*. The temperature range for growth is 10–36°C, with an optimum at 30°C. The pH range for growth is pH 5.0–8.5, with an optimum at pH 6.5–7.5. Growth occurs at up to 5% (w/v) NaCl. Hydrolyzes hypoxanthine and Tweens 20, 40, 60 but not xanthine and L-tyrosine. Negative for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase. H_2S is not produced. Utilizes esculin, melezitose, starch, and D-lyxose as sole carbon and energy sources. The major fatty acids (>10% of total) are $C_{15:0}$ iso and $C_{16:0}$ iso. The polar lipids contain phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, and two unidentified phospholipids.

Source: soil.

DNA G+C content (mol%): 70.7 (HPLC).

Type strain: DS-8, CCUG 54521, KCTC 19248.

Sequence accession no. (16S rRNA gene): EF555583.

Genus XII. **Serinicoccus** Yi, Schumann, Sohn and Chun 2004, 1587[VP]

Peter Schumann

Se.ri.ni.coc′cus. N.L. neut. n. *serinum* serine; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos*) a grain, seed; N.L. masc. n. *Serinicoccus* a coccus with serine in the cell wall.

Cells are nonmotile cocci. Gram-stain-positive, strictly aerobic, moderately halophilic. Oxidase-negative, catalase-positive, not acid-fast. Nonsporeforming. The **peptidoglycan** type is of the **A type** of cross-linkage and **contains ornithine, alanine, lysine, serine, and glutamic acid**. The acyl type of the glycan chain of peptidoglycan is acetyl. The major menaquinone is **MK-8(H_4)**. The major **cellular fatty acids** are of the **iso- and anteiso-methyl-branched type**. The polar lipids are **phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol**, and one unknown glycolipid. Phylogenetically, this genus is affiliated to the family *Intrasporangiaceae*.

DNA G+C content (mol%): 72.

Type species: **Serinicoccus marinus** Yi, Schumann, Sohn and Chun 2004, 1587[VP].

Further descriptive information

The genus *Serinicoccus* is a member of the family *Intrasporangiaceae* belonging to the order *Micrococcales*, class *Actinobacteria* according to the taxonomic outline for the present volume. The genus *Serinicoccus* clusters in neighbor-joining trees based on 16S rRNA gene sequences together with the genera *Ornithinimicrobium*, *Kribbia*, and *Arsenicicoccus* (Jung et al., 2006; Lee, 2006) but also with *Demetria terragena* and *Dermacoccus nishinomiyaensis* (Mayilraj et al., 2006; Yi et al., 2004). A search by using the EzTaxon server (Chun et al., 2007) revealed the following pair-wise similarity values for close relatives: *Ornithinimicrobium kibberense* DSM 17687[T] (96.3%), *Kribbia dieselivorans* N113[T] (95.5%), *Dermacoccus nishinomiyaensis* DSM 20448[T] (95.2%), *Kytococcus sedentarius* DSM 20547[T] (94.7%), *Arthrobacter cumminsii* DSM 10493[T] (94.3%), *Demetria terragena* DSM 11295[T] (93.9%), *Arthrobacter albus* DSM 13068[T] (94.0), *Janibacter limosus* DSM 11140[T] (93.7%), and *Arseniciccoccus bolidensis* CCUG 47306[T] (93.7%). Except for the two *Arthrobacter* species which represent a distant lineage of their genus (Pukall et al., 2006), the closest phylogenetic neighbors belong to the families *Dermacoccaceae* and *Intrasporangiaceae*. The comparison of the available 16S rRNA gene sequences of *Serinicoccus marinus* JC1078[T], *Ornithinimicrobium humiphilum* DSM 12362[T], and *Demetria terragena* DSM 11295[T] is hampered by the fact that the first ~50 nucleotides of sequence AY382898 (JC1078[T], 1421 nucleotides in total) and the last ~140 nucleotides of sequence AJ277650 (DSM 12362[T], 1306 nucleotides in total) are missing when compared to the sequence of *Demetria terragena* DSM 11295[T] (1457 nucleotides in total). The revised set of signature nucleotides for the family *Intrasporangiaceae* (Family *Intrasporangiaceae*, this volume), the phylogenetic association, and agreement in chemotaxonomic characteristics with members of this family support the affiliation of the genus *Serinicoccus* to the family *Intrasporangiaceae* as it has been proposed recently (Garrity et al., 2007; Montero-Barrientos et al., 2005).

The cells of the type strain of *Serinicoccus marinus* JC1078[T] are nonmotile cocci and share the presence of the diamino acid L-ornithine in the peptidoglycan with the closest phylogenetic neighbor *Ornithinimicrobium humiphilum* (Groth et al., 2001). The peptidoglycan of strain JC1078[T] contains the amino acids ornithine (Orn), alanine (Ala), glycine (Gly), serine (Ser), and glutamic acid (Glu). Ser represents the *N*-terminus of the interpeptide bridge. The peptide L-Ala→D-Glu typical of peptidoglycans cross-linked according to the A-type was detected in the partial hydrolysate of the peptidoglycan. The muramic acid residues of the glycan chain are acetylated. However, a detailed peptidoglycan structure could not be concluded from the analytical data.

Colonies of strain JC1078[T] on Marine agar 2216 (MA; Difco) are yellow, circular, convex, entire, glistening, opaque, and butyraceous. They are approximately 1 mm in diameter after 3 d and 3–4 mm after incubation for 5 d at 30°C. The type strain grows optimally at 35°C in the presence of 2–3% NaCl at pH 8. Growth is slow without NaCl and concentrations up to 14% NaCl were tolerated. An extended incubation time is required at low temperatures (e.g. 20 d at 5°C). Sparse growth was observed at pH 6 and 11. Strain JC1078[T] is strictly aerobic.

Serinicoccus marinus JC1078[T] originates from a surface seawater sample of the East Sea, Korea.

Isolation and maintenance procedures

Strain JC0178[T] was isolated from a surface seawater sample collected from the East Sea (Korea) by the standard dilution plating technique using MA and incubation at 30°C. The isolate was routinely cultured on MA with serial transfers at 4-week intervals. The strain was maintained as agar cultures at 4°C and as 20% (w/v) glycerol suspension at −80°C. Long-term preservation is possible by freeze-drying in skim milk or maintenance in liquid nitrogen.

Differentiation of the genus *Serinicoccus* from other genera

The genus *Serinicoccus* shares with the genus *Ornithinimicrobium* the diagnostic diamino acid L-Orn but can be differentiated by this criterion from members of the families *Intrasporangiaceae* and *Dermacoccaceae* (Table 134) as well as from *Arthrobacter albus* (Wauters et al., 2000) and *Arthrobacter cumminsii* (Funke et al., 1996) which show either the peptidoglycan variation A4α based on the diamino acid L-lysine or peptidoglycans based on diaminopimelic acid isomers like *Kribbia* and *Arsenicicoccus*. The menaquinone MK-8(H_4) occurs in the genera *Serinicoccus*, *Ornithinimicrobium*, *Kribbia*, *Arsenicicoccus*, and *Demetria* whereas MK-8(H_2) or completely unsaturated menaquinones were characteristic of *Dermacoccus* or *Kytococcus*, respectively.

The genus *Serinicoccus* differs from the phylogenetically closest genus *Ornithinimicrobium* in displaying Ser but lacking aspartic acid in the peptidoglycan and in its invariably coccoid morphology. Additional differentiating characteristics of *Serinicoccus* are its capability to decompose Tween 80 and tyrosine but negative

TABLE 134. Characteristics differentiating the genus *Serinicoccus* and phylogenetically related genera[a]

reactions for nitrate reduction and decomposition of xanthine and hypoxanthine as well as the absence of alkaline and acid phosphatases, cystine arylamidase, and naphthol-AS-BI phosphohydrolase as revealed by the API ZYM test. *Serinicoccus marinus* can tolerate a NaCl concentration of 12% (Yi et al., 2004) and differs in this feature from *Ornithinimicrobium humiphilum* (Groth et al., 2001) and *Ornithinimicrobium kibberense* (Mayilraj et al., 2006). In contrast to *Ornithinimicrobium humiphilum* DSM 12362[T], *Serinicoccus marinus* is unable to grow at temperatures above 35°C (Groth et al., 2001; Yi et al., 2004).

List of species of the genus *Serinicoccus*

1. **Serinicoccus marinus** Yi, Schumann, Sohn and Chun 2004, 1587[VP]

ma.ri′nus. L. masc. adj. *marinus* of or belonging to the sea, marine.

In addition to the characteristics that define the genus, it has the characteristics described below. Growth occurs at NaCl concentrations of 0–14% (w/v), the optimum being 2–3%. The pH range for growth is pH 6–11, the optimum being pH 8. The temperature range for growth is 10–35°C, with the optimum being 35°C. Extended incubation (up to 20 d) is required at 5°C. Cells are cocci with diameters of 0.5–0.9 μm. Colonies on MA are yellow, circular, convex, entire, glistening, opaque, and butyraceous. Colonies are approximately 1 mm in diameter after 3 d (on MA at 30°C) and reach the maximum diameter of 3–4 mm after 5 d. Nitrate is reduced to nitrite. Does not show arginine dihydrolase activity. β-Galactosidase activity is weakly present. Does not produce H_2S on TSI agar, acid from glucose in API 20NE kit, or indole from tryptophan. Casein, DNA, esculin, gelatin, starch, Tween 80, and tyrosine are decomposed; adenine, alginate, cellulose, chitin, hypoxanthine, urea, and xanthine are not. Tested by the API ZYM enzyme assay, strain JC1078[T] is positive for esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, and α-glucosidase; variable for trypsin and β-glucosidase; negative for alkaline phosphatase, lipase (C14), cystine arylamidase, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase,

α-mannosidase, and α-fucosidase. Utilizes acetate, D-cellobiose, D-fructose, D-galactose, D-glucose, D-mannitol, D-mannose, D-sorbitol, D-trehalose, glycerol, and sucrose as a sole carbon source. Does not utilize acetamide, benzoate, citrate, D-ribose, ethanol, glycine, inulin, 2-propanol, lactose, L-arginine, L-ascorbate, L-lysine, L-rhamnose, *N*-acetylglucosamine, polyethylene glycol, salicylate, or tartrate. The major fatty acids are $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:1}$ ω9*c* iso, $C_{17:0}$ iso, $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: a seawater sample from the East Sea, Korea.

DNA G+C content (mol%): 72 (HPLC).

Type strain: JC1078, DSM 15273, JCM 13024, KCTC 9980, IMSNU 14026.

Sequence accession no. (16S rRNA gene): AY382898.

Genus XIII. **Terrabacter** Collins, Dorsch and Stackebrandt 1989, 4^VP

Erko Stackebrandt

Ter.ra.bac′ter. L. n. *terra* earth; N.L. masc. n. *bacter* masc. equivalent of Gr. neut. n. *baktron* a rod; N.L. masc. n. *Terrabacter* earth (soil) rod.

A rod–coccus growth cycle occurs during growth in complex media. Irregular rods are observed in exponential phase cultures; stationary phase cultures are composed mainly of coccoid cells. Both rods and coccoid forms are Gram-stain-positive. Cells are non-acid-fast and nonsporeforming. Rods nonmotile or motile. Growth at 10°C and 35°C. Optimum temperature for growth approximately 25–30°C. Growth in 5% NaCl. Catalase-positive. Oxidase-negative. **Obligatory aerobic**. Acid is not produced from glucose and other sugars in peptone-based media. Cellulose is not hydrolyzed. Nitrate is reduced to nitrite by two species. **The cell-wall peptidoglycan contains LL-2,6-diaminopimelic acid (variation A3γ) as the diamino acid; the interpeptide bridge consists of three glycine residues. Mycolic acids are absent. Major long-chain cellular fatty acid is $C_{15:0}$ iso; $C_{14:0}$ iso, $C_{15:0}$ anteiso, and $C_{16:0}$ iso are present in lesser amounts; $C_{17:0}$ anteiso and $C_{16:1}$ iso may be present. The polar lipids comprise diphosphatidylglycerol, phosphatidylethanolamine, and phosphatidylinositol. The major isoprenoid quinones are tetrahydrogenated menaquinones with eight isoprene units [MK-8(H_4)].**

DNA G+C content (mol%): 69.8 to 73.4.

Type species: **Terrabacter tumescens** (Jensen 1934) Collins, Dorsch and Stackebrandt 1989, 6 (*Corynebacterium tumescens* Jensen 1934, 45; *Arthrobacter tumescens* Conn and Dimmick 1947, 302; *Pimelobacter tumescens* Suzuki and Komagata 1983, 70).

Further descriptive information

The genus *Terrabacter* belongs to the family *Intrasporangiaceae* (Stackebrandt et al., 1997), defined by phylogenetic position and the presence of a common set of 16S rRNA gene signature nucleotides. Originally described as *Arthrobacter tumescens* (Jensen) the species was reclassified as *Pimelobacter tumescens* (Suzuki and Komagata, 1983). Differences in some chemotaxonomic properties of members of this genus (Collins et al., 1983; O'Donnell et al., 1982) pointed towards the taxonomic heterogeneity of the genus, which was dissolved by Collins et al. (1989) on the basis of the phylogenetic analysis of reverse transcribed 16S rRNA gene sequences. While *Pimelobacter jensenii* was reclassified as *Nocardioides jensenii*, *Pimelobacter tumescens* formed the nucleus of the new genus *Terrabacter*. The phylogenetically closest neighbors of *Terrabacter* species are *Terracoccus luteus* (97.6% 16S rRNA gene sequence similarity) and *Intrasporangium calvum* (97.3%). This intrafamily substructure is in accord with the composition of the peptidoglycan of its members (see the chapter on *Intrasporangiaceae*, above, and Table 125 for a description of characteristics that differentiate between the genera of the *Intrasporangiaceae*).

The type strain PPLB^T of the species *Terrabacter terrae*, (Montero-Barrientos et al., 2005) differs from *Terrabacter tumescens* DSM 20308^T in morphology, fatty acid composition, and some phenotypic properties (Table 135). The two type strains share 98.8% 16S rRNA gene sequence similarity and a low DNA–DNA reassociation value of 36.6%. The third species *Terrabacter aerolatus* 5516J-36^T (Weon et al., 2007b) differs from *Terrabacter terrae* CECT 3379^T and *Terrabacter tumescens* DSM 20308^T with respect to fatty acid composition and morphological, cultural, and phenotypic properties (Table 135). Phylogenetically, the three type strains are closely related (16S rRNA gene sequence similarities 98.7–98.9%). DNA–DNA reassociation values of less than 52% determined among the three *Terrabacter* type strains support their genomic separateness (Weon et al., 2007b).

According to API 20NE and API ZYM strips, the type strains of the three *Terrabacter* species are positive for esculin hydrolysis, gelatin hydrolysis, and β-galactosidase, esterase (C4), esterase lipase (C8), leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, and α-glucosidase activities. All strains are negative for indole production, glucose fermentation, and arginine dihydrolase, urease, alkaline phosphatase, cystine arylamidase, trypsin, α-chymotrypsin, β-glucuronidase, *N*-acetyl-β-glucosaminidase, and α-fucosidase activities. According to API 20NE and API ID32GN strips, all strains assimilate D-glucose, D-mannose, *N*-acetylglucosamine, maltose, potassium gluconate, malic acid, inositol, sucrose, sodium malonate, sodium acetate, L-alanine, glycogen, propionic acid, valeric acid, L-histidine, and 3-hydroxybutyric acid. None of the strains assimilate capric acid, trisodium citrate, phenylacetic acid, L-rhamnose, itaconic acid, suberic acid, potassium 5-ketogluconate, salicin, L-fucose, potassium 2-ketogluconate, or 4-hydroxybenzoic acid. The following reactions differ from the description of *Terrabacter terrae* listed as negative by Montero-Barrientos et al. (2005): mannose, *N*-acetylglucosamine, gluconate, esterase, *β*-galactosidase, and -glucosidase; these reactions are indicated in the species description below as in the original description.

Terrabacter species have frequently been isolated from unpolluted but also from polluted soil, e.g. from biphenyl-adapted soils (Wagner-Döbler et al., 1998). Organisms affiliated to the genus *Terrabacter* have been demonstrated to metabolize a variety of polycyclic aromatic hydrocarbons. Several catabolites were determined and genes characterized involved in

the degradation of biphenyl (Aislabie et al., 1999), dibenzofuran (Iida et al., 2002; Kasuga et al., 2001), fluorene analogs (Habe et al., 2004), and chlorinated dioxin (Habe et al., 2002). Whether these strains represent novel species will have to await their thorough characterization.

Enrichment and isolation procedures

Terrabacter tumescens can be isolated by standard methods on "poor" medium to obtain arthrobacters from soil: (g/liter) $Ca(H_2PO_4)_2$, 0.25; K_2HPO_4, 1.0; $MgSO_4·7H_20$ 0.25; $(NH_4)_2SO_4$, 0.25; Casein, 1.0; yeast extract, 0.7; glucose, 1.0; agar, 10.0; pH 6.9–7.0. Other media have been listed by Keddie and Jones (1981).

Terrabacter terrae strain PPLB^T was isolated from a soil sample mixed with Iberian pig hair by dilution plating on feather agar (g/liter: NH_4Cl, 0.5; NaCl, 0.5; K_2HPO_4, 0.3; KH_2PO_4, 0.4; $MgCl_2·6H_2O$, 0.1; yeast extract, 0.1; hammer-milled chicken feathers, 10; agar, 20) at 32°C (Kim et al., 2001; Williams et al., 1990). Colonies showed transparent "haloes" produced by the hydrolysis of keratin from chicken feathers.

Terrabacter aerolatus strain 5516J-36^T was isolated from an air sample from the Jeju region of Korea, by collecting air using an MAS-100 air sampler (Merck; single-stage multiple-hole impactor) which contained Petri dishes with R2A agar (BBL) amended with 200 mg cycloheximide ml21 (Sigma). Plates were incubated at 30°C and strain 5516J-36^T was recovered after 5 d.

Maintenance procedures

All strains grow on R2A medium (pH 7.0; Difco) at 30°C. Serial transfers on nutrient agar at 4-week intervals followed by maintenance at 4°C are recommended. Storage of cells as 20% (w/v) glycerol suspensions at −20°C and at −80°C is a suitable preservation method. Long-term preservation methods include freeze drying in skim milk and maintenance in liquid nitrogen at −196°C.

Differentiation of the genus *Terrabacter* from other genera

Properties in which the genus *Terrabacter* differ from phylogenetically neighboring taxa are indicated in Table 135 of the chapter on the genus *Terracoccus.*

List of species of the genus *Terrabacter*

1. **Terrabacter tumescens** (Jensen 1934) Collins, Dorsch and Stackebrandt 1989, 6^{VP} (*Corynebacterium tumescens* Jensen 1934, 45; *Arthrobacter tumescens* Conn and Dimmick 1947, 302; *Pimelobacter tumescens* Suzuki and Komagata 1983, 70)

   tu.mes´cens. L. part. adj. *tumescens* swelling up.

   A rod–coccus cycle occurs during growth on complex media. Cells from older cultures are coccoid (diameter, 0.5–8 µm). After transfer to fresh complex media, long, irregular rods (0.6–1.2 × 2.0–6.0 µm) are formed. The long rods show primary branching. Aerial mycelium is not

formed. Generally nonmotile (occasionally motile strains occur). Colonies are glossy, entire, smooth, and gray or white. Growth at 10 and 35°C; may or may not grow at 37°C. Optimum temperature for growth approximately 25–30°C. Most strains grow in 5% NaCl. Obligatory aerobic. Acid is not formed from glucose and other sugars in peptone-based media. Thiamine is the only growth factor required (when thiamine is provided, the organism utilizes an ammonium salt or nitrate as the sole nitrogen source in mineral salts medium with glucose as the carbon-plus-energy source). A wide range of organic compounds is utilized as sole or principal carbon-plus-energy sources for growth including D-alanine, crotonate, inositol, α-D-glucosamine, and raffinose; D-glucuronate, L-ornithine, D-phenylalanine, and uric acid are not utilized. Hippurate, and tyrosine are hydrolyzed. Starch may or may not be hydrolyzed. Some strains hydrolyze Tween 80. Sulfatase-negative. Some strains produce H_2S. Other reactions are listed in Table 135 and above. The major polyamine is putrescine, while spermidine and spermin occur in smaller amounts. There are major amounts of $C_{14:0}$ iso, $C_{15:0}$ iso, and $C_{16:0}$ iso whole cell fatty acids. In addition to polar lipids described for the genus, unidentified phospholipids may occur.

In most respects the description of the type strain corresponds to that of the species. The type strain is nonmotile. Starch and Tween 80 are hydrolyzed. H_2S is not produced.

Source: soil.

DNA G+C content (mol%): 69.8–72.4 (T_m).

Type strain: ATCC 6947, CCUG 23928, CIP 102515, DSM 20308, IAM 12345, NBRC 12960, JCM 1365, LMG 3818, NCIMB 8914, NRRL B-4012, VKM Ac-1120.

Sequence accession no. (16S rRNA gene): X83812, X83815.

2. **Terrabacter aerolatus** Weon, Schumann, Kroppenstedt, Kim, Song, Kwon, Go and Stackebrandt 2007b, 2108[VP]

a.e.ro.la′tus. Gr. n. *aer*, *aeros* air; L. part. adj. *latus* carried; N.L. masc. part. adj. *aerolatus* airborne.

Cells are strictly aerobic, Gram-stain-positive, motile rods or cocci (0.9–1.06 × 1.0–3.5 mm). Catalase-positive and oxidase-negative. Colonies are white, convex, and round. Optimal temperature for growth is 30°C. Growth occurs in the range 5–35°C. Optimal pH for growth is 7.0–8.0; growth occurs in the range pH 4–9. Growth occurs in the presence of 0–5% (w/v) NaCl. Casein, starch, tyrosine, and Tween 80 are hydrolyzed, but chitin, CMcellulose, pectin, hypoxanthine, and xanthine are not. Other reactions are listed in Table 135 and above. Whole-cell sugars are glucose, ribose, rhamnose, xylose, and galactose (in decreasing order of abundance). The major fatty acids (>5% of total fatty acids) are $C_{15:0}$iso (49.0%), $C_{16:0}$iso (14.5%), $C_{14:0}$iso (7.9%), $C_{17:0}$iso (5.8%), and $C_{15:0}$ anteiso (5.2%). In addition to polar lipids described for the genus, an unidentified phosphoglycolipid is present.

Source: from an air sample in Jeju, Korea.

DNA G+C content (mol%): 71.7 (HPLC).

Type strain: 5516J-36, DSM 18562, KACC 20556.

Sequence accession no. (16S rRNA gene): EF212039.

3. **Terrabacter terrae** Montero-Barrientos, Rivas, Velázquez, Monte and Roig 2005, 2293[VP]

ter′ra.e. L. gen. n. *terrae* of the earth.

Gram-stain-positive cells are long irregular rods 2.0 × 6.0 μm in length. Aerial mycelium is not formed. Nonmotile, nonsporeforming, and aerobic. Colonies are glossy and yellow on feather and nutrient agar. Oxidase-negative and catalase-positive. Chemoorganotrophic. Metabolism is respiratory; acid is not produced from glucose or other carbohydrates. A wide range of organic compounds are utilized for growth including mannitol, citrate, and chicken feathers. Does not assimilate arabinose, mannose, *N*-acetylglucosamine, maltose, gluconate, caprate, adipate, malate, or phenylacetate. Lipase, keratinase, and valine aminopeptidase are produced. Esterase, leucine aminopeptidase, cystine aminopeptidase, trypsin, chymotrypsin, acid phosphatase, β-galactosidase, α-glucosidase, β-glucosidase, and α-mannosidase are not produced. Negative for the Voges–Proskauer reaction and H_2S production. Negative for decomposition of esculin and Tween 80. Hydrolyzes urea, arginine, starch, and casein. Other reactions are listed in Table 135 and above. In addition to polar lipids described for the genus an unidentified phosphoglycolipid is present.

DNA G+C content (mol%): 71 (T_m)

Type strain: PPLB, CECT 3379, JCM 14283, LMG 22921.

Sequence accession no. (16S rRNA gene): AY944176.

Genus XIV. **Terracoccus** Prauser, Schumann, Rainey, Kroppenstedt and Stackebrandt 1997, 1222[VP]

Peter Schumann

Ter.ra.coc′cus. L. fem. n. *terra* soil; Gr. masc. n. *kokkos* berry; N.L. masc. n. *Terracoccus* coccus isolated from soil.

Spherical to slightly ellipsoidal cells existing singly, in pairs, in tetrads, in irregular small clusters, or in more or less regular sarcinoid packets which may form large irregular clusters. Gram-stain-positive. Not acid-fast. Nonmotile. Nonsporeforming. Strictly aerobic. Chemoorganotrophic. Oxidase-negative. Catalase-positive. The **LL-diaminopimelic acid**-containing **peptidoglycan** of group **A3γ** has **three glycine residues as an interpeptide bridge** and **a fourth glycine residue bound to the α-carboxyl group of D-glutamic acid** in position 2 of the peptide subunit. The major **menaquinone** is **MK-8(H_4)**. The **fatty acid profile** represents the **iso, anteiso type** with predominately $C_{15:0}$ iso followed by $C_{15:0}$ anteiso. Minor straight-chain fatty acids occur. The **polar lipids** are **phosphatidylethanolamine, phosphatidylinositol**, **phosphatidylglycerol, and diphosphatidylglycerol**. Mycolic acids are absent. Phylogenetically, this genus is affiliated to the family *Intrasporangiaceae*, order *Micrococcales.*

DNA G+C content (mol%): 73.

Type species: **Terracoccus luteus** Prauser, Schumann, Rainey, Kroppenstedt and Stackebrandt 1997, 1223^{VP}.

Further descriptive information

The genus *Terracoccus* belongs to the family *Intrasporangiaceae* (Stackebrandt et al., 1997) as revealed by the occurrence of signature nucleotides defining this family (Stackebrandt and Schumann, 2000) except those at base pair positions 1134:1140, at which strain IMET 7848^T has an A–U rather than a C–G pair. At signature nucleotide positions which are variable for members of the family *Intrasporangiaceae*, *Terracoccus luteus* has a U–A pair (586:55), C (223), and a G–C pair (615:625). Initially, the family *Intrasporangiaceae* (Stackebrandt et al., 1997) was established to harbor only the type genus *Intrasporangium* (Kalakoutskii et al., 1967), the genus *Terrabacter* (Collins et al., 1989), and the peripherally related genus *Sanguibacter* (Fernández-Garayzábal et al., 1995a). The genus *Terracoccus* was described as the fourth member of the family *Intrasporangiaceae* (Prauser et al., 1997). As a consequence of the rapid taxonomic developments within the phylogenetic radiation of the genus *Terracoccus*, 15 genera are now included in the family *Intrasporangiaceae*. Therefore, the set of family-specific 16S rRNA gene signature nucleotides has been modified, and the family *Intrasporangiaceae* has been redefined recently under inclusion of phenotypic characteristics (see the family *Intrasporangiaceae*, above). A search by using the EzTaxon server (Chun et al., 2007) revealed the following pair-wise 16S rRNA gene similarity values for the closest relatives of *Terracoccus* that share the membership in the family *Intrasporangiaceae*: *Terrabacter tumescens* DSM 20308^T (98.1%) (Collins et al., 1989), *Intrasporangium calvum* DSM 43043^T (97.7%) (Kalakoutskii et al., 1967), *Terrabacter aerolatus* 5516J-36^T (97.57%) (Weon et al., 2007b), *Terrabacter terrae* LMG 22921^T (97.5%) (Montero-Barrientos et al., 2005), and *Humihabitans oryzae* KV-657^T (96.8%) (Kageyama et al., 2007a). The phylogenetic clustering of these genera (see Figure 161) is in agreement with the detection of a peptidoglycan structure which is unique among bacteria for all strains of the genera *Terracoccus* (Prauser et al., 1997), *Terrabacter* (Montero-Barrientos et al., 2005; Schleifer and Kandler, 1972; Weon et al., 2007b), and *Intrasporangium* (Schumann et al., 1997). The diamino acid at position 3 of the peptide subunit is LL-diaminopimelic acid (LL-A_2pm), the interpeptide bridge consists of three glycine residues, and a fourth glycine residue is bound to the α-carboxyl group of D-glutamic acid at position 2 of peptide subunit (variation A41.2 of peptidoglycan type A3γ according to http://www.peptidoglycan-types.info). Unfortunately, no information on this significant feature is available for the phylogenetic relative *Humihabitans oryzae* (Kageyama et al., 2007a).

The cells of *Terracoccus luteus* are invariably coccoid. Colonies were yellow with slight tendency to orange and appeared after 24–48 h under optimal conditions. The type strain of *Terracoccus luteus* DSM 44267^T gives rise to two stable colony forms on all applied agar media: (1) rough, irregularly raised and lobed (DSM 44274), and (2) smooth, convex, and circular (DSM 44275). Cells of the two colony forms cannot be differentiated by using 16S rRNA gene sequence comparison, DNA–DNA hybridization, analysis of cellular fatty acids, and RiboPrinting (P. Schumann, unpublished data), suggesting that *Terracoccus luteus* DSM 44267^T can develop rough as well as smooth colonies (Prauser et al., 1997).

Strain DSM 44267^T grows well on organic media such as R medium (Yamada and Komagata, 1972), medium 79m (Schumann et al., 1997), and tryptone soya broth (Oxoid CM129) medium, on agar media as well as in liquid shaken cultures. The addition of vitamins did not influence the growth. Growth on these media was optimal at 28°C and pH 6.0–7.2 but was sparse at pH 4.5 and 9.5. Growth was less rapid at 20°C, very poor at 15 and 37°C, and no growth occurred at 10 and at 45°C.

Cells grew only at the surface of stab cultures, and no growth was detectable on agar slant cultures covered with paraffin oil, indicating that *Terracoccus luteus* DSM 44267^T is strictly aerobic.

The type strain was not susceptible to any of eleven phages active against LL-A_2pm-containing actinomycetes according to the study of Prauser et al. (1997).

Strain DSM 44267^T originated from soil sampled from a dug pond. Information provided with sequences deposited in EMBL point also to the occurrence of *Terracoccus* strains in the phyllosphere (AB242812) and rhizosphere (AY143777). *Terracoccus luteus* is considered nonpathogenic.

Enrichment and isolation procedures

Strain DSM 44267^T was isolated from soil at the water-soil interface of the bank of a duck pond by the procedure described by Prauser et al. (1997). A diluted soil suspension in phosphate buffer was mixed with solubilized agar medium 79m modified by reduction of the agar content to 0.6% (w/v) at 48°C. This mixture was subsequently poured on agar medium 79m containing 1.5% (w/v) agar in Petri dishes and incubated at 28°C for 4–6 d until colonies became visible for isolation under a binocular microscope of low magnification.

Maintenance procedures

Serial transfers at 4-week intervals followed by maintenance at 4°C and storage of cells as 20% (w/v) glycerol suspensions at −20°C and at −80°C were suitable provisions for preservation. Long-term preservation methods include freeze drying in skim milk and maintenance in liquid nitrogen at −196°C.

Procedures for testing special characters

Since the peptidoglycan type A3γ, variation A41.2, is an extraordinary feature of members of the genera *Terracoccus*, *Terrabacter*, and *Intrasporangium*, its elucidation is described in the following.

The peptidoglycan was isolated and purified by disintegration of cells by shaking with glass beads and subsequent trypsine digestion as described by Schleifer and Kandler (1972) and Schleifer (1985). The peptidoglycan structure was determined by analyzing two hydrolysates of purified cell walls according to Schleifer (1985). The first hydrolysis was carried out with 4N HCl at 100°C for 16 h and resulted in amino acids. The second hydrolysate obtained under milder conditions (4 N HCl, 100°C, 45 min), in addition, contained dipeptides. The amino acids and peptides were separated and identified by two-dimensional ascending TLC on cellulose plates with the solvent systems of Schleifer and Kandler (1972). The isomer of A_2pm was determined by ascending chromatography on cellulose plates and comparison with authentic standards according to Rhuland et al. (1955). The structural variation A41.2 of peptidoglycan type A3γ was concluded from the presence of the amino acids LL-A_2pm, alanine (Ala), glycine (Gly), and glutamic acid (Glu)

as well as of the characteristic peptides L-Ala→D-Glu, Gly→D-Glu, LL-A_2pm→D-Ala, Gly→LL-A_2pm, and Gly→Gly. The structure was confirmed by the molar ratio of the amino acids of approximately 1:1:4:2 for LL-A_2pm:Glu:Gly:Ala, determined by gas chromatography as described by MacKenzie (1987).

Differentiation of the genus *Terracoccus* from other genera

The genus *Terracoccus* is differentiated from all members of the family *Intrasporangiaceae* (except its closest phylogenetic neighbors *Intrasporangium* and *Terrabacter*) by its peptidoglycan type A3γ, variation A41.2 (Table 125, in the family *Intrasporangiaceae*, above). *Arsenicicoccus bolidensis* is only distantly related to *Terracoccus luteus* (94.9%) and its peptidoglycan based on LL-A_2pm contains only a single glycine residue in the interpeptide bridge (Collins et al., 2004). *Terracoccus* differs in morphology from representatives of its most closely related genera *Intrasporangium*, *Terrabacter*, and *Humihabitans*. *Terracoccus* and *Terrabacter* contain menaquinone MK-8(H_4), which is found in all representatives of the family *Intrasporangiaceae* except for the genus *Intrasporangium* (MK-8) (Table 125). The DNA G+C value of *Terracoccus luteus* exceeds that of *Intrasporangium calvum* by 5 mol%. *Terracoccus* and *Terrabacter* show phosphatidylethanolamine as characteristic phospholipid which is absent from *Intrasporangium*. *Terracoccus luteus* differs from *Terrabacter* in containing phosphatidylglycerol and is not susceptible to the *Terrabacter tumescens* phages TB1 (DSM 49116) and Tb2 (DSM 49158). *Terracoccus luteus* contains $C_{15:0}$ iso, $C_{15:0}$ anteiso, and $C_{16:0}$ as major components of the cellular fatty acid profile, differing significantly from that of its closest relatives *Terrabacter tumescens* and *Intrasporangium calvum* by lower amounts of $C_{16:0}$ iso and higher amounts of $C_{15:0}$ anteiso (Prauser et al., 1997; Schumann et al., 1997).

Strain DSM 44267^T shows DNA–DNA similarity values of only 38.8% and 36.5% to the type strains of *Intrasporangium calvum* and *Terrabacter tumescens*, respectively (Prauser et al., 1997). These low values suggest that the level at which execution of DNA–DNA hybridization for organisms of the peptidoglycan type A3γ, variation A41.2, is indicated lies above a 16S rRNA gene sequence similarity threshold of 98% (see also: Stackebrandt and Ebers, 2006).

List of species of the genus *Terracoccus*

1. **Terracoccus luteus** Prauser, Schumann, Rainey, Kroppenstedt and Stackebrandt 1997, 1223^{VP}

lu′te.us. L. masc. adj. *luteus* yellow.

In addition to the properties given in the genus description and in Table 125, this species has the following characteristics. The cells are 0.7–1.3 µm in diameter. The colonies, 0.05–2.0 mm in diameter, may be rough or smooth. Rough colonies are lobed and irregularly raised; smooth colonies are circular and convex. The cells of rough colonies are mostly arranged in more or less regular sarcinoid packets which may form large irregular clusters. The cells of smooth colonies occur singly, in pairs, in tetrads, or in small irregular clusters. Urease and H_2S are produced. Nitrate is not reduced to nitrite. Formation of acids from sugars and alcohols is not observed. Only a few of the tested compounds are utilized for growth, i.e. D-arabitol, gluconate, *N*-acetyl-D-glucosamine, *myo*-inositol, L-proline, succinate, sucrose, and D-turanose. Starch, casein, gelatin, esculin, and DNA are hydrolyzed; Tween 80 is not hydrolyzed. Sodium acetate, formate, aconitate, benzoate, citrate, hippurate, disodium succinate, and potassium tartrate are not utilized. Xanthine, hypoxanthine, adenine, and DL-tyrosine are not decomposed.

Sequence accession no. (16S rRNA gene): Y11928.

Genus XV. **Tetrasphaera** Maszenan, Seviour, Patel, Schumann, Burghardt, Tokiwa and Stratton 2000, 601^{VP} emend. Ishikawa and Yokata 2006, 1371

Robert J. Seviour and Abdul M. Maszenan

Te.tra.spha.e′ra. Gr.n. *tetra* four; L. fem. n. *sphaera* sphere; N.L. fem. n. *Tetrasphaera* four spherical bacterial cells.

Cells show a highly variable morphology with some growing as highly irregularly septate filaments, cocci in tetrads, often clustered or in pairs, as single cells, or irregular elongated clusters of rods, or showing an ability to change from rods to cocci, from filamentous forms to single often swollen cocci, or to and from V or T shaped arrangements. Gram-stain-positive, but can stain Gram variably. Member of the family *Intrasporangiacaeae*, order ***Micrococcales***. Cells are nonmotile, and do not form endospores. Aerobic and chemoheterotrophic, often growing very slowly on a limited range of substrates. All strains may store polyphosphate

granules; poly-β-hydroxyalkanoates are only detected in some strains. Growth occurs at 10–35°C, but not in all strains, and at pH 6.0–9.0. Catalase-positive, and usually oxidase-positive, but indole-negative. Where tested, all strains can grow on acetate and glucose, and, in most cases, on propionate. **Cell-wall peptidoglycan contains *meso*-diaminopimelic acid, characterizing the A1γ murein, or 3-hydroxy-*meso*-diaminopimelic acid (A4γ) *for Tetrasphaera duodecadis* (formerly known as *Arthrobacter duodecadis*)**. **Menaquinone composition varies, but, in most strains, the major menaquinone is MK-8**(H_4). Polar lipid composition of isolates varies too, but diphosphatidylglycerol, phosphatidylinositol, and phosphatidylglycerol are generally present. The major fatty acids in all isolates except *Tetrasphaera elongata* Lp2^T are the branched fatty acids ($C_{16:0}$ iso and $C_{17:0}$ anteiso), although 10-methyl branched fatty acids may be present.

Isolated from activated sludge and arable soil.

DNA G+C content (mol%): 68–73.

Type species: **Tetrasphaera japonica** Maszenan, Seviour, Patel, Schumann, Burghardt, Tokiwa and Stratton 2000, 601^{VP}.

Further descriptive information

It is now clear that members of the genus *Tetrasphaera* are very diverse morphologically, and not all grow as cocci in tetrads. Sequence analyses of 16S rRNA and *rpoc1* genes from several isolates of the filamentous bacterium "*Candidatus* Nostocoida limicola" (Blackall et al., 2000) obtained from activated sludge plants suggested that these were probably members of the genus *Tetrasphaera* (Figure 170) despite showing marked differences in their cell morphologies from those originally described as typifying this genus (Maszenan et al., 2000). This view was substantiated after analyses of their peptidoglycan, fatty acid compositions, polar lipid and menaquinone compositions (Table 136), DNA–DNA hybridization values, and 16S–23S intergenic spacer region fingerprints. Thus, the "*Candidatus* Nostocoida

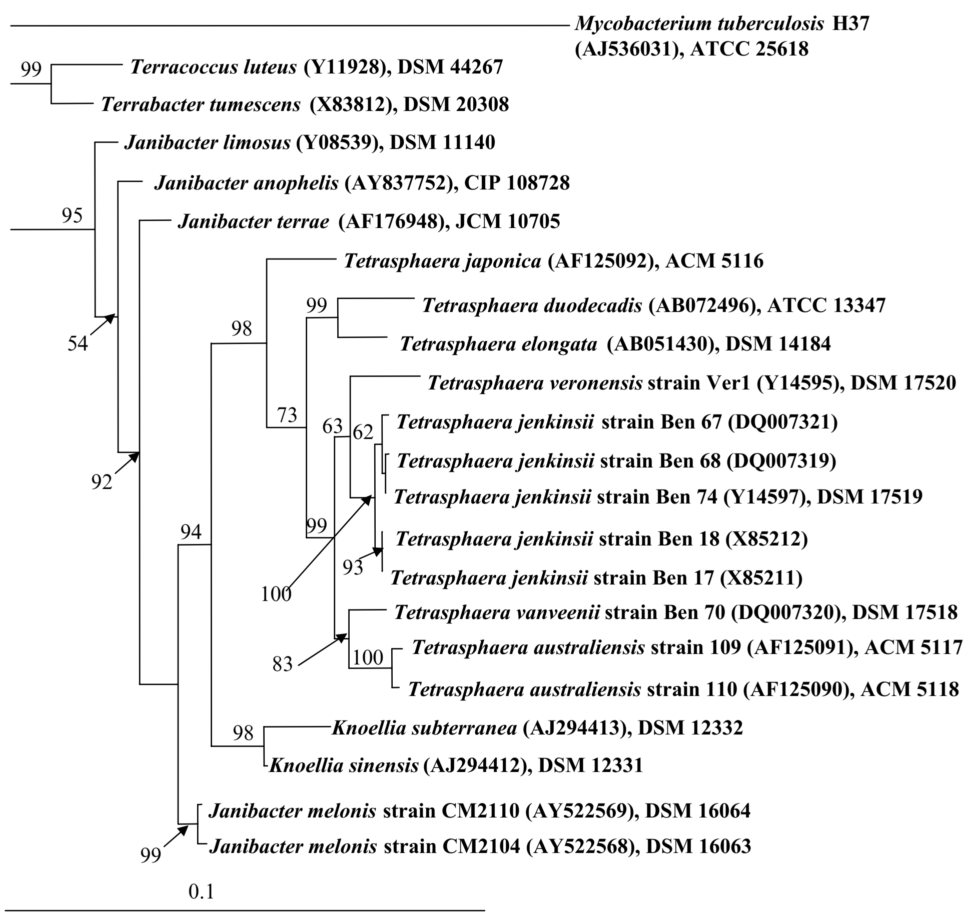

FIGURE 170. Phylogenetic analysis of 16S rRNA gene sequences of currently described members of the genus *Tetrasphaera* species, and their nearest relatives based on almost complete sequences, using maximum-likelihood. Bootstrap values based on 1000 replicates. Scale bar = 0.1 nucleotide substitutions per site.

limicola" isolates currently in culture have been allocated to three new *Tetrasphaera* species (McKenzíe et al., 2006).

Several fluorescently labeled 16S rRNA targeted FISH probes have been designed and applied for the *in situ* identification of members of the filament morphotype in wastewater treatment plants, but not for each of the individual species (Liu and Seviour, 2001). This filament was originally isolated and named by van Veen (1973), and has been held responsible in several countries for episodes of bulking and possibly foaming in activated sludge systems. In pure culture, the *Tetrasphaera* and "*Candidatus* Nostocoida limicola" isolates described by Maszenan et al. (2000), Blackall et al. (2000), and Hanada et al. (2002) all accumulated polyphosphate granules. Later, Liu et al. (2001) showed that *Tetrasphaera*-related organisms identified by FISH and filamentous bacteria morphologically closely resembling "*Candidatus* Nostocoida limicola" also contained polyphosphate granules in a wastewater treatment plant designed to remove phosphorus (P), and thus were thought to behave as polyphosphate-accumulating organisms (PAO) there (Eschenhagen et al., 2003). All characterized isolates of *Tetrasphaera* contain polyphosphate (Hanada et al., 2002; McKenzíe et al., 2006) except *Tetrasphaera duodecadis* (Ishikawa and Yokota, 2006), which was isolated from arable soil (Lochhead, 1958). *Tetrasphaera elongata* (Hanada et al., 2002) was isolated from a laboratory scale plant designed to remove polyphosphate. Kong et al. (2005) confirmed that *Tetrasphaera*-related organisms were important PAO in activated sludge, but with a phenotype different from that expected of a PAO (Seviour et al., 2003), since these cells identified by FISH probing could not accumulate acetate anaerobically.

Furthermore, and agreeing with the pure culture data of Maszenan et al. (2000) and *in situ* observations of Liu et al. (2001), these strains did not accumulate polyhydroxyalkanoates, although all the characterized "*Candidatus* Nostocoida limicola" isolates do (Blackall et al., 2000; McKenzíe et al., 2006). Instead, the PAO *Tetrasphaera* species appeared to preferentially assimilate amino acids under anaerobic conditions (Kong et al., 2005). Kong et al. (2005) could not culture their *Tetrasphaera* related PAO, but, on the basis of the 16S rRNA gene sequences retrieved in their clone library study, they appear to differ from the *Tetrasphaera* species so far characterized in pure culture. Those *Tetrasphaera* described by Kong et al. (2005) did not fluoresce with the FISH probe of Kong et al. (2002) designed against the *Tetrasphaera* strains described by Maszenan et al. (2000). This suggests further phylogenetic diversity exists among members of this genus. Ishikawa and Yokata (2006) later reclassified *Arthrobacter duodecadis* Lochhead (1958) as another species, *Tetrasphaera duodecadis*, using both genotypic and chemotaxonomic characters.

In pure culture, cells of members of this genus demonstrate considerable morphological variations which are often medium dependent. This is especially true of the "*Candidatus* Nostocoida limicola" members (Blackall et al., 2000; McKenzíe et al., 2006). Unusual filamentous growth is formed on GS medium (Williams and Unz, 1985), where swollen, flattened, and irregularly septate cells are present. On R2A medium (Reasoner and Geldreich, 1985), the same strain grows as swollen and irregular cocci with occasional budding, often in short chains or clusters (Figure 171). *Tetrasphaera duodecadis* can switch its morphology between rods and coccoid forms (Ishikawa and Yokota, 2006).

Enrichment and isolation procedures

Strain T1-X7 was first isolated by Kataoka et al. (1996), after a prolonged enrichment of activated sludge under starvation conditions at very high biomass levels in a 0.1% peptone/0.1% glucose medium, and repeatedly fed batch culture (fill and draw conditions) with very low feed rate of the carbon source. After 6 months, the enriched cultures were streaked out onto a cell extract/agar medium. Colonies that grew were isolated and cultured. The strain T1-X7 obtained in this way grew as cocci in pairs and tetrads, and on the basis of a few phenotypic characters, was tentatively identified as a *Micrococcus*. It was shown subsequently to be *Tetrasphaera japonica*^{T} (Maszenan et al., 2000). Strain Lp2, *Tetrasphaera elongata*^{T} was isolated from the community of an anaerobic:aerobic sequencing batch reactor designed to remove PAO microbiologically, onto GM1 medium (Hanada et al., 2002). *Tetrasphaera duodecadis* (previously known as *Arthrobacter duodecadis*) was isolated from soil on medium containing vitamin B_{12} as an essential growth factor (Lochhead, 1958).

All other cultured strains including Ben 17, Ben18, Ben 67, Ben 68, and Ben 74^{T} (members of *Tetrasphaera jenkinsii*; McKenzíe et al., 2006), Ben 70^{T} (*Tetrasphaera vanveenii*; McKenzíe et al., 2006), Ver 1^{T} (*Tetrasphaera veronensis*; McKenzíe et al. (2006), and both Ben109^{T} and Ben 110 (both *Tetrasphaera australiensis*; Maszenan et al., 2000), were obtained after micromanipulation (Skerman, 1968) from activated sludge biomass onto either GS or R2A (Reasoner and Geldreich, 1985) medium, where they grew, but very slowly (Blackall et al., 2000; Maszenan et al., 2000; McKenzíe et al., 2006). Once in culture, these isolates could then grow on a range of other media, but always very slowly.

Differentiation of the genus *Tetrasphaera* from other genera

Members of the genus *Tetrasphaera* are most closely phylogenetically related to those of the genera *Janibacter* (Martin et al., 1997) and *Knoellia* (Groth et al., 2002) (Table 137). They share many chemotaxonomic characters with them, including cell-wall type (A1γ), although *Tetrasphaera duodecadis* (Ishikawa and Yokota, 2006) is distinctive in possessing an A4γ peptidoglycan. Groth et al. (2002) suggested that the type strain of *Tetrasphaera*, *Tetrasphaera japonica* T1-X7^{T}, differed from the known *Knoellia* species in possessing phosphatidylethanolamine. While *Tetrasphaera australiensis* (strain BEN110) and *Tetrasphaera elongata* strain Lp2^{T} contain this phospholipid (Hanada et al., 2002; Maszenan et al., 2000), neither *Tetrasphaera jenkinsii*, *Tetrasphaera vanveenii*, or *Tetrasphaera veronensis* (McKenzíe et al., 2006) do so. It is not clear whether it is present in *Tetrasphaera duodecadis* but has not been detected in any *Janibacter* species.

Fatty acid profiles can help distinguish *Tetrasphaera* species from *Knoellia* species and *Janibacter* species, as shown in Table 136. For example, although $C_{17:0}$ iso is a major fatty acid in *Knoellia* species (Groth et al., 2002), it is often absent or only a minor component in *Tetrasphaera* species (Hanada et al., 2002; Ishikawa and Yokota, 2006; Maszenan et al., 2000; McKenzíe et al., 2006), which in most cases produce $C_{16:0}$ iso as their major fatty acid. *Tetrasphaera elongata* Lp2^{T} has a distinctive profile, with $C_{15:0}$ anteiso as its major fatty acid (Hanada et al., 2002), as does *Tetrasphaera jenkinsii* (McKenzíe et al., 2006) with $C_{17:0}$ anteiso. With *Janibacter* species, $C_{17:1}$ ω8*c* and $C_{18:1}$ ω9*c* are major fatty

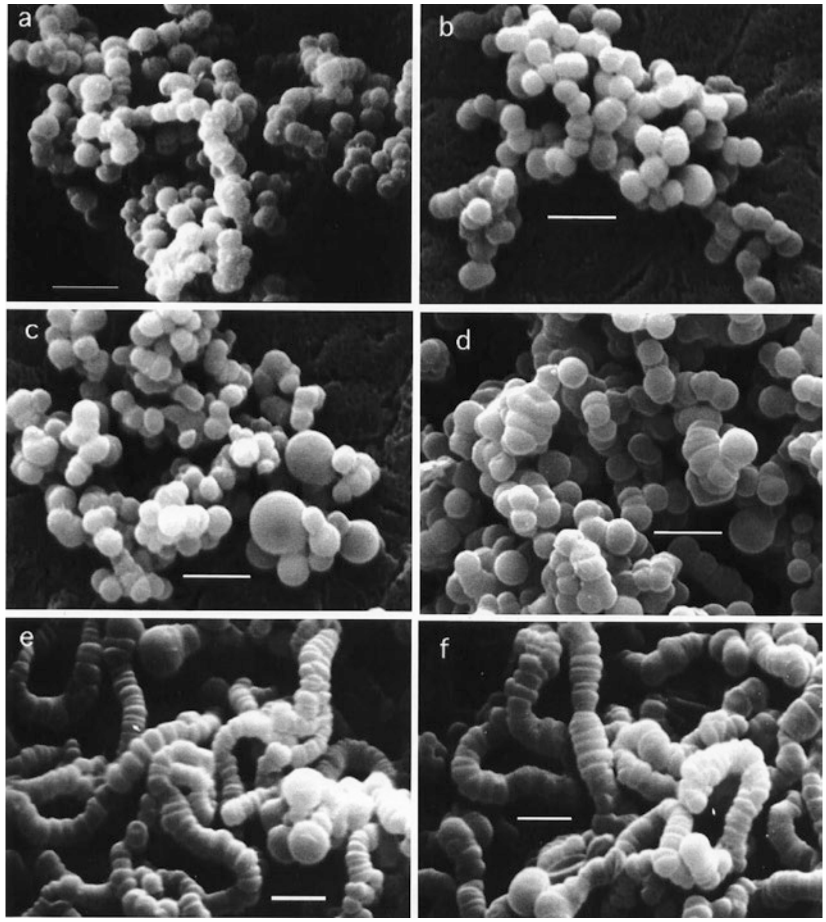

FIGURE 171. SEM of *Tetrasphaera jenkinsii* (Ben 17, Ben 67, Ben 68, and Ben74) and *Tetrasphaera veronensis* (Ver1^{T}) strains showing medium-dependent morphological variations. (a and b) Ben 17 and Ben 70, respectively, grown on R2A, where both appear as regular cocci in clusters and short chains. In Ben 70 (c) and Ben 74 (d), these cocci can appear inflated and, in some cases, appear to bud. (e and f) Ben 67 and Ben 68, respectively, showing typical features of all these strains when grown on GS agar, i.e. irregular flattened discoid cells in chains with occasional terminal swollen coccoid cells (McKenzíe et al., 2006).

acids, making their profiles quite different from those detected in *Tetrasphaera* species (Kämpfer et al., 2006). However, their fatty acid profiles vary with growth conditions (Ishikawa and Yokota, 2006; Kämpfer et al., 2006; Martin et al., 1997; McKenzíe et al., 2006; Yoon et al., 2004; Yoon et al., 2000), hence their taxonomic value should be interpreted cautiously.

Taxonomic comments

Individual members of the genus *Tetrasphaera* are morphologically very variable and differ in many phenotypic characteristics. 16S rRNA gene sequence analyses, while clearly placing the genus *Tetrasphaera* in the family *Intrasporangiaceae* in the order *Micrococcales*, also suggest that seven species of *Tetrasphaera* can currently be recognized as falling within the radiation of this genus (Figure 170). Thus, the 16S rRNA gene sequences of strains Ben 17, Ben 18, Ben 67, Ben 68, and Ben 74 (members of the genus *Tetrasphaera jenkinsii*) are more than 99.5% similar to each other, while those of Ben 109 and Ben 110 (*Tetrasphaera australiensis*) are 99.7% similar (Maszenan et al., 2000; McKenzíe et al., 2006). On the other hand, strains T1-X7 (*Tetrasphaera japonica*), Lp2 (*Tetrasphaera elongata*), Ver1 (*Tetrasphaera veronensis*), Ben 70 (*Tetrasphaera vanveenii*), and *Tetrasphaera duodecadis* are less than 98.5% similar to each other and to all of the other *Tetrasphaera* strains. Available DNA–DNA hybridization and certain chemotaxonomic data (Table 136) support this speciation (Hanada et al., 2002; Ishikawa and Yokota, 2006; Maszenan et al., 2000; McKenzíe et al., 2006).

Differentiation of the species of the genus *Tetrasphaera*

The individual *Tetrasphaera* species are separated mainly on the basis of their 16S rRNA gene sequences, chemotaxonomic attributes, and available DNA–DNA hybridization values, since, where examined, intraspecies differences are common in many of the biochemical characters used in their descriptions. This variation might reflect their very slow growth rates and overall low levels of metabolic activity. Furthermore, some species contain only a single isolate. The chemotaxonomic features which help differentiate the seven species of *Tetrasphaera* from each other and from members of their most closely related genera *Janibacter* and *Knoellia* are given in Table 136.

TABLE 137. Characteristics of *Tetrasphaera* and the genera *Janibacter* and *Knoellia*[a]

Characteristics	*Tetrasphaera*	*Janibacter*	*Knoellia*
Morphology	Varies with growth conditions; rods or cocci, sometimes swollen in pairs, tetrads, or irregular aggregates, showing V or T arrangements, and in some, flattened irregular discoid cells arranged as filaments	Coccoid to rod-shaped cells appearing in short chains or aggregates	Coccoid cells formed in stationary phase but reverted to irregular rod-shaped cells in fresh medium, appearing mycelial like, with outgrowths
Motility	Nonmotile	Nonmotile	Nonmotile
Endospores	Absent	Absent	Absent
Habitat	Activated sludge or soil	Sewage sludge, melon, mosquito gut, soil	Soil in a cave
DNA G+C content (mol%)	68–73	70–73	68–69
Cell-wall type	A1γ or A4γ	A1γ	A1γ
Catalase	+	+	+
Oxidase	+/−	−, weak for *J. terrae*	−
Nitrate reduction to nitrite	+/− (+ for *T. elongata*)	+ *J. terrae*	+
Polyphosphate granules	+	−	−
Signature nucleotides:			
952/1229	T–A	C–G	na
1133/1141	G–C	A–T	na

[a]Symbols: +, positive; −, negative; na, not available.

List of species of the genus *Tetrasphaera*

1. **Tetrasphaera japonica** Maszenan, Seviour, Patel, Schumann, Burghardt, Tokiwa and Stratton 2000, 601[VP]

ja.po′ni.ca. N.L. fem. adj. *japonica* pertaining to Japan, the source of the type strain.

Grows very slowly as cocci in clusters of tetrads. Weakly catalase-positive and oxidase-positive. Cell-wall type is A1γ. The major respiratory menaquinone is MK-8(H_4), although MK-7(H_4) and MK-6(H_4) are also produced, and it contains an unknown amino phospholipid. Its major fatty acids are $C_{16:0}$ iso and $C_{17:0}$ anteiso, and it produces tuberculostearic acid. It utilizes pyruvate, but failure to detect utilization of other substrates may be an artifact, reflecting its very low level of metabolic activity.

DNA G+C content (mol%): 71 (T_m).

Type strain: T1-X7, ACM 5116, DSM 13192, JCM 21381, NBRC 103088.

Sequence accession no. (16S rRNA gene): AF125092.

2. **Tetrasphaera australiensis** Maszenan, Seviour, Patel, Schumann, Burghardt, Tokiwa and Stratton 2000, 601[VP]

aus.tra.li.en′sis. N.L. fem. adj. *australiensis* pertaining to Australia, the source of the type strain.

Grows very slowly as cocci in clusters of tetrads. Cell-wall type is A1γ. The major menaquinone is MK-8(H_4), and MK-8(H_2) is present in smaller amounts. One strain, Ben 110[T], contains large amounts of MK-6(H_4), while Ben 109[T] has trace amounts of MK-8. Can utilize adenosine-5′-monophosphate, 3-methylglucose, sucrose, D-trehalose, Tween 40, Tween 80, and D-xylose. Major fatty acids are $C_{16:0}$ iso and $C_{17:0}$ anteiso.

DNA G+C content: 68–70 (T_m).

Type strain: Ben 109, ACM 5117, DSM 12890, JCM 21391, NBRC 103087.

Sequence accession no. (16S rRNA gene): 125091.

3. **Tetrasphaera duodecadis** (Lochhead 1958) Ishikawa and Yokata 2006, 1371 (*Arthrobacter duodecadis* Lochhead 1958, 170)

du.o.de′ca.dis. L. n. *duodecas -adis* the number twelve; L. gen n. *duodecadis* of twelve, referring to the requirement of the organism for vitamin B_{12}.

Cells are Gram-stain-variable and can change morphology from rods to coccoid cells. Require vitamin B_{12} and thiamine for growth. Grows at 10°C but not at 37°C. Negative for aminopeptidase, H_2S, acetoin, and indole production, but positive for catalase and nitrate reduction, β-galactosidase production, and for the oxidative and fermentative (O/F) test. Assimilates glucose, fructose, mannitol, and sucrose. Acetamide, esculin, and gelatin are hydrolyzed, but arginine or urea are not. Cell-wall peptidoglycan is type A4γ, where 3-hydroxy *meso*-diaminopimelic acid is present. The menaquinone is MK-8(H_4). Major fatty acids are $C_{17:0}$ 10 methyl, $C_{15:0}$ iso, and $C_{16:0}$ iso, Tuberculostearic acid and $C_{16:0}$ 10 methyl are also found.

DNA G+C content(mol%): 73 (HPLC).

Type strain: ATCC 13347, CIP 102696, IAM 14868, JCM 11564, LMG 17308, NBRC 12959, NCIMB 9222, VKM Ac-1108.

Sequence accession no. (16S rRNA gene): AB072496.

4. **Tetrasphaera elongata** Hanada, Liu, Shintani, Kamagata and Nakamura 2002, 886[VP]

e.lon′ga.ta. L. fem. part. adj. *elongata* elongated, pertaining to the formation of elongated clumps.

Grows as oval to short rods, sometimes forming elongated linear clumps. Can reduce nitrate to nitrite but not to dinitrogen. Acetate, alanine, arginine, cellobiose, glucose, lactose, maltose, mannose, sucrose, melibiose, trehalose, xylose, dulcitol, inositol, mannitol, and pyruvate are oxidized

aerobically; starch and glycogen are hydrolyzed. Cell-wall type is A1γ. The major menaquinone is MK-8(H_4), and major fatty acids are $C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{14:0}$ iso, and $C_{16:0.}$

DNA G+C content (mol%): 70 (T_m).

Type strain: Lp2, DSM 14184, JCM 11141, NBRC 103079.

Sequence accession no. (16S rRNA gene): AB030911.

5. **Tetrasphaera jenkinsii** McKenzie, Seviour, Schumann, Maszenan, Liu, Webb, Monis, Saint, Steiner and Seviour 2006, 2288[VP]

jen.kin′si. i. N.L. gen. masc. n. *jenkinsii* of Jenkins, referring to David Jenkins, a contemporary American environmental engineer who has made a considerable contribution to our understanding of the filamentous bacteria causing bulking and foaming in activated sludge processes.

The phenotypic features of this species are those given by Blackall et al. (2000) for "*Candidatus* Nostocoida limicola" strains Ben 17, Ben 18, Ben 67, and Ben 68, supplemented by results for Ben 74[T], as follows: morphology varies from long irregular filaments on GS medium to swollen clustered cells on R2A medium. Cells are often Gram-stain-variable. Nonfermentative. No anaerobic growth or with nitrite as sole electron acceptor, but can reduce nitrate to nitrite. Utilizes acetate, fructose, glucose, glycerol, lactose, pyruvate, propionate, mannose, and Tween 80, but not citrate, ethanol, lactate, oleate, or succinate, as sole carbon sources, and nitrate, nitrite, peptone and urea as N sources. Catalase- and oxidase-positive. All strains stained positively for polyphosphate and on some media for poly-β-hydroxyalkanoates. Cell-wall type is A1γ. Major menaquinone is MK-8(H_4), and MK-6(H_4), MK-8, and MK-8(H_2) occur in minor amounts. The polar lipid pattern contains phosphatidylinositol, phosphatidylglycerol, and an unidentified aminophospholipid. Major cellular fatty acids are $C_{17:0}$ anteiso, $C_{16:0}$ iso, $C_{16:1}$ iso, and $C_{15:0}$ iso.

DNA G+C content (mol%): not available.

Type strain: Ben 74, DSM 17519, JCM 15590, NCIMB 14128.

Sequence accession no. (16S rRNA gene): DQ007321.

6. **Tetrasphaera vanveenii** McKenzie, Seviour, Schumann, Maszenan, Liu, Webb, Monis, Saint, Steiner and Seviour 2006, 2288[VP]

van.vee′ni.i. N.L. gen. masc. n. *vanveenii* of van Veen, referring to a contemporary Dutch microbiologist, W.L. van Veen, who originally isolated this filamentous bacterium from activated sludge.

The morphological and phenotypic attributes of this species are the same as those described for *Tetrasphaera jenkinsii.* Cells stain positively for both poly-β hydroxy alkanoates and polyphosphate. Cell-wall type is A1γ. The major menaquinone is MK-8, with MK-8(H_2) and MK-8(H_4) produced in smaller amounts. The polar lipid pattern consists of phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, and an unidentified aminophospholipid. Major cellular fatty acids are $C_{16:0}$ iso and $C_{15:0}$ iso.

DNA G+C content (mol%): not available.

Type strain: Ben 70, DSM 17518, JCM 15591, NCIMB 14127.

Sequence accession no. (16S rRNA gene): DQ007320.

7. **Tetrasphaera veronensis** McKenzie, Seviour, Schumann, Maszenan, Liu, Webb, Monis, Saint, Steiner and Seviour 2006, 2288[VP]

ve.ro.nen′sis. L. fem. adj. *veronensis* of Verona, Italy, where the isolates originated.

The morphological and phenotypic features of this species are the same as those described for *Tetrasphaera jenkinsii*[T], except that sucrose can be used as a carbon source. Cell-wall type is A1γ. Isoprenoid quinones could not be detected in the type strain. The polar lipid pattern contains phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, and an unidentified phospholipid. Major cellular fatty acids are $C_{16:0}$ iso, $C_{16:1}$ iso, and $C_{15:0}$ iso.

DNA G+C content (mol%): not available.

Type strain: Ver 1, DSM 17520, JCM 15592, NCIMB 14129.

Sequence accession no. (16S rRNA gene): Y14595.

Family X. **Jonesiaceae** Stackebrandt, Rainey and Ward-Rainey 1997, 485[VP] emend. Zhi, Li and Stackebrandt 2009, 598

Erko Stackebrandt

Jone.si.a′ce.ae. N.L. fem. n. *Jonesia* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Jonesiaceae* the *Jonesia* family.

Gram-stain-positive, branched rods. Mycelium absent. Chemotaxonomic and metabolic properties as for the genus *Jonesia*.

The pattern of 16S rRNA gene signatures consists of nucleotides at positions 120 (A), 131:231 (A–G), 196 (C), 342:347 (C–G), 444:490 (A–U), 580:761 (C–G), 602:636 (C–G), 670:736 (A–U), 822:878 (U–C), 823:877 (A–C), 826:874 (U–G), 827 (G), 843 (C), 950:1231 (U–A), 1047:1210 (G–C), 1109 (C), 1145 (G), 1309:1328 (G–C), 1361 (G), and 1383 (C) (Zhi et al., 2009). The set of signature nucleotides is defined on the basis of the two type strains, representing the family. It may need to be changed when more genera and species are added to *Jonesiaceae*.

DNA G+C content (mol%): 56–58.

Type genus: **Jonesia** Rocourt, Wehmeyer and Stackebrandt 1987, 268[VP].

Genus I. **Jonesia** Rocourt, Wehmeyer and Stackebrandt 1987, 268[VP]

Erko Stackebrandt

Jones′i.a. L. fem. n. *Jonesia* of Jones, honoring Dorothy Jones, a British microbiologist

Nonsporeforming rods (0.3 × 0.5 µm) showing branched Y- and club-like forms. Irregular, branching rods may occur. Gram-stain-positive, but many cells, especially in older cultures, are readily decolorized. Filamentous and coccoid cells may also occur in older cultures. Colonies on nutrient agar are 0.5–1.5 mm in diameter (24–48 h), convex, smooth, grayish, and translucent to opaque, becoming yellowish in 10–20 d. Catalase-positive; oxidase-negative. Cell wall contains peptidoglycan of the L-Lys–L-Ser–D-Glu type (A4α) and teichoic acid of the poly(ribitol phosphate) type (ribitol:galactose-amine:galactose, 1:0.2:0.1) (Only *Jonesia denitrificans* was investigated.) No lipoteichoic acid. Predominant fatty acids are $C_{15:0}$ ante and $C_{16:0}$; $C_{16:0}$ iso may occur. Polar lipids are phosphatidylglycerol and phosphatidylinositol; diphosphatidylglycerol, unknown phosphoglycolipids and small amounts of unidentified phospholipids may occur. No mycolic acids. Major isoprenoid type is MK-9. Members of the genus are phylogenetically remotely related to the genera *Dermabacter* and *Brachybacterium*.

DNA G+C content (mol%): 56–58.

Type species: **Jonesia denitrificans** (Prévot 1961) Rocourt, Wehmeyer and Stackebrandt 1987, 269[VP] (*Listeria denitrificans* Prévot 1961, 512.)

Further descriptive information

Jonesia (*Listeria*) *denitrificans* is serologically distinct from *Listeria* species and from *Erysipelothrix* (Welshimer and Meredith, 1971; Wilkinson and Jones, 1975). It is pathogenic to rats and mice when injected intraperitoneally but does not cause conjunctivitis when instilled into the eyes of rabbits and guinea pigs.

Enrichment and isolation procedures

Jonesia (*Listeria*) *denitrificans* was isolated from cooked ox blood (Sohier et al., 1948), but the natural habitat of the organism is not known. It grows well on tryptic soy broth agar (TSBA, Difco, containing 1.5% Difco agar).

Jonesia qinghaiensis (Schumann et al., 2004) was isolated from a mud sample of a soda lake (~pH 9.0) in the west of China. Isolation was done at 28°C by dilution plating on Bacto marine broth agar (MBA), pH 7.2.

Maintenance procedures

Strains may be preserved for some months by stab inoculation in nutrient agar (Tryptose Agar or other similar media) in screw-capped vials. These should be stored at room or, preferably, refrigerator temperature. Strains may be preserved long-term by lyophilization or in liquid nitrogen.

Differentiation from closely related taxa

The genus *Jonesia* is not closely related to any other genus of the suborder *Micrococccineae* (Rainey et al., 1995; Stackebrandt et al., 1997; Figure 172), which has been elevated to order *Micrococcales* in the present volume. Some diagnostic morphological and chemotaxonomic properties of *Jonesia denitrificans* and other taxa to which this species appears related today and has appeared to be related in the past are indicated in Table 138. The closest relatives are members of the family *Dermabacteraceae* Stackebrandt et al. 1997 embracing *Dermabacter* and *Brachybacterium* and, more distantly related, *Brevibacteriaceae* Breed 1953 emend. Stackebrandt et al. 1997, containing *Brevibacterium. Jonesia* species differ from those of *Dermabacter* and *Brachybacterium* in peptidoglycan composition, but they share fully unsaturated menaquinones and similar composition in fatty acids and polar lipids; these, however, are also frequently represented in other members of *Micrococcales*. A loose relationship between *Jonesia* (*Listeria*) *denitrificans* and *Brachybacterium faecium* was observed earlier in a numerical phenetic study (Jones, 1975).

Taxonomic comments

Originally placed into the genus *Listeria*, evidence accumulated on the basis of results from morphological, biochemical, serological, chemical, and nucleic acid studies that *Listeria denitrificans* is not a member of the genus *Listeria* (Chatelain and Second, 1976; Collins et al., 1983; Fiedler et al., 1984; Fiedler and Seger, 1983; Jones, 1975; Stuart and Welshime, 1973, 1974;

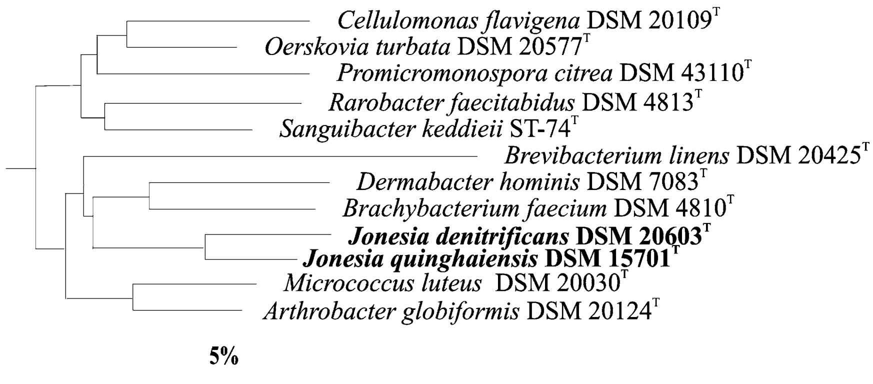

FIGURE 172. Neighbor-joining dendrogram of nearly complete 16S rRNA gene sequences displaying the phylogenetic relationship between *Jonesia* type strains and some representatives of members of the order *Micrococcales*. Numbers at nodes refer to bootstrap values (1000 resamplings). Scale bar = 5% nucleotide substitutions.

Welshimer and Meredith, 1971; Wilkinson and Jones, 1975; Wilkinson and Jones, 1977). In the pre-16S rRNA gene sequencing era, *Listeria denitrificans* was found more closely related to coryneform bacteria than to other members of the genus *Listeria*. Relatedness to *Oerskovia*, *Renibacterium*, and *Arthrobacter* was discussed but excluded on the basis of individual chemotaxonomic properties (see Seeliger and Jones, 1986). 16S rRNA oligonucleotide analysis then separated *Listeria denitrificans* CIP 55134^T from the other members of *Listeria*, leading to the description of *Jonesia denitrificans* (Rocourt et al., 1987), which was placed among the Gram-positive bacteria with a high DNA G+C mol%.

Major differences in the DNA G+C value (mol%), peptidoglycan structure, lipid pattern, isoprenoid quinone and the 16S rRNA oligonucleotides supported the taxonomic placement of *Jonesia denitrificans* within the class *Actinobacteria*. This conclusion was challenged on the basis of results of a comparative study of intracellular proteins (Finn and Rowe, 1996) of *Listeria* species and *Jonesia* (*Listeria*) *denitrificans*. However, the recent description of a second *Jonesia* species (Schumann et al., 2004) fully supports the membership of *Jonesia* within the class *Actinobacteria* (Stackebrandt et al., 1997) and outside the realm of authentic *Listeria* and related taxa.

The higher order relationship of the genus *Jonesia* has seen some changes over the past decade. Based on a rather restricted dataset of 16S rRNA gene sequences and emphasizing chemotaxonomic data, especially the peptidoglycan type, the genera *Cellulomonas*, *Oerskovia*, *Promicromonospora*, and *Jonesia* were included in a new family *Cellulomonadaceae* (Stackebrandt and Prauser, 1991). The distinct position of *Jonesia* within the new family was clearly stated as it was the only species that differed in the possession of teichoic acids, menaquinone type (MK-9), and a significantly lower base composition of DNA (56–58 mol% G+C) (properties also found in *Jonesia quinghaiensis*) from other members of the family [MK-9(H_4) and 70–76 mol% G+C, respectively]. A few years later, the sequence database of members of the order *Micrococcales* (Stackebrandt et al., 1997; Zhi et al., 2009) increased considerably, resulting in a phylogenetic picture that differs significantly from that in 1991. While *Cellulomonas* and *Oerskovia* are still seen as phylogenetic neighbors, the type species of *Promicromonospora* branches separately from, though closely to, the *Cellulomonas/ Oerskovia* lineage, but this branching is not supported by high statistical significance. The phylogenetic separation of *Jonesia* from these organisms is supported by chemotaxonomic evidence, and the new data finds *Jonesia* to be only remotely related to any member of the *Micrococcales*. *Brachybacterium*, *Dermabacter*, and *Brevibacterium* are the genera grouping most closely to *Jonesia*, but the low branching points are not statistically significant. As a consequence, *Jonesia* was proposed to be excluded from the family *Cellulomonadaceae* (Rainey et al., 1995); a formal description of the family *Jonesiaceae* Stackebrandt, Rainey and Ward-Rainey, (1997) followed a few years later (Stackebrandt et al., 1997).

Differentiation of the species of the genus *Jonesia*

The type strains of the two *Jonesia* species share 96.6% 16S rRNA gene sequence similarity. The nearest neighbors of the order *Micrococcales* are less than 93.5% related. According to API 50 CHE (*indicates a positive reaction also in the Biolog GP2 substrate panel) the type strains of both species utilize: glycerol, L-arabinose*, D-xylose*, galactose, D-glucose*, D-fructose*, D-mannose*, arbutin*, esculin, salicin*, cellobiose, maltose*, lactose, sucrose*, trehalose, starch, glycogen, β-gentiobiose, D-turanose, and 5-ceto-gluconate. None of them utilized (*negative reaction also in the Biolog GP2 substrate panel): erythritol, D-arabinose, ribose, L-xylose, adonitol, β-methyl-xyloside, L-sorbose, rhamnose*, dulcitol, inositol*, mannitol*, sorbitol, inulin, melezitose*, D-raffinose*, xylitol, D-tagatose, D-fucose, L-fucose*, D-arabitol*, L-arabitol, 2-keto-gluconate, α-methyl-D-mannoside*, α-methyl-D-glucoside*, and *N*-acetyl-D-glucosamine*. According to the Biolog GP2 substrate panel, the following substrates were utilized in addition: dextrin, glycerol, maltotriose, D-psicose, D-ribose, adenosine, and 2′-deoxyadenosin. The other substrates of the Biolog GP2 substrate panel were not used.

Differentiating properties are indicated in Table 139.

List of species of the genus *Jonesia*

1. **Jonesia denitrificans** (Prévot 1961) Rocourt, Wehmeyer and Stackebrandt 1987, 269[VP]

de.ni.tri′fi.cans. N.L. a inf. *denitrificare* to denitrify; N.L. part. adj. *denitrificans* denitrifying.

In addition to properties given in the genus description, the species is characterized as follows: irregular rods, 0.3–0.5 µm in diameter and 2–3 µm in length. Filamentous forms may develop. Gram-stain-positive, but many cells, especially in older cultures, fail to retain the Gram stain completely. Coccoid forms which develop in older cultures always stain Gram-positive. The coccoid forms give rise to rod forms on transfer to a fresh medium. Non-acid-fast. Nonsporeforming. Motile by peritrichous flagella at both 25°C and 37°C. Facultatively anaerobic; organoheterotrophic. Colonies on nutrient agar are 0.5–1.5 mm in diameter (24–48 h), convex, smooth, edge entire, grayish, and translucent to opaque. Rough forms produce rough type colonies with a depressed center. As cultures become older (10–21 d) a yellowish pigmentation may develop. Optimum growth temperature ~30°C. Temperature limits of growth 10–40°C. Cells do not survive heating at 60°C for 30 min. Grow in 5% but not 10% (w/v) NaCl. Grow in presence of 4.5% (w/v) potassium thiocyanate, 0.01% (w/v) potassium tellurite, 0.01% (w/v) 2,3,5-triphenyltetrazolium chloride, and 0.02% (w/v) thallous acetate. Do not grow in the presence of 0.01% (w/v) sodium azide. Catalase-positive. Oxidase-negative. Acid but no gas produced from glucose, cellobiose, fructose, mannose, galactose, maltose, lactose, melibiose, sucrose, trehalose, glycerol, L-arabinose, D-xylose, amygdalin, arbutin, glycogen, starch, dextrin, β-gentiobiose, D-turanose, D-lyxose, salicin, and esculin. Weak acid production from melezitose. No acid produced from L-fucose, D-arabinose, sorbose, D-tagatose, ribose, L-xylose, adonitol, methyl β-xyloside, rhamnose, erythritol, inositol, mannitol, dulcitol, sorbitol, α-methyl-D-glucoside, α-methyl-D-mannoside, *N*-acetylglucosamine, inulin, D-raffinose, xylitol, D-fucose, D-arabitol, L-arabitol, gluconate, 2-keto-gluconate, and 5-keto-gluconate. Amygdalin, melibiose D-lyxose, and gluconate not utilized (API50CH). Inosine, D-cellobiose, D-galactose, 3-methyl-glucose, D-sorbitol, turanose, acetic acid, thymidine, and uridine are utilized (Biolog GP2).

Methyl red-positive. Voges–Proskauer-negative. Exogenous citrate not utilized. Growth requirements not determined. Sensitive, *in vitro*, by agar diffusion method to penicillin, streptomycin, chloramphenicol, aureomycin, terramycin, erythromycin, tetracycline, bacitracin, novobiocin, oleandomycin, kanamycin, vancomycin, colomycin, polymyxin B, and nitrofurantoin. Resistant to sulfonamide, neomycin, and nalidixic acid. β-Hemolysis negative; CAMP test against *Staphylococcus aureus* and *Rhodococcus equi* are negative.

Extracellular enzymes hydrolyze DNA, RNA, cellulose, and starch but not gelatin, chitin, casein, lecithin (egg yolk), xanthine, tyrosine, Tween 20, or Tween 80; slight hydrolysis of Tweens 40 and 60 takes place after 7 d. Phosphatase, sulfatase, and urease are not produced. Esculin is hydrolyzed. Sodium hippurate is not hydrolyzed or only weakly hydrolyzed (H_2SO_4 method) after 10 d. Acid produced in litmus

milk. Nitrates are reduced to nitrites. H_2S-negative. Indole-negative. Galactosamine is a diagnostic whole-cell sugar. Mycolic acids are not present.

Source: cooked ox blood.

DNA G+C content (mol%): 56–58 (T_m).

Type strain: ATCC 14870, CCUG 15532, CIP 55.134, DSM 20603, NBRC 15587, JCM 11481, = NCTC 10816.

Sequence accession no. (16S rRNA gene): X78420, X83811.

2. **Jonesia quinghaiensis** Schumann, Cui, Stackebrandt, Kroppenstedt, Xu and Jiang 2004, 2183[VP]

quing.hai.en′sis. N.L. fem. adj. *quinghaiensis* pertaining to Qinghai, Western province of China, where the type strain was isolated.

Gram-stain-positive; non-acid-fast. On tryptic soy broth agar, rhizoidal colonies are 4 mm in diameter after 7 d incubation at 28°C. On marine broth agar, medium light-yellowish colonies (about 0.5 mm in diameter) with rhizoid appearance (diameter 4–5 mm). Cells are rod shaped (0.5 x 1.5–2 μm) and nonmotile. Optimal growth temperature is 20–30°C; optimal pH is 7–9; optimal salt concentration is 2.0–7.5% (w/v) NaCl. Amygdalin, melibiose, D-lyxose, and gluconate utilized (API 50CH). Amygdalin, D-gluconic acid, and methyl pyruvate utilized (Biolog GP2). The polar lipids consist of phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and two unknown phospholipids. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{16:0}$.

Source: mud of a soda lake in Qinghai, a Western province of China.

DNA G+C content (mol%): 57.3 (HPLC).

Type strain: QH3A7, CGMCC 1.3459, DSM 15701, JCM 13009.

Sequence accession no. (16S rRNA gene): AJ626896.

Family XI. **Microbacteriaceae** Park, Suzuki, Yim, Lee, Kim, Yoon, Kim, Kho, Goodfellow and Komagata 1995, 418^VP (Effective publication: Park, Suzuki, Yim, Lee, Kim, Yoon, Kim, Kho, Goodfellow and Komagata 1993, 312.) emend. Rainey, Ward-Rainey and Stackebrandt 1997, 485

LYUDMILA I. EVTUSHENKO

Mi.cro.bac.te.ri.a.ce′a.e. N.L. neut. n. *Microbacterium* type genus of the family; suff. *-aceae* denoting a family; N.L. fem. pl. n. *Microbacteriaceae* the *Microbacterium* family.

Predominantly slender irregular rods of varying shape and length, often **showing V forms. Irregular spherical or ovoid cells** to short rods or **branched fragmenting vegetative mycelium** are typical of some taxa. Aerial hyphae are observed on very rare occasions. Nonmotile or motile. Nonsporeforming**. Gram-stain-positive** in terms of cell-wall architecture, but **the Gram reaction frequently appears to be negative or variable.** Non-acid-fast. **Colonies are mostly colored due to carotenoid pigments.**

Chemo-organotrophic; metabolism is primarily respiratory with oxygen as the terminal electron acceptor. **Predominantly aerobic;** microaerophilic or facultatively anaerobic bacteria occur. **Mostly catalase-positive;** some species display negative reaction for catalase. Strains usually grow on standard laboratory media based on yeast extract and peptone. Various carbon compounds are commonly used as sole carbon and energy sources. Many species require vitamins and amino acids for growth. Some species are nutritionally very exacting. Mostly **mesophiles** and **neutrophiles;** psychrophylic, psychrotolerant, acidophilic, and alkaliphilic species occur in some genera.

Cell-wall peptidoglycan is of the B group; contains the diamino acids lysine, ornithine, 2.4-diaminobutyric acid (Dab), or their combinations. The only respiratory quinones detected are **menaquinones** with 7–14 **unsaturated** isoprene units in the side chain. Fatty acids are predominantly **saturated anteiso- and iso-methyl branched**; ω-cyclohexylundecanoic acid and 1,1-dimethyl alkanes occur in some taxa in significant amounts. At a lower growth temperature, 12-methyl-tetradecenoic ($C_{15:1}$ anteiso) acid can be produced. **Mycolic acids are absent**. **Polar lipid patterns** include mostly **diphosphatidylglycerol, phosphatidylglycerol, and a variety of glycolipids**; other components may be detected in some genera.

An insertion between helices 54 and 55 of the 23S rRNA gene typical of actinobacteria has been determined for some species.

Natural habitats are various terrestrial and aquatic environments. Some species are associated with plants, animals, algae, fungi, as well as clinical specimens. Several species and subspecies include plant pathogens, some of which are under regulatory control in different countries.

DNA G+C content (mol%): 60–76.

Type genus: **Microbacterium** Orla-Jensen 1919, 179^AL emend. Takeuchi and Hatano 1998b, 744^VP.

Further descriptive information

The family *Microbacteriaceae* (Park et al., 1993; Stackebrandt et al., 1997) is the member of the order *Micrococcales* (formerly suborder *Micrococcineae*), class *Actinobacteria* (Stackebrandt et al., 1997), and currently embraces the following genera: *Microbacterium*, *Agreia*, *Agrococcus*, *Agromyces*, *Clavibacter*, *Cryobacterium*, *Curtobacterium*, *Frigoribacterium*, *Frondhabitans**, *Gulosibacter*, *Humibacter*, *Labedella*, *Leifsonia*, *Leucobacter*, *Microcella*, *Microterricola*, *Mycetocola*, *Okibacterium*, *Phycicola*, *Plantibacter*, *Pseudoclavibacter*, *Rathayibacter*, *Rhodoglobus*, *Salinibacterium*, *Subtercola*, *Yonghaparkia*, and *Zimmermannella*† (a homotypic synonym of *Pseudoclavibacter*).

Bacteria of the family *Microbacteriaceae* form a coherent 16S rRNA-based clade and are clearly distinguished from all other families of the order *Actinomycetales* mainly by their unusual B group cell-wall peptidoglycan (Schleifer and Kandler, 1972) and unsaturated respiratory menaquinones (Collins and Jones, 1981) with isoprene units ranging from 7–8 (*Frondicola*) to 13–14 (representatives of *Microbacterium* and *Microcella*) (Table 140). Group B peptidoglycan is characterized by a cross-linkage between the α-carboxyl group of D-glutamic acid in position 2 of the peptide subunit and the C-terminal D-alanine of an adjacent subunit. In contrast, other actinobacteria are known to have A type peptidoglycans, in which cross-linkages are formed between the ω-amino group of the diamino acid in position 3 of the peptide subunit to the carboxyl group of the C-terminal D-alanine in position 4 of the adjacent subunit (Schleifer and Kandler, 1972). A diamino acid such as 2,4-diaminobutyric acid (Dab), lysine, or ornithine in L- or/and D-configuration is always present in the interpeptide bridge of B-type peptidoglycan, since two carboxyl groups must be cross-linked (Schleifer and Seidl, 1985). An amino acid (Dab, homoserine, or lysine) in L-configuration occupies position 3 of the peptide subunit in the structural types so far determined (DSMZ, 2001; Schleifer and Kandler, 1972).

Cells of the majority of species are slender irregular rods (~0.2–0.7 µm) which vary considerably in length and may be arranged in V-formation. The morphological features are prominent for some members of the family. Irregular spherical or ovoid cells to short rods (0.7–1.0 × 1.1–1.7 µm) are characteristic of most *Agrococcus* species; very small rods (~0.2–0.4 µm × ~0.5–1.1 µm) have been reported, for instance, for representatives of *Microbacterium*, *Frondicola*, *Leucobacter*, *Pseudoclavibacter*, and *Zimmermannella*. A fragmenting vegetative mycelium (commonly penetrating into agar media) is characteristic of many *Agromyces* species. A budding-like mode of cell division has been observed in *Phycicola gilvus*. Ultramicro-sized cells (width, 0.15–0.25 µm; volume, <0.1 μm^3) of selenoid shape, occasionally forming rings (when dissociation does not occur after septum formation), were reported for freshwater aerobic isolates affili-

*The name *Frondihabitans* Greene et al. (2009) was proposed to replace the illegitimate name *Frondicola* Zhang et al. (2007c) (Greene et al., 2009).

†According to the Bacteriological Code, the genus name *Zimmermannella* is a later (junior) homotypic synonym of the genus name *Pseudoclavibacter* Manaia et al. (2004) (see the *Taxonomic comments* section and the chapter on the genus *Pseudoclavibacter* for more information).

[a]Data compiled from the original descriptions of the genera listed; the species composing these genera and publications are cited in respective generic chapters in this volume.

[b]Symbols, +, present; −, absent; D, different between species (character for the type species is indicated).

[c]Data for the *Leifsonia sensu stricto* species (*Leifsonia aquatica*, *Leifsonia naganoensis*, *Leifsonia poae*, *Leifsonia shinshuensis*, and *Leifsonia xyli*). See chapters on *Leifsonia* and *Rhodoglobus* in this volume for information concerned with the remaining *Leifsonia* species.

[d]The genus name *Zimmermannella* Lin et al. (2004) is a later (junior) homotypic synonym of the genus name *Pseudoclavibacter* Manaia et al. (2004); the data presented are as given in the original description of the genus *Zimmermannella* which includes, along with *Zimmermannella helvola*, the species *Zimmermannella alba*, *Zimmermannella bifida*, and *Zimmermannella faecalis* (see the text and the chapter Genus *Pseudoclavibacter* in this volume for more information).

[e]Abbreviations: BL, blue to black (bipyridyl pigment, indigiodine Starr, 1958; Kuhn et al., 1965); Cr, cream; O, orange; P, pink; PG, pink gray to pink white; PB, pale brown; R, reddish to red; RO, rose-orange; W, white; Y, yellow. The pigmentation intensity and tints may vary depending on the growth conditions and age of culture.

[f]Rods usually become shorter with the age of culture and a proportion of cells may be coccoid in many genera (see the generic chapters for details). Aerial hyphae were reported for *Agromyces aurantiacus* on glycerol-asparagine agar (Shirling and Gottlieb, 1966); young cells of *Subtercola frigoramans* are frequently swollen at the pole or in the middle.

[g]Abbreviations: M, mesophilic to psychrotolerant organisms with temperature optima for growth ~25–30°C unless indicated; Ps, psychrophilic or psychrotolerant organisms with lower temperature optima (in parentheses).

[h]Abbreviations: Dab, 2,4-diaminobutyric acid; Orn, ornithine; Lys, lysine; Asp, aspartic acid; Thr, threonine; Gab, γ-aminobutyric acid; Hyg, 3-*threo*-hydroxy glutamic acid; Hyo, 3-*threo*-hydroxy ornithine. In addition, alanine, glutamic acid, and glycine are usually present in all organisms. L- and D-, enantiomeric isomers of diamino acids (where available at least for the type species). Oblique strokes separate diamino acids reported for different species within a genus. Amino acids given in parentheses occur in some species of a genus.

[i]Both aspartic acid and threonine are absent in the cell-wall peptidoglycan of *Agrococcus casei*.

[j]No data are available on the peptidoglycan amino acid composition for *Gulosibacter*.

[k]Unsaturated menaquinones, ~20% and more (were available). Numerals indicate the numbers of isoprene units in the side chain.

[l]The majority of *Microbacterium* species contain MK-11 and MK-12 or MK-12 and MK-13 as the predominant menaquinones.

[m]Abbreviations: Ch, ω-cyclohexylundecanoic acid; DMA, 1,1-dimethoxy-alkanes. Brackets indicate that a compound reaches more than 10% only in some species as reported; minor (less than 10%) but characteristic components if available are given in square brackets. Oblique stroke separate different fatty acid patterns reported for different species within a genus. *Note*: Relative amounts of the predominant fatty acids may vary depending on growth conditions and growth phase.

[n]Along with *Cryobacterium* species and *Frigoribacterium* species, the monounsaturated 12-methyl-tetradecenoic acid ($C_{15:1}$ anteiso) may be present in organisms of other genera grown at lower temperatures.

[o]The retention time of the methyl esters of $C_{18:1}$ ω7*c* and $C_{14:0}$ 2-OH fatty acids is almost identical to that of cyclohexyl-$C_{17:0}$ and $C_{15:0}$ DMA, respectively, in the standard MIDI system (Kämpfer et al., 2000; Qiu et al., 2007). The following fatty acids have recently been reported by Greene et al. (2009) as characteristic components: $C_{16:0}$, $C_{14:0}$ 2-OH, $C_{14:0}$ iso 3-OH, $C_{17:1}$ ω9*c* and $C_{18:1}$ ω7*c* (no quantitative data are available).

[p]Abbreviations: DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; PI, phosphatydylinositol; AP, aminophospholipid; PC, phosphatidylcholine; PGM, phosphatidylglycerol mannoside; PL, unknown phospholipid(s); GL, glycolipid(s). Trace amounts of polar lipids may present additionally in representatives of some genera (see respective genera chapters in this volume).

[q]No data on studying the possible presence of glycolipids.

[r]Data for *Pseudoclavibacter helvolus* (*Zimmermannella helvolum*) (see the text and the chapter Genus *Pseudoclavibacter* in this volume for more information).

[s]Oblique strokes separate the lower values reported for *Agrococcus casei* and *Agromyces neolithicus* and higher value for *Cryobacterium mesophilum*.

ated to the family (Hahn et al., 2003). Cells of a copiotrophic isolate, strain 12–8 (>99% 16S rRNA gene sequence similarity with *Yonghaparkia alkaliphila*) are divided by multiple longitudinal and transverse septa resulting in formation of very small cells of different size and shape (Iizuka et al., 1998).

Bacteria of the family *Microbacteriaceae* are predominantly heterotrophic and obligate aerobes, but some show microaerophilic growth, e.g. representatives of *Agromyces* (Jurado et al., 2005a, 2005b, 2005c) and *Microbacterium* (Buczolits et al., 2008b), or require microaerobic conditions for growth (*Agromyces ramosus*). Some *Microbacterium* species were reported to give weak anaerobic growth and produce acids under anaerobic conditions (for references, see Collins and Keddie, 1986). Representatives of the family, identified as members of the genera *Microbacterium* and *Leifsonia*, were shown to grow chemolithotrophically in a medium containing thiosulfate and exhibit growth coupled with thiosulfate oxidation (Anandham et al., 2008). A strain identified as *Microbacterium* was reported to reduce toxic Cr(VI) under anaerobic conditions at the expense of acetate as the electron donor (Pattanapipitpaisal et al., 2001). Some strains from alkaline environments, that exhibited close phylogenetic relatedness to *Yonghaparkia alkaliphila*, *Microcella alkaliphila* or *Microbacterium* species, are dependent on elevated levels of CO_2 for growth (Ueda et al., 2008).

Most bacteria of the family are pigmented on complex media in shades of yellow, orange, pink, and red due to production of carotenoid pigments (Saperstein and Starr, 1954; Saperstein et al., 1954; Starr and Saperstein, 1953; Trutko et al., 2005). The color intensity and shade may vary depending on the species, growth medium, culture age, exposure to light, and incubation temperature. Qualitative and quantitative changes in the carotenoid pigments were observed, for instance, for *Curtobacterium flaccumfaciens* (pv. *poinsettiae*), when the level of the required growth factor, thiamine, is altered in the basal medium. The cells grown under conditions of low thiamine concentration were red-pigmented, with two major pigments produced: spirilloxanthin and lycoxanthin. Under conditions of high thiamine concentrations, the cells were orange-yellow and three major pigments were produced: lycoxanthin, cryptoxanthin, and a small amount of spirilloxanthin (Starr and Saperstein, 1953). In some bacteria tested so far (e.g. representatives of the genera *Agrococcus*, *Agromyces*, *Leifsonia*, *Microbacterium*, and *Leucobacter*), the pigments are light-induced (Groth et al., 1996; Muir and Tan, 2007; Trutko et al., 2005; Zlamala et al., 2002a). Most strains of *Clavibacter michiganensis* subsp. *insidiosus* contain the dark blue-gray bipyridyl pigment indigiodine (Kuhn et al., 1965; Starr, 1958). Similar dark blue-gray extracellular pigment, along with a rose carotenoid-like pigment, is also produced by some *Clavibacter* strains isolated from desert ecosystems (Dobrovolskaya et al., 1999).

The DNA base ratios range from 60 mol% as determined for *Rathaibacter toxicus* by HPLC (Sasaki et al., 1998) to 76.1 mol% (T_m) reported for *Clavibacter michiganensis* subsp. *insidiosus* (Döpfer et al., 1982). Somewhat higher values were reported in early works for other members of the family *Microbacteriaceae*.

Members of the family *Microbacteriaceae* are widely distributed in nature and have been isolated from or detected by molecular methods in diverse terrestrial, marine, and freshwater environments (for references and details, see respective generic chapters in this volume). Cells of some representatives of the family were reported to survive rather extreme conditions and were found, for instance, in more than 500,000-year-old glacial ice (Christner, 2002), in a deep Greenland glacier ice core at least 120,000 years old (Miteva et al., 2004a), in 1.8–3 million years old permafrost sediments (Kochkina et al., 2001; Vishnivetskaya et al., 2006), and in desert ecosystems including the Atacama Desert which represents one of the driest places on Earth (Osman et al., 2008b). Some *Microbacterium* species (along with *Arthrobacter* species) were shown to be highly resistant to UV-radiation (Osman et al., 2008b; Wu and Liu, 2007), desiccation, and a simulated Martian atmosphere (Osman et al., 2008b). These actinobacteria were suggested for consideration as prime candidates for possible contamination of Mars (Osman et al., 2008b). Representatives of the family were also reported to resist and reduce heavy metal contaminations due to specific mechanisms (Idris et al., 2004; Mokashi and Paknikar, 2002; Morais et al., 2004; Pattanapipitpaisal et al., 2001; Sarangi and Krishnan, 2008; Sheng et al., 2008; Zhu et al., 2008).

Microbacteriaceae can be associated with different eukaryotic organisms (Evtushenko and Takeuchi, 2006; Mendes et al., 2007; Muir and Tan, 2007; Nishiwaki et al., 2007; Somvanshi et al., 2007; Wang et al., 2007; Wichels et al., 2006; Xin et al., 2008; Zachow et al., 2008), and are being cited among opportunistic human pathogens and clinical isolates (mostly *Microbacterium* species and also representatives of *Leifsonia*, *Leucobacter*, *Okibacterium*, *Pseudoclavibacter*, and some others) (Adderson et al., 2008b; Bosshard et al., 2003; Dempsey et al., 2007; Funke et al., 1997; Gneiding et al., 2008; Mages et al., 2008; Siala et al., 2008). There are also plant pathogens among *Microbacteriacea* which belong to several species and subspecies of the genera *Clavibacter*, *Curtobacterium*, *Leifsonia*, and *Rathayibacter* (Young et al., 1996, 2004a).

Besides the microorganisms belonging to the genera reviewed by the following chapters, great diversity of not yet precisely identified members of the family *Microbacteriaceae* has been discovered in various ecosystems. As it might be supposed from the analysis of 16S rRNA gene sequences available in public databases, many of these bacteria represent separate lines of descent and form the nuclei of novel genera to be described in the future.

Taxonomic comments

The first isolation of bacteria of the family *Microbacteriaceae* was reported about a century ago (Hutchinson, 1917; Smith, 1910, 1913; Spieckermann and Kotthoff, 1914). Those included the plant-pathogenic organisms currently belonging to *Clavibacter michiganensis* subsp. *michiganensis*, *Rathayibacter rathayi*, *Clavibacter michiganensis* subsp. *sepedonicus*, and *Rathayibacter tritici*. The type species of the type genus of the family, *Microbacterium lacticum*, isolated from dairy products, was described shortly afterwards (Orla-Jensen, 1919).

The chemical analyses of cell walls and lipids played the most important role in development of the classification system of the family in the "pre-molecular" era (for details and references see Collins and Bradbury, 1986). Early phylogenetic studies, e.g. oligonucleotide cataloguing (Stackebrandt et al., 1980), DNA/rRNA similarities (Döpfer et al., 1982), 5S rRNA gene sequence clustering (Park et al., 1987), and the levels of sequence similarity of an insertion within the 23S rRNA between helices 54 and 55 (Roller et al., 1992) confirmed the relatedness of bacteria

possessing the group B type peptidoglycan and menaquinones with unsaturated isoprene units in the side chain. Collins and Bradbury (1986) suggested that the target bacteria possessing a group B type peptidoglycan merit a family status (the name *Microbacteriaceae* was provisionally proposed).

Later on, Park et al. (1993) concluded from the results of 5S rRNA gene sequence comparisons of representatives of the target bacterial group and representatives of other actinomycete genera that the sequence similarity and associated chemotaxonomic characteristics provide compelling grounds for classifying the bacteria with a group B type peptidoglycan in a single family. The authors established the family *Microbacteriaceae* comprising the type genus *Microbacterium* and the genera *Aureobacterium*, *Agromyces*, *Curtobacterium*, and *Clavibacter* (the family name was validated in 1995). In 1997, Stackebrandt and co-authors suggested a hierarchic classification scheme of actinobacteria, in which delineation of higher taxa was based on the 16S rRNA gene sequence-based phylogenetic clustering and distribution of signature nucleotides. Along with other taxonomic proposals, the authors emended the description of the family *Microbacteriaceae*, adding the genera *Agrococcus* and *Rathayibacter*. The following characteristic patterns of 16S rRNA gene signature nucleotides were proposed for the family *Microbacteriaceae*: nucleotides at positions 45:396 (U–A), 144:178 (C–G), 258:268 (A–U), 497 (A), 615:625 (A–U), 694 (G), 771:808 (G–C), 839:847 (G–U), 1256 (G), 1310:1327 (A–U), and 1414:1486 (U–A) (Stackebrandt et al., 1997).

The current classification system of the family *Microbacteriaceae* and affiliated genera (Figure 173) is an example of using a taxonomic strategy based on the polyphasic approach (Colwell, 1970; Stackebrandt, 2006; Vandamme et al., 1996) which assumes a certain level of consensus while interpreting genotypic and phenotypic data in establishing of taxa and delineating their boundaries. Delineation of genera within this family is primarily based on the 16S rRNA-based phylogenetic clustering (as a rule the genus taxon is considered to be monophyletic) and chemotaxonomic characteristics, such as cell-wall diamino acids and other diagnostic amino acids, the cell-wall peptidoglycan composition, the type of acyl groups on the muramyl residues of the peptidoglycans determined in a glycolate test (detection of *N*-glycolyl residues) (Uchida and Aida, 1977), the number of isoprene units of the major menaquinone(s), the predominant or specific components of fatty acid profiles including various 1,1-dimethyl alkanes (Kämpfer et al., 2000; Schumann et al., 2003) and the DNA G+C content (Table 140) and some morphological features mentioned above. Physiological, biochemical and some other chemotaxonomic characteristics including the cell-wall sugar composition and quantitative fatty acid profiles (determined from cells grown under similar conditions and standardized analysis) are presently considered to be the phenotypic traits of secondary importance for differentiation of genera within this family but are commonly used for species delineation.

The 16S rRNA gene sequence similarity between representatives of different genera of the family *Microbacteriaceae* ranges from ~91 to 97–98%. It is noteworthy that in other contexts (and with other bacteria) the 97–98% cut-off value is often assumed to delineate species (rather than genus) category. In some cases, the establishment of novel genera phylogenetically very close to previously described genera is based on the suggested priority of chemotaxonomic features over the high 16S rRNA gene sequence similarity. One example is the genus *Yonghaparkia* (Yoon et al., 2006b) exhibiting 2,4-diaminobutyric acid in the peptidoglycan and more than 98% 16S rRNA gene sequence similarity to the type species of the genus *Microcella* (Tiago et al., 2005b) which contains a lysine-based peptidoglycan. Several closely related genera and species which are phylogenetically interspersed among such genera (Figure 173) have been described almost simultaneously by different authors (without their being aware of the similarity of their research subjects) from different taxonomic perspectives. Those include (i) the genera *Rhodoglobus* (Sheridan et al., 2003), *Salinibacterium* (Han et al., 2003), and the species *Leifsonia aurea* and *Leifsonia rubra* (Reddy et al., 2003b); (ii) *Pseudoclavibacter*, *Gulosibacter* (Manaia et al., 2004) and *Zimmermannella* with four species (Lin et al., 2004); (iii) *Microterricola* (Matsumoto et al., 2008), *Phycicola* (Lee et al., 2008), and *Leifsonia pindariensis* (Reddy et al., 2008).

It is worth noting in this context that the descriptions of type species of the genera *Zimmermannella* and *Pseudoclavibacter* are based on the same strain ("*Brevibacterium helvolum*" ATCC 13715 = DSM 20419 = JCM 9491= NBRC 15775) designated the type strain. The genus name *Pseudoclavibacter* Manaia et al. (2004) that was validly published somewhat earlier is therefore a senior homotypic synonym of the genus name *Zimmermannella* Lin et al. (2004) according to Rule 24b of the *Bacteriological Code* (1990 Revision) (Lapage et al., 1992). Strict application of the Rules of the Bacteriological Code also indicates that the genus name *Zimmermannella* Lin et al. 2004 is illegitimate [Rule 51b(1)] and the species included (*Zimmermannella alba*, *Zimmermannella bifida*, and *Zimmermannella faecalis*) cannot be maintained in the genus *Zimmermannella* in accordance with Rule 37a(1) (Euzéby, 2009). Moreover, the genera *Pseudoclavibacter* and *Zimmermannella* were reported to differ in their circumscriptions, where *Zimmermannella* with its four species has broader boundaries in terms of the essential diagnostic characteristics, as follows from the formal descriptions of these genera (Lin et al., 2004; Manaia et al., 2004). The species *Zimmermannella alba*, *Zimmermannella bifida*, and *Zimmermannella faecalis* are distinguished from each other and from *Pseudoclavibacter helvolus* at least in their peptidoglycan structures and/or predominant menaquinones (both characteristics usually delineate genera within the family *Microbacteriaceae*). The above data, along with the similarity values of the 16S rRNA gene sequences of these species that are of the same level as recorded for representatives of separate genera of the family, suggest that *Zimmermannella alba*, *Zimmermannella bifida*, and *Zimmermannella faecalis* can be classified into at least two different genera.

In some of the aforementioned examples, different interpretations of the data on 16S rRNA gene sequence comparison, along with different chemotaxonomic characteristics recorded for the phylogenetically very close organisms lead authors to the discrepant taxonomic conclusions (prominent examples are the pairs *Rhodoglobus vestalii*–*Leifsonia rubra* and *Microterricola viridarii*–*Leifsonia pindariensis*). It is thus apparent that the taxonomic status of such genera and species is in need of further revision. It also seems quite likely that the taxonomic status of *Agrococcus casei* (Bora et al., 2007), which branches outside the cluster of all remaining *Agrococcus* species and differs from these at least by its cell-wall peptidoglycan composition and a

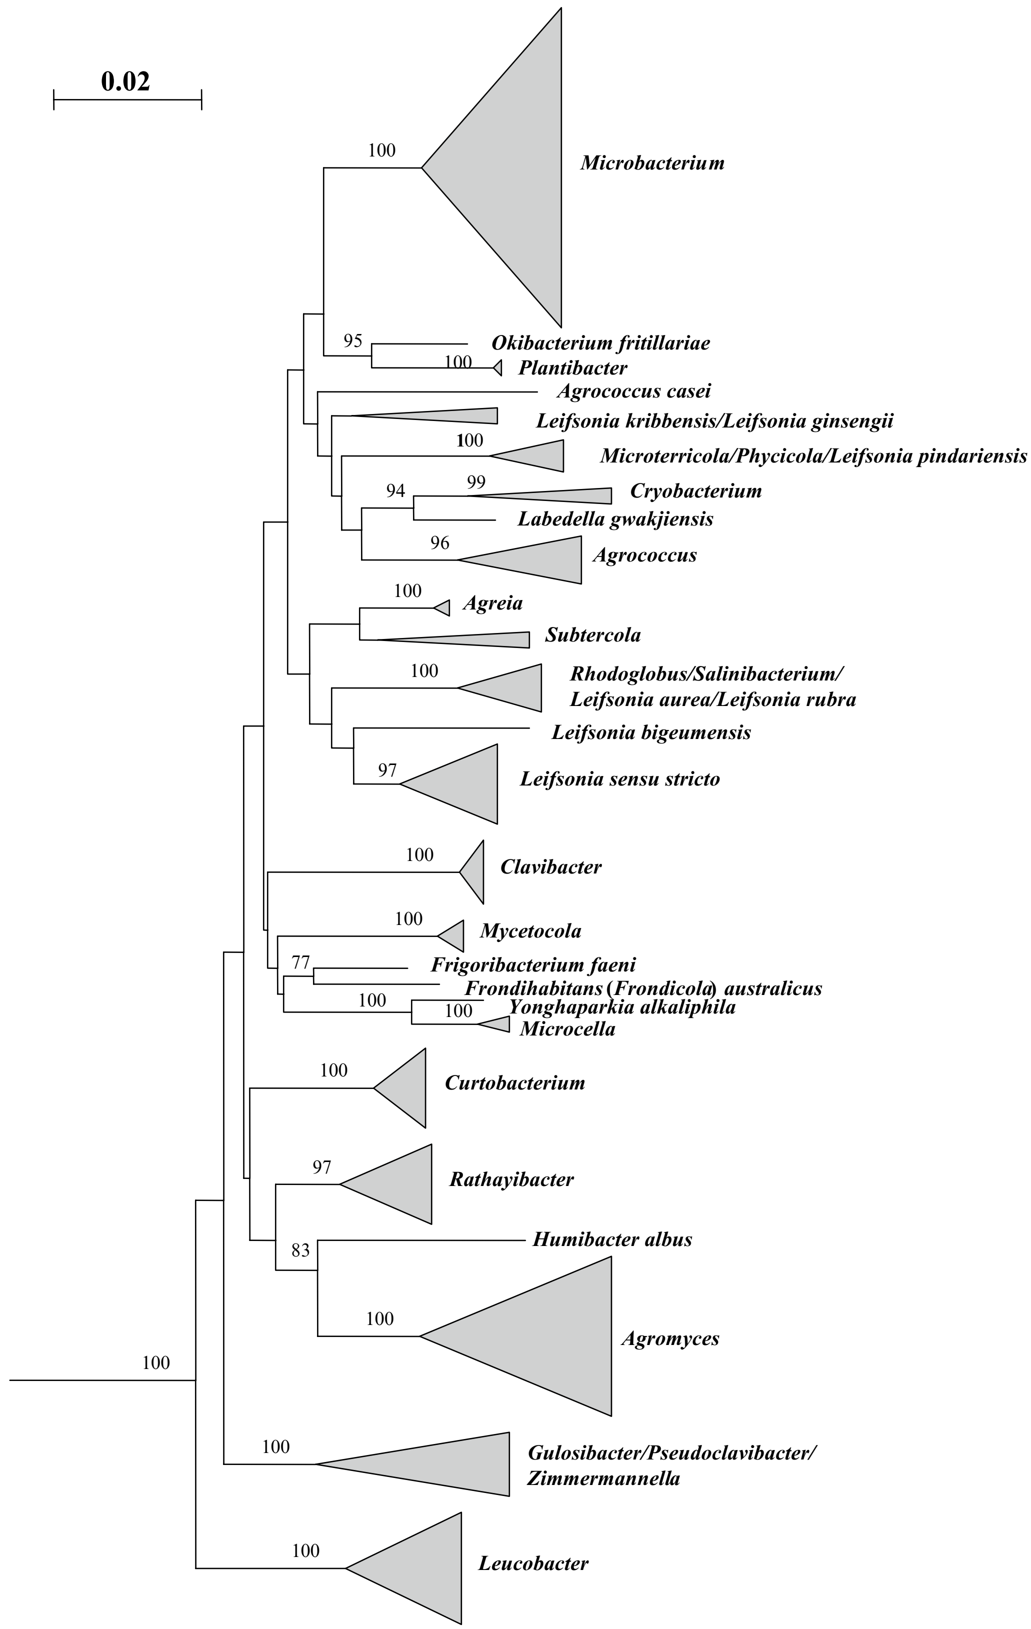

FIGURE 173. Phylogenetic dendogram based on 16S rRNA comparison of the type strains of the type species of the family *Microbacteriaceae*. Bar = 0.02 inferred nucleotide substitution per nucleotide. Values at nodes indicate bootstrap values for 500 replicates.

lower G+C content of DNA (65 mol%), requires re-evaluation. Similarly, the generic assignment of some recently described *Leifsonia* species, such as *Leifsonia ginsengi* (Qiu et al., 2007), *Leifsonia kribbensis* (Dastager et al., 2009), and *Leifsonia bigeumensis* (Dastager et al., 2008c), which do not form a robust 16S rRNA-based phylogenetic cluster with the *Leifsonia sensu stricto* species and tend to differ from them in the phenotypic characteristics available, is in need of re-evaluation (see the chapter Genus *Leifsonia* for more information).

On the other hand, the distantly related species within the type genus *Microbacterium* (which so far comprises the largest number of species within the family) share relatively low 16S rRNA gene sequence similarities (~94–95%), which are equal to or lower than values reported for representatives of different genera of this family. The genus *Microbacterium* also looks heterogeneous in terms of chemotaxonomic markers (the species are characterized at least by different structural types of the cell-wall peptidoglycans based on different diamino acids and different quinone systems). At the same time, members of this genus form a well-defined 16S rRNA-based clade (Figure 173) and the species with different structural types of peptidoglycan are phylogenetically intermixed (Takeuchi and Hatano, 1998b).

Recently, an attempt has been made to clarify the phylogeny and taxonomic structure of the genus *Microbacterium* and the family *Microbacteriaceae* by analyzing the partial housekeeping genes encoding DNA gyrase subunit B (*gyrB*), RNA-polymerase subunit B (*rpoB*), recombinase A (*recA*), and polyphosphate kinase (*ppk*) (Richert et al., 2007; Stackebrandt et al., 2007). It was shown that the phylogenetic groupings of the type strains of species within the genus *Microbacterium* differed with each protein-coding gene sequenced and from the 16S rRNA based phylogeny as well. Only the *ppk* gene tree and a concatenated tree based on the sequences of 16S rRNA and all four housekeeping genes, placed *Microbacterium* strains with lysine-based peptidoglycan as a coherent cluster within the radiation of *Microbacterium* species having ornithine in the peptidoglycan (Richert et al., 2007). The extended multilocus sequence analysis (Stackebrandt et al., 2007) performed with the type strains of 32 species of 13 genera of the family *Microbacteriaceae* demonstrated that members of most genera with more than one strain formed phylogenetically coherent clusters based on nucleic acid sequences and protein sequences of housekeeping genes. However, the topology of phylogenetic trees differed from one another and from the 16S rRNA-based tree. Furthermore, problems identified related to drawing conclusions from individual gene sequences for bacterial systematics and lack of conserved PCR primer targets in the genes applicable to the full set of type strains under investigation have also been illustrated. The result of this study led the authors to the conclusion that the 16S rRNA-based phylogenetic analysis will continue to serve as "gold standard" for decisions about taxonomic ranks from species to family categories until a substantially higher degree of genomic information is available (Stackebrandt et al., 2007).

In recent years, the study of newly isolated organisms has highlighted some problems in the current taxonomy of the family associated with the shortage of chemotaxonomic markers and other phenotypic characteristics routinely examined in bacteria that are useful for delineating phylogenetically distant bacterial groups or single strains (supposedly belonging to new genera). This particularly concerns the organisms whose generic assignment cannot be unambiguously interpreted in terms of 16S rRNA phylogeny and probably other genes used for phylogenetic analysis. Meanwhile, more detailed analysis of the cell-wall composition, e.g. determination of stereoisomers of Dab of the cell-wall peptidoglycan (Sasaki et al., 1998), or identification of some "unknown" or minor lipid components including polar lipids (Buczolits et al., 2008b; Kämpfer et al., 2000; Lee et al., 2008; Lee, 2007; Schumann et al., 2003) uncover additional chemotaxonomic markers useful in differentiating genera and species of this family. One may note that some other cell molecules and polymers reported for several representatives of the family appear to be useful for taxonomic purposes in the group concerned, e.g. the polyamine pattern (Altenburger et al., 1997), the heme composition and the associated cytochrome and quinole oxidases of respiratory chains (Trutko et al., 2003), the cell wall anionic polymers (Naumova et al., 2001; Ortiz-Martinez et al., 2004; Shashkov et al., 1993, 1995), and probably some biochemical characteristics. Further, employment of fourier-transform infrared (FT-IR) spectroscopy, which reflects common physical-chemical profiles of bacterial cells (Oberreuter et al., 2002), was shown to be helpful in differentiating members of related genera within this family (Behrendt et al., 2002). In addition, some studies, as mentioned before, revealed unusual cell morphology in some representatives of the family. Such findings, along with clearly distinguishable morphological features of some so-called "irregular rods", as well as different reactions in Gram-staining and KOH tests (Gregersen, 1978) and sensitivity to lysozyme (indicating differences in the cell envelope chemistry), point to potential usefulness of the detailed study of cell morphology, life cycles, and the fine cell architecture for discovering and documenting additional phenotypic characteristics associated with phylogenetic distinctness of organisms.

Comparative genomics has recently greatly facilitated the evaluation of the current taxonomic system and contributed substantially to exploration of the limits of the currently recognized species and genus categories in some bacterial groups (Konstantinidis and Tiedje, 2007). The prospects for harmonizing genomic and phenotypic information at the level of family (at least with some *Proteobacteria*) are not fully satisfying. So far, genome sequences of three representatives of the family *Microbacteriaceae*, including the plant pathogens *Leifsonia xyli* subsp. *xyli* (Monteiro-Vitorello et al., 2004), *Clavibacter michiganensis* subsp. *michiganensis* (Gartemann et al., 2008), and *Clavibacter michiganensis* subsp. *sepedonicus* (Bentley et al., 2008), are available. Showing the genome characteristics typical of actinobacteria as a whole, these species/subspecies have also many similar genes and proteins indicative of their lifestyle and recent niche adaption. The published data on comparative genomics and proteomics of some actinobacteria, which emphasize also some aspects relevant to the possible future development in taxonomy of these organisms, have been discussed in a review (Ventura et al., 2007).

Acknowledgements

This work was supported by the program MCB of the Russian Academy of Sciences. The author is grateful to Dr Vladimir N. Akimov for valuable discussions on the phylogenetic structure of the family *Microbacteriaceae* and construction of phylogenetic tree.

Further comments

After this chapter was completed, three novel genera of the family *Microbacteriaceae* were added to the family: *Klugiella* (Cook et al., 2008), *Glaciibacter* (Katayama et al., 2009), and *Schumannella* (An et al., 2008, 2009).

Genus I. **Microbacterium** Orla-Jensen 1919, 179[AL] emend. Takeuchi and Hatano 1998b, 744[VP]

Ken-ichiro Suzuki and Moriyuki Hamada

Mic.ro.bac.te′ri.um. Gr. adj. *mikros* small; L. neut. n. *bacterium* a small rod; N.L. neut. n. *Microbacterium* a small rodlet.

Cells of young cultures (from 12 to 24 h) are small, slender, irregular rods, generally 0.4–0.6 µm in diameter by 1.0–2.0 µm in length. Some species form cells up to 6.0 µm in length. Some of the rods are arranged at angles to each other to give a "V" formation. Primary branching may occur but is not common in mycelia formation. Cells of old cultures (from 3 to 7 d) are shorter and coccoid cells are often formed. However, the rod–coccus cycle does not occur. Cells stain Gram-positive and are not acid-fast. Endospores are not formed. Nonmotile or motile. Colonies on solid media are yellowish white, yellow to orange in color. **Generally strictly aerobic and catalase-positive. Chemo-organotrophic.** Acid is produced from glucose and some carbohydrates, but only slowly or weakly on peptone. Some organic acids are assimilated.

The cell-wall peptidoglycan **contains L-lysine or D-ornithine** with glycine, alanine, and D-glutamic acid, which is often partially substituted by hydroxylglutamic acid. D-Ornithine-containing species and some L-lysine-containing species contain homoserine. **Muramic acid of the peptidoglycan occurs in the *N*-glycolyl form.** Cell-wall sugars are principally galactose and rhamnose. The presence of glucose, mannose, fucose, 6-deoxytalose, and/or xylose is variable, depending on the species. Major menaquinones are unsaturated **MK-11, MK-12, MK-13, and/or MK-14.** MK-10 is found as a minor component in some species. The **polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and one or some glycolipids.** Cellular fatty acids are predominantly $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. Signature nucleotides in the 16S rRNA gene sequences are at positions: 69:99 (G/A–T), 129 (C/T), 232 (G), 279 (T), 443:491 (C/T–G), 770:809 (G–C/G), 780 (A), 830:856 (T–A), and 929:1386 (A–T).

DNA G+C content (mol%): 63–75 (HPLC, T_m).

Type species: **Microbacterium lacticum** Orla-Jensen 1919, 179[AL].

Further descriptive information

The genus *Microbacterium*, represented by *Microbacterium lacticum*, was established for small, rod-shaped bacteria isolated from dairy products and equipment (Orla-Jensen, 1919). *Microbacterium lacticum* was characterized by its thermotolerance, surviving at 63°C for 30 min in skim milk or 72°C for 15 min (Collins and Keddie, 1986). Since the establishment of the genus *Microbacterium* by Orla-Jensen, the first reclassification of the genus *Microbacterium* was done by Collins et al. (1983c), who defined the genus for species containing peptidoglycan with lysine. At the same time, Collins et al. (1983a) proposed the genus *Aureobacterium* for those species containing ornithine in the peptidoglycan, with *Aureobacterium liquefaciens* as the type species. While these proposals were in accordance with the peptidoglycan diamino acids, phylogenetic relationships based on 16S rRNA gene sequences of the two genera were intermixed (Rainey et al., 1994; Takeuchi and Yokota, 1994). Considering these phylogenetic relationships, Takeuchi and Hatano (1998b) proposed the union of the two genera into the emended genus *Microbacterium*. Thus, the variation of the diamino acids is regarded as a species and not a genus characteristic.

Cells of species of the genus *Microbacterium* are short rods, generally as small as those of members of other genera of the family *Microbacteriaceae*. Although cells of older cultures become shorter, no pleomorphic cell cycle is observed.

Principally strictly aerobic. Although *Microbacterium gubbeenense* and *Microbacterium ulmi* are described as facultatively anaerobic, good growth is shown in aerobic culture.

Chemotaxonomy. Chemotaxonomic profiles are important for characterization and identification of species of the genus *Microbacterium*. While polar lipids and cellular fatty acids are similar for most species of the genus, the structure of the cell-wall peptidoglycan and menaquinone composition vary, as shown in Table 141.

Cell-wall peptidoglycan. Like other members of the family *Microbacteriaceae*, the genus *Microbacterium* possesses B group peptidoglycan (Collins et al., 1983a, 1983c; Schleifer and Kandler, 1972). The peptidoglycan contains either lysine or ornithine as the characteristic diamino acid in the interpeptide bridge. In addition, variation is found in the amino acid at position 3 of the peptide side-chain. So far, five variations are known (Figure 174). Note that the classification of species based upon the presence of either ornithine or lysine in the cell-wall is no longer used (Rainey et al., 1994; Takeuchi and Yokota, 1994).

Muramic acid of the glycan moiety of the peptidoglycan is glycolated, as also found in the genera *Mycobacterium* and *Nocardia* (Uchida and Aida, 1979). The glycolyl type of the cell-wall peptidoglycan is one of the useful differential characteristics that distinguish the genus *Microbacterium* from other members of the family *Microbacteriaceae*, except for the genus *Okibacterium* (Evtushenko et al., 2002). It is determined by the glycolate test developed by Uchida and Aida (1979). Early studies of Uchida and Aida (1977) analyzed the molar ratio of glycolyl residues in the unit cell-wall to determine the ratio of substitution by glycolyl muramic acid. *N*-Glycolyl muramic acid is formed by hydroxylation of the *N*-acetyl muramic acid. This activity is also responsible for the hydroxylation of glutamic acid of the peptide subunit. Similarly, some species of the family *Micromonosporaceae* have both glycolyl muramic acid and a hydroxylated diaminopimelic acid in their peptidoglycan.

Cell-wall sugars. The cell-wall sugars of members of the genus *Microbacterium* have been well characterized by the studies of Yokota et al. (1993a, 1993b) and Takeuchi and Hatano (1998a). Most of the species contain galactose and rhamnose. The presence of glucose, mannose, fucose, 6-deoxytalose, and/or xylose varies depending on the species. The first observation of 6-deoxytalose was reported by Imai et al. (1984) in *Microbacterium arborescens*. 6-Deoxytalose has a different configuration of

the hydroxyl base at the C4 position of rhamnose, which is a common component of the cell-walls of *Microbacterium*.

Isoprenoid quinones. Species of the genus *Microbacterium* contain menaquinone exclusively as the respiratory quinone. The isoprenoid side-chains are unsaturated and range from 9 to 14 (Collins et al., 1979, 1980; Collins and Jones, 1981; Yamada et al., 1976). The majority of species contain MK-12 as a major component, together with MK-11 or MK-13 as a second major compound (Table 141). Some species have MK-11 as the major component, with MK-10 as the second major compound, and other species have MK-13 and MK-14 as major components. Often, small amounts of menaquinones with one more or less isoprenoid units in the side-chain may be detected. However, as demonstrated by Buczolits et al. (2008a) for *Microbacterium paraoxydans*, the relative amounts of the different menaquinones in a single species are rather constant. Thus, quantitative analysis by HPLC is desirable for determination of menaquinone profile.

Polar lipids. Diphosphatidylglycerol, phosphatidylglycerol, and a glycolipid are generally found as major components of the polar lipids studied so far. In addition, other unidentified glycolipids, phosphoglycolipids, phospholipids, and lipids not containing a sugar moiety, a phosphate, or an amino group may also be present.

Cellular fatty acids. The cellular fatty acid profiles of species of the genus *Microbacterium* are rather similar. Branched fatty acids, either iso or anteiso, are abundant, and the proportion of straight-chain acids is small. The major cellular fatty acids

Phylogeny. The family *Microbacteriaceae* was proposed by Park et al. (1993) based on the phylogenetic relationship derived from the 5S rRNA sequences and confirmed by subsequent analyses of the 16S rRNA genes (Rainey et al., 1994; Takeuchi and Yokota, 1994). Although the genus *Microbacterium* accommodates a large number of species, it forms a single cluster in the phylogenetic tree of the family (Figure 175). This observation is in agreement with studies of Takeuchi and Hatano (1998b), who showed that species containing lysine in the peptidoglycan belonging to the genus *Microbacterium sensu* Collins et al. (1983c) and those containing ornithine, formerly classified in the genus *Aureobacterium* (Collins et al., 1983a), could not be separated from each other on the basis of 16S rRNA gene phylogeny. Thus, they proposed the union of the two genera. The 16S rRNA gene sequence similarity values between species in the genus *Microbacterium* emended by Takeuchi and Hatano (1998b) range from 92.2 to 100%. For comparison, the similarity values of *Microbacterium lacticum*, the type species of the genus, to the other type species of the genera of the family *Microbacteriaceae* range from 89.6 to 96.4% among the type strains.

The phylogeny of species with different types of peptidoglycan was studied extensively using housekeeping genes, such as DNA gyrase subunit B (*gyrB*), RNA-polymerase subunit B (*rpoB*), recombinase A (*recA*), and polyphosphate kinase (*ppk*) (Richert et al., 2007). Analysis of the *ppk* genes and the concatenate tree, combining sequences of all five genes, demonstrated a coherent cluster for the species which contain lysine in the peptidoglycan within the radiation of the current genus *Microbacterium*, including former *Aureobacterium* species and *Microbacterium* species with ornithine in the peptidoglycan (Figure 175).

Biochemical and physiological characteristics. Species of the genus *Microbacterium* are generally aerobic, catalase-positive, and grow at 25–30°C. Oxidase and other activities, such as hydrolysis of starch, gelatin, and Tweens, are variable. Acid is produced from various carbohydrates. However, the production of acid is generally slow or weak. Organic acids and other carbon compounds are assimilated as sole carbon sources, indicated by turbidity in liquid media or by alkalinization of solid media due to consumption of organic acids. These characteristics are dependent on the species. The properties are summarized in Table 141.

Some species of the genus *Microbacterium*, such as *Microbacterium flavescens* and *Microbacterium terregens*, require special nutritional supplements for good growth (Lochhead, 1958). Terregens factor, biotin, thiamine, pantothenic acid, and L-methionine may be required for growth. The terregens factor is replaceable by other siderophores, such as coprogen and ferrichrome (Komagata and Suzuki, 1986b; Lochhead, 1958).

Enrichment and isolation procedures

Species of the genus *Microbacterium* have been isolated from various sources. The type strain of the type species, *Microbacterium lacticum*, was isolated from dairy products and is thermotolerant (Orla-Jensen, 1919). Many species have been isolated from soil, sediment, or activated sludge, as well as from freshwater and seawater. Some have been isolated from animals. *Microbacterium flavum* and *Microbacterium marinilacus* were isolated from a marine ascidian and hydroid, respectively (Kageyama et al., 2007c, 2007d). *Microbacterium imperiale* and *Microbacterium saperdae* were isolated from the moth *Eacles imperialis* and dead *Saperda caracharias* insects, respectively (Lysenko, 1959; Steinhaus, 1941). Some species were isolated from clinical specimens. *Microbacterium binotii* and *Microbacterium paraoxydans* were isolated from human blood (Clermont et al., 2009; Laffineur et al., 2003a), *Microbacterium hominis* was from a lung aspirate (Funke et al., 1995), *Microbacterium oxydans* was from hospital material (Chatelain and Second, 1966), and *Microbacterium resistens* was from a corneal ulcer (Funke et al., 1998).

While most species were isolated without special selective media, medium containing superoxide dismutase and catalase to remove oxygen radicals (Takahashi et al., 2003) was used to isolate *Microbacterium aoyamense*, *Microbacterium deminutum*, *Microbacterium pumilum*, and *Microbacterium terricola* (Kageyama et al., 2006, 2007a)

Microbacterium hydrocarbonoxydans and *Microbacterium oleivorans* were isolated by enrichment culture with 1–5% crude oil in the medium. Some *Microbacterium* strains were isolated through some special screening procedures; D-arabinofuranosidase production by *Microbacterium arabinogalactanolyticum* (Kotani et al., 1972), keratansulfate endo-β-galactosidase production by *Microbacterium keratanolyticum* (Nakazawa et al., 1975; Nakazawa and Suzuki, 1975), reduction of 2,5-diketo-D-gluconic acid to 2-keto-gluconic acid by *Microbacterium ketosireducens* (Takeuchi and Hatano, 1998a), production of *N*-acyl-D-amino acid amidohydrolase by *Microbacterium natoriense* (Liu et al., 2005), degradation of trichothecene mycotoxin by *Microbacterium trichothecenolyticum* (Nakayama et al., 1980), and production of exopolysaccharide by *Microbacterium kitamiense* (Matsuyama et al., 1999).

Maintenance procedures

Most of the species grow well on nutrient agar or trypticase soy agar (TSA). Supplementation with yeast extract generally enhances growth. Cultures of most species stored at 4–8°C will remain viable for 1 or 2 months, depending upon the strain and medium. For long-term preservation, freezing at −80°C or lower or in the vapor phase of liquid nitrogen and freeze-drying are recommended. For freezing, cells are suspended in liquid medium containing 5–20% glycerol. For freeze-drying, cells are suspended in 10% skimmed milk containing 1% monosodium glutamate. Attention should be paid to repeated serial transfers to fresh medium that may lead to weak growth.

Differentiation of the genus *Microbacterium* from other genera

The species of the genus *Microbacterium* can be differentiated from those in other genera of the order *Micrococcales* by chemotaxonomic features, as well as by phylogenetic analysis. Amino acid composition of the peptidoglycan suggesting the B group structure (Schleifer and Kandler, 1972) and menaquinones with

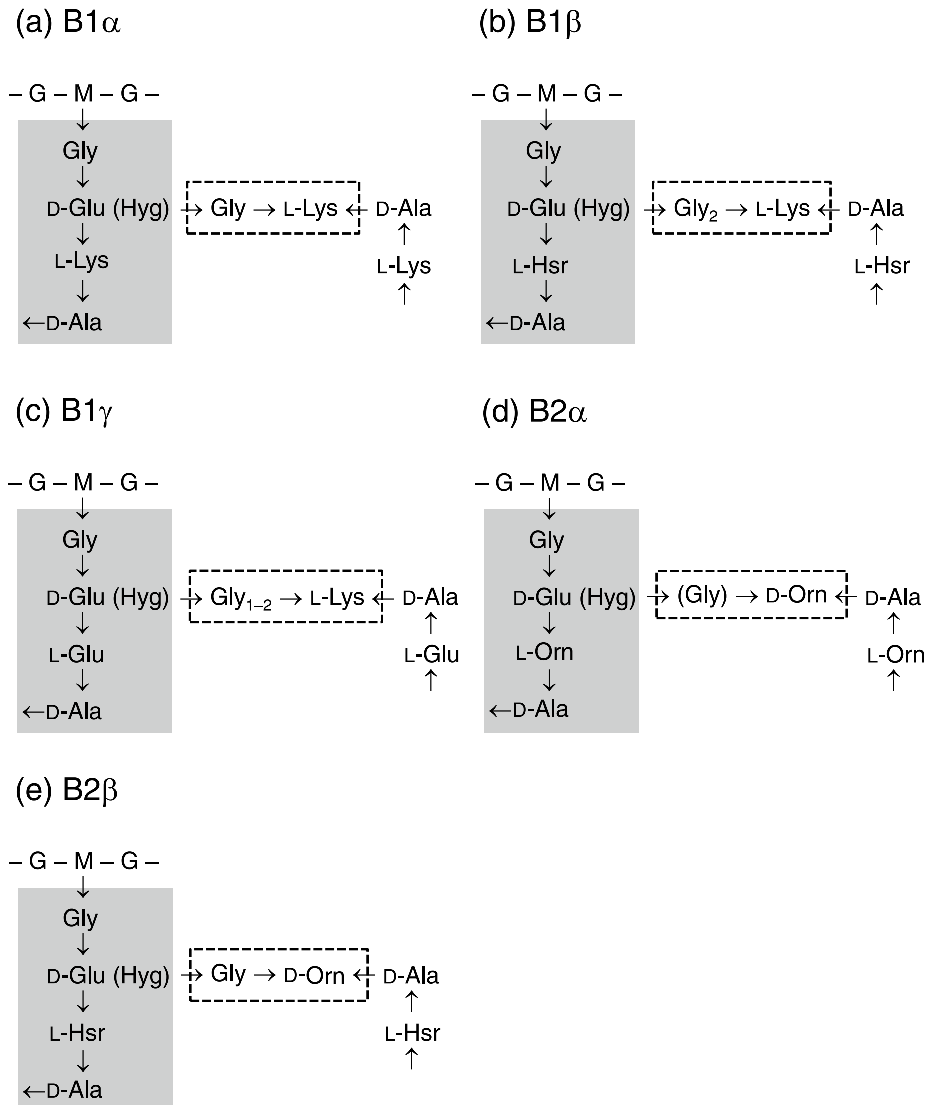

FIGURE 174. Varieties of peptidoglycan structure found in the members of the genus *Microbacterium*. M, *N*-acetyl or glycolyl muramic acid; G, *N*-acetylglucosamine; Ala, alanine; Glu, glutamic acid; Gly, glycine; Hsr, homoserine; Hyg, hydroxyglutamic acid; Lys, lysine; Orn, ornithine. The shaded box and the box with broken line indicate the peptide subunit and interpeptide bridge, respectively. In addition to these units, the amino acids outside of the boxes are those of the neighboring side-chains.

long unsaturated isoprenoid side-chains, i.e. MK-11 to MK-13 as the major components (Collins and Jones, 1981; Schumann et al., 2009), are indicative of the genus. Differentiation of the genus from other genera of the family *Microbacteriaceae* can be also observed by 16S rRNA gene analysis including phylogenetic grouping and chemotaxonomically. The members of the genus *Microbacterium* form a distinct cluster within the family in the phylogenetic tree. Signature nucleotides in the 16S rRNA gene sequences have been proposed by Takeuchi and Hatano (1998b) as follows: positions 69:99 (G/A–T), 129 (C/T), 232 (G), 279 (T), 443:491 (C/T–G), 770:809 (G–C/G), 780 (A), 830:856 (T–A), and 929:1386 (A–T).

While the amino acid composition of the peptidoglycan and the menaquinone profile are useful tools, the glycolation of the cell-wall, as determined by the glycolate test (Uchida et al., 1999), is especially informative. Among the family *Microbacteriaceae*, this trait is only shared by members of the genus *Okibacterium* (Evtushenko et al., 2002), which can be distinguished by phylogenetic analyses. The ornithine-containing *Microbacterium* species can also be further distinguished from *Curtobacterium* by the

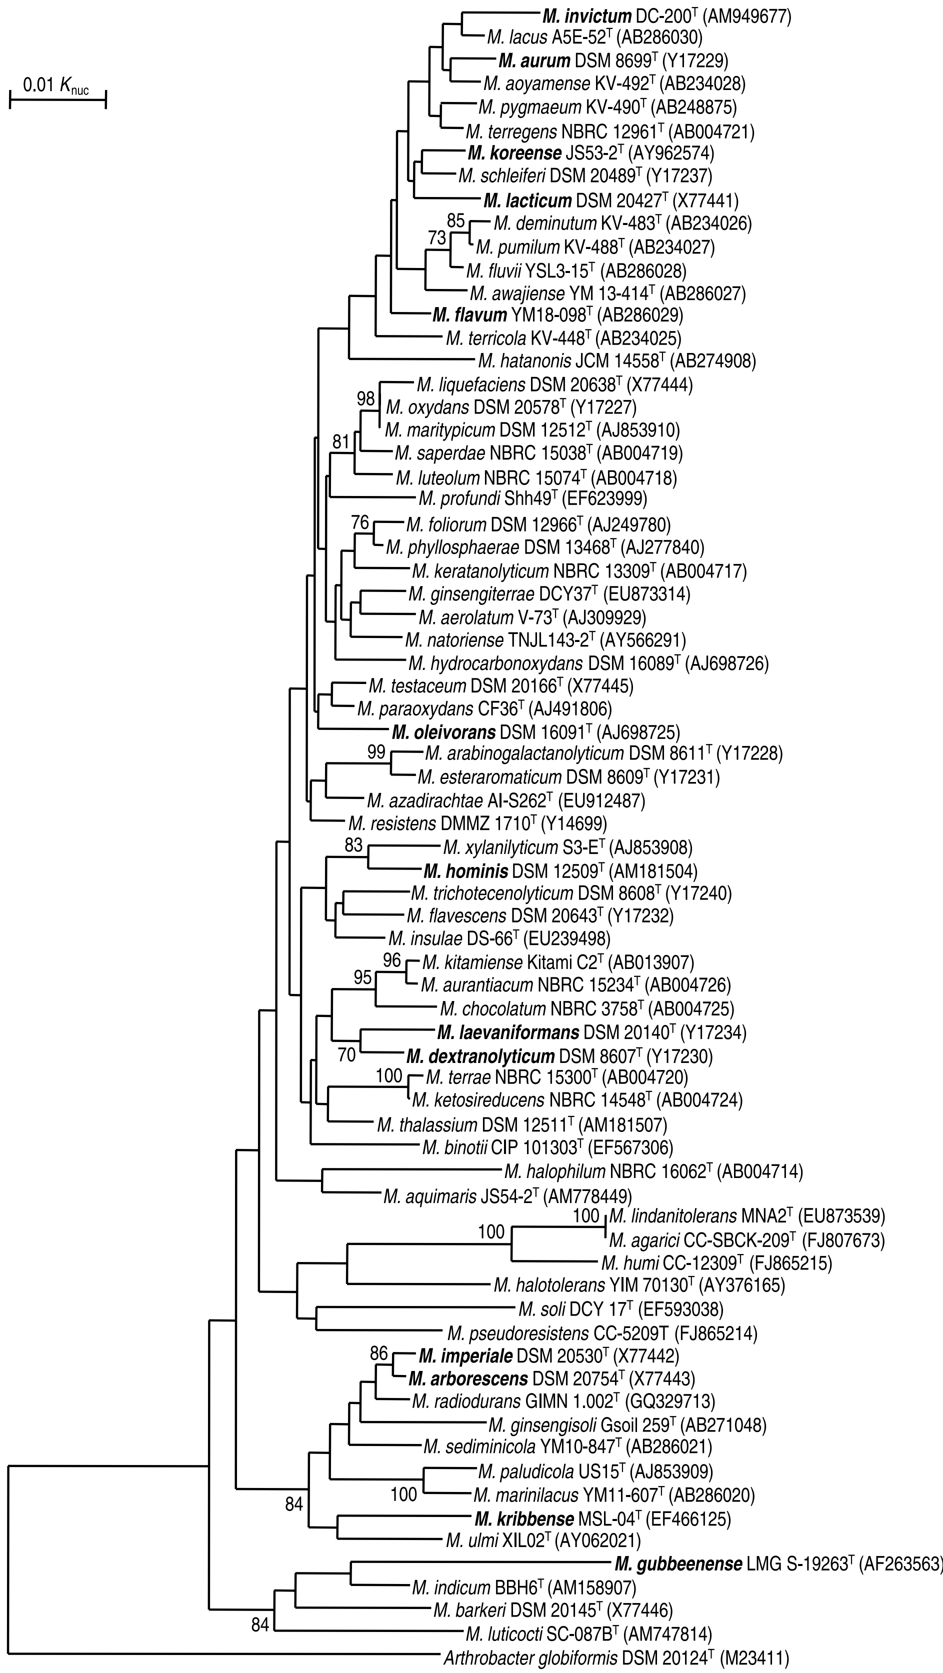

FIGURE 175. Phylogenetic tree derived from 16S rRNA gene sequences of the members of the genus *Microbacterium* constructed with the neighbor-joining method. Bootstrap values (>70%) based on 1000 replicates are shown at branch nodes. The species with names in bold contain lysine in the cell-wall peptidoglycan. Bar = 0.01 K_{nuc} substitutions per nucleotide position.

presence of 1 mole of glycine in the interpeptide bridge and the length of the menaquinone side-chain. Confirmation of the taxonomic placement by polyphasic characterization combining several methods is also recommended.

Taxonomic comments

Orla-Jensen described the genus *Microbacterium* in 1919 with three species, *Microbacterium lacticum*, *Microbacterium liquefeciens*, and "*Microbacterium flavum*," for strains isolated from dairy products or associated equipment. Later, Orla-Jensen (1921) recognized the heterogeneity of the genus *Microbacterium*. Schleifer (1970) revealed that each of the three species had different peptidoglycan structures and only *Microbacterium lacticum* appeared in the Approved Lists of Bacterial Names (Skerman et al., 1980). Improved chemotaxonomy enhanced the reclassification of the Gram-stain-positive, aerobic, irregular rods, namely coryneform-shaped bacteria. "*Microbacterium flavum*" Orla-Jensen (1919) was reclassified in the genus *Corynebacterium* as *Corynebacterium flavescens* (Barksdale et al., 1979). This species is different from the recognized species *Microbacterium flavum* proposed by Kageyama et al. (2007a). Strains with group B peptidoglycan were also found in the coryneform group of bacteria, i.e. *Corynebacterium laevaniformans* and *Brevibacterium imperiale*, which possess type B1α or B1β peptidoglycan (Schleifer and Kandler, 1972).

Collins et al. (1983c) reclassified those bacteria containing lysine in the peptidoglycan in the genus *Microbacterium* with *Microbacterium lacticum*, the type species of the genus. In addition, Collins et al. (1983a) proposed a new genus *Aureobacterium*, with *Aureobacterium liquefaciens* (formerly "*Microbacterium liquefaciens*" Orla-Jensen 1919) as the type species, for species possessing group B peptidoglycan with D-ornithine (Schleifer, 1970). The genus *Aureobacterium* also accommodated the coryneform group of bacteria classified in the genera *Arthrobacter* (Lochhead, 1958), *Corynebacterium* (Dias et al., 1962), and *Curtobacterium* (Yamada and Komagata, 1972a), containing the same peptidoglycan (namely B2β; Schleifer and Kandler, 1972). These genera were well characterized and novel species were added to both genera (Imai et al., 1984; Yokota et al., 1993a, 1993b). Later, Rainey et al. (1994) and Takeuchi and Yokota (1994) revealed that the genera were not phylogenetically distinct. Consequently, Takeuchi and Hatano (1998b) proposed the union of the two genera. At that time, the genera *Microbacterium* and *Aureobacterium* contained 6 and 13 species, respectively. Since the union of the genera, the number of species assigned to the emended genus *Microbacterium* rapidly increased to 71 species.

Phylogenetic trees including all these 71 species also indicate that the species formerly assigned to the two genera are not distinguishable in 16S rRNA gene trees. Because the majority of species share sequence similarities higher than 97%, 16S rRNA gene phylogenies may not be informative. Analyses of house-keeping genes, which may be more reliable molecular chronometers, were able to distinguish species possessing lysine in their peptidoglycan from those with ornithine (Richert et al., 2007). The question then arises as to whether the 16S rRNA gene is a suitable marker for the phylogenetic relationships within the genus *Microbacterium*. Until this question has been answered, the chemotaxonomic varieties in the genus *Microbacterium* must be regarded as species characteristics.

Differentiation of species of the genus *Microbacterium*

Species differentiation is finally concluded by phylogenetic analysis based on 16S rRNA gene sequences and DNA–DNA relatedness analysis. The novelty of species can be reliably determined by DNA–DNA hybridization if the values are less than 70%. When the 16S rRNA gene similarity is 98.0% or greater, DNA–DNA hybridization should be performed for the proposal of a novel species (Schumann et al., 2009). Since many of the species of the genus *Microbacterium* are represented by a single strain, little is known concerning intraspecies variability. Hence, biochemical and physiological characteristics are not reliable for identification of species or differentiation between species. Nevertheless, these traits should be considered for the differentiation and characterization of *Microbacterium* species.

List of species of the genus *Microbacterium*

1. **Microbacterium lacticum** Orla-Jensen 1919, 179[AL]

   lac′ti.cum. L. masc. n. *lac*, *lactis* milk; L. neut. -*icum* suffix used with the sense of pertaining to; N.L. neut. adj. *lacticum* pertaining to milk, lactic.

   The following characteristics are based mainly on Orla-Jensen (1919), Yamada and Komagata (1972b), Schleifer and Kandler (1972), Collins et al. (1983c), and Yokota et al. (1993b).

   Cells are small, slender, nonmotile rods arranged at angles; V forms are observed but no branching. In older cultures, rods become shorter but no rod–coccus cycle is seen. Colonies are 1–3 mm in diameter, circular, convex with entire margins, opaque, and moist. Color of colonies varies from gray-white to yellow. Aerobic. Catalase-positive. Optimum temperature for growth is 30°C. No growth occurs at 37°C. Starch is hydrolyzed. Gelatin, and Tweens 20, 40, 60 and 80 are not hydrolyzed. Urease-negative. Nitrate is reduced. H_2S is not produced. Arginine is not decarboxylated. Acid is produced from glucose, fructose, mannose, galactose, lactose, maltose, cellobiose, dextrin, starch, mannitol, *N*-acetylglucosamine, arbutin, esculin, and salicin, but not from L-arabinose, xylose, rhamnose, ribose, sorbose, sucrose, trehalose, raffinose, inulin, glycerol, erythritol, adonitol, dulcitol, sorbitol, inositol, or methyl α-glucoside. The following organic acids are assimilated: acetate, pyruvate, L-lactate, D-lactate, malate, succinate, fumarate, citrate, and butyrate. The following organic acids are not assimilated: 2-oxoglutarate, formate, propionate, oxalate, malonate, glutarate, adipate, pimelate, glycolate, glyoxylate, gluconante, hippurate, and uriate.

   Cell-wall peptidoglycan contains L-lysine as the diamino acid, conforming to type B1α (Figure 174). Cell-wall acyl

type is glycolyl. Cell-wall sugars are rhamnose, mannose, and galactose. Major menaquinones are MK-11 and MK-12. The polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and dimannosyldiacylglycerol. In addition, an unknown monoglycosyldiacylglycerol and a phosphoglycolipid are also present. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: usually found in milk, dairy products and on dairy equipment.

DNA G+C content (mol%): 69–74.9 (T_m), 70 (HPLC; type strain).

Type strain: ATCC 8180, CCUG 28998, CIP 69.3, DSM 20427, HAMBI 2287, JCM 1379, NBRC 14135, VKM Ac-1145.

Sequence accession no. (16S rRNA gene): X77441.

2. **Microbacterium aerolatum** Zlamala, Schumann, Kämpfer, Valens, Rosselló-Mora, Lubitz and Busse 2002b, 1233[VP]

a.e.ro.la′tum. Gr. n. *aer* air; L. neut. part. adj. *latum* carried; N.L. neut. part. adj. *aerolatum* airborne.

Cells are nonmotile, small rods from 0.5 to 0.7 µm wide by 1.5 to 1.9 µm long, occurring singly or in irregular clusters. Colonies are translucent, yellow-pigmented, circular, slightly convex, opaque, moist, and 2–7 mm in diameter on TSA.

Aerobic. Good growth is observed at 4 and 37°C. Growth occurs in the presence of 6.5% (w/v) NaCl. Catalase-positive and oxidase-negative. Nitrate is reduced to nitrite. β-Galactosidase is positive. Casein and gelatin are not hydrolyzed.

Acid is produced from D-glucose, L-arabinose, D-sucrose, D-galactose, D-mannose, D-maltose, L-rhamnose, D-mannitol, and D-xylose but not from D-trehalose, D-lactose, or glycerol. The following carbon compounds are utilized: L-arabinose, *N*-acetyl-D-glucosamine, cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-mannose, maltose, L-rhamnose, D-ribose, maltitol, sucrose, trehalose, D-xylose, and DL-lactate.

The cell-wall peptidoglycan is B2β type, [HSr]–D-Glu(Hyg)–Gly–D-Orn (Figure 174), containing ornithine as characteristic diamino acid and glycine and homoserine at positions 1 and 3 of the peptide side-chain, respectively. The polar lipid profile is composed of diphosphatidylglycerol, phosphatidylglycerol, and two unknown glycolipids. The major menaquinones are MK-12 and MK-13, with a minor amount of MK-11. Cellular fatty acids contain predominantly $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: air in the chapel "Virgilkapelle" in Vienna, Austria.

DNA G+C content (mol%): 69.3–69.7 (HPLC).

Type strain: V-73, CCM 4955, DSM 14217, JCM 12137, NBRC 103071.

Sequence accession no. (16S rRNA gene): AJ309929.

3. **Microbacterium agarici** Young, Busse, Langer, Chu, Schumann, Arun, Shen, Rekha and Kämpfer 2010, 857[VP]

a.ga.ri′ci. N.L. gen. n. *agarici* of *Agaricus*, the generic name of the mushroom *Agaricus blazei* from where the type strain was isolated.

Cells are short rods, approximately 1–1.2 µm in width and 2–3 µm in length. Aerobic. Catalase and oxidase are positive. Good growth occurs on nutrient agar and R2A agar (Oxoid) at 25–30°C and yellow colonies appear in 3 d.

Acid is produced from D-mannitol and weakly produced from adonitol but not from L-arabinose, cellobiose, glucose, lactose, D-mannose, sucrose, D-xylose D-arabitol, dulcitol, erythritol, maltose, melibiose, methyl D-glucoside, raffinose, rhamnose, salicin, sorbitol, or trehalose. Positive for hydrolysis of esculin (weak reaction), pNP-α-D-glucopyranoside, pNP-β-D-glucopyranoside, L-alanine-pNA oNP-β-D-galactopyranoside, pNP-β-D-xylopyranoside, and L-proline-pNA (oNP, *o*-nitrophenyl; pNP, *p*-nitrophenyl; pNA, *p*-nitroanilide), but negative for pNP-β-D-glucuronide, bis-pNP-phosphate, pNP-phenyl-phosphate, pNP-phosphoryl-choline, 2-deoxythymidine-5′-pNP-phosphate, and L-glutamate-γ-3-carboxy-pNA. Cellobiose, D-fructose, D-glucose, DL-lactate, D-mannose, maltose, D-mannitol, sucrose, trehalose, L-arabinose, D-galactose, L-rhamnose, D-ribose, salicin, D-xylose, adonitol, maltitol, D-sorbitol, putrescine, L-malate, L-proline, and L-aspartate are assimilated, but *N*-acetyl-D-glucosamine, *N*-acetyl-D-galactosamine, *p*-arbutin, gluconate, α-melibiose, *i*-inositol, acetate, propionate, *cis*-aconitate, citrate, fumarate, oxoglutarate, pyruvate, *trans*-aconitate, adipate, 4-aminobutyrate, azelate, glutarate, DL-3-hydroxybutyrate, itaconate, L-leucine, mesaconate, phenylacetate, L-phenylalanine, suberate, L-tryptophan, L-alanine, β-alanine, L-histidine, L-ornithine, L-serine, 3-hydroxybenzoate, and 4-hydroxybenzoate are not assimilated.

The cell-wall peptidoglycan is B2α with an interpeptide bridge of D-Glu–Gly–D-Orn (Figure 174). The predominant quinones are MK-11 and MK-12, with MK-10 as a minor component. The polar lipid profile is composed of diphosphatidylglycerol, phosphatidylglycerol, and one unknown glycolipid. Minor amounts of two phospholipids and another glycolipid are also found. Major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. Predominant polyamines are spermidine and spermine.

Source: the type strain was isolated from the stalk of the edible mushroom *Agaricus blazei* cultivated in the laboratory.

DNA G+C content (mol%): Not known.

Type strain: CC-SBCK-209, CCM 7686, DSM 21798.

Sequence accession no. (16S rRNA gene): FJ807673.

4. **Microbacterium aoyamense** Kageyama, Takahashi and Ōmura 2006, 2115[VP]

a.o.ya.men′se. N.L. neut. adj. *aoyamense* of or belonging to Aoyama, Tokyo, Japan, where the type strain was isolated.

Cells are nonmotile, irregular rods, 0.3–0.5 × 0.4–0.8 µm in size. Colony color is pale yellow. Aerobic and catalase-positive. Growth occurs at pH 5–11 and 14–34°C. Tolerates up to 5% NaCl on 5× diluted nutrient agar medium. D-Glucose, D-galactose, maltose, mannitol, D-mannose, raffinose, L-rhamnose, sucrose, and trehalose are assimilated, but arabinose, fructose, and xylose are not. Esterase (C4), esterase lipase (C8), lipase (C14), leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase, β-glucosidase, and *N*-acetyl-β-glucosamidase are detected with the API ZYM enzyme assay; alkaline phosphatase, cystine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-glucuronidase, α-mannosidase, and α-fucosidase are negative; weak reaction for valine arylamidase.

The peptidoglycan contains ornithine as the diagnostic amino acid. Cell-wall acyl type is glycolyl. The menaquinone profile is predominantly MK-13, with small amounts of MK-14 and MK-12. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. Cell-wall sugars are rhamnose, galactose, and xylose.

The type strain was isolated by adding superoxide dismutase and catalase to the medium to scavenge oxygen radicals.

Source: the type strain was isolated from soil from Aoyama Cemetery, Tokyo, Japan.

DNA G+C content (mol%): 69 (HPLC; type strain).

Type strain: KV-492, NBRC 101280, NRRL B-24451.

Sequence accession no. (16S rRNA gene): AB234028.

5. **Microbacterium aquimaris** Kim, Lee, Oh and Lee 2008a, 1619[VP]

a.qui.ma′ris. L. n. *aqua* water; L. n. *mare -is* sea; N.L. gen. n. *aquimaris* of seawater.

Cells are nonmotile, short rods, 0.6–0.8 × 1.0–1.5 µm in size. Yellowish, translucent, and circular colonies with entire edges (1–2 mm in diameter) are formed in 3 d culture on TSA at 30°C. Aerobic. Catalase and oxidase are positive. Growth occurs at 15–37°C, pH 6–10, and in up to 10% (w/v) NaCl. Indole and H_2S are not produced. Nitrate is not reduced to nitrite. Esculin is hydrolyzed but starch, gelatin, and urea are not. β-Galactosidase is produced but arginine dihydrolase, ornithine dehydroxylase, and lysine decarboxylase are not. Voges–Proskauer test is positive but methyl red test is negative.

In the API 50 CH gallery, acid is produced from esculin, arbutin, cellobiose, glucose, maltose, mannitol, mannose, and salicin and weakly from fructose, galactose, gluconate, glycerol, 5-ketogluconate, methyl β-D-xylose, ribose, and turanose, but not from *N*-acetylglucosamine, adonitol, amygdalin, D- and L-arabinose, D- and L-arabitol, dulcitol, erythritol, D- and L-fucose, gentiobiose, glycogen, inositol, inulin, 2-ketogluconate, lactose, D-lyxose, melezitose, melibiose, methyl α-D-glucoside, methyl α-D-mannoside, raffinose, sorbitol, sorbose, starch, D-tagatose, trehalose, xylitol, or L-xylose. 5-Ketogluconate is utilized as a sole carbon source, but acetate, *N*-acetylglucosamine, adipate, L-alanine, L-arabinose, caprate, citrate, L-fucose, gluconate, D-glucose, glycogen, histidine, 3-hydroxybenzoate, 4-hydroxybenzoate, 3-hydroxybutyrate, inositol, itaconate, 2-ketogluconate, DL-lactate, malate, malonate, maltose, mannitol, mannose, melibiose, phenylacetate, L-proline, propionate, rhamnose, D-ribose, salicin, L-serine, D-sorbitol, suberate, sucrose, and valerate are not.

The peptidoglycan contains ornithine and conforms to type B2β: [L-Hsr]–D-Glu(Hyg)–Gly–D-Orn (Figure 174). The cell-wall acyl type is glycolyl. The cell-wall sugars are glucose and galactose. The menaquinone is composed of predominantly MK-11, with MK-12 and MK-10. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. The polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and an unknown glycolipid.

Source: the type strain was isolated from seawater at Jeju, Korea.

DNA G+C content (mol%): 69.3–69.9 (HPLC), 69.3 (type strain).

Type strain: JS54-2, DSM 19713, JCM 15625, KCTC 19124.

Sequence accession no. (16S rRNA gene): AM778449.

6. **Microbacterium arabinogalactanolyticum** (Yokota, Takeuchi, Sakane and Weiss 1993a) Takeuchi and Hatano 1998b, 745[VP] (*Aureobacterium arabinogalactanolyticum* Yokota, Takeuchi, Sakane and Weiss 1993a, 560)

a.ra.bi.no.ga.lac.ta.no.ly′ti.cum. N.L. n. *arabinogalactanum* arabinogalactan, polysaccharide produced by the bacterium *Mycobacterium tuberculosis*; N.L. neut. adj. *lyticum* (from Gr. neut. adj. *lutikon*) able to loosen, able to dissolve; N.L. neut. adj. *arabinogalactanolyticum* arabinogalactan dissolving.

The following characteristics are based mainly on the data of Yokota et al. (1993a).

Cells are nonmotile rods arranged at angles; V forms are observed but no branching. Colonies are 1–3 mm in diameter, circular, low convex with entire margins, opaque, and moist. No pigment is produced. Aerobic. Optimum temperature for growth is 28°C. Growth occurs in the presence of 2% NaCl. Oxidative. Gelatin, starch, and Tweens 60 and 80 are hydrolyzed but Tweens 20 and 40 are not. Nitrate is not reduced. Voges–Proskauer test is negative. Positive for methyl red test, urease, and arginine decarboxylase. Positive for production of H_2S. Acetate, malate, succinate, oxalate, fumarate, DL-lactate, propionate, and hippurate are assimilated. Formate and citrate are assimilated weakly.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid (and hydroxyglutamic acid), glycine, and alanine, conforming to type B2β (Figure 174). A small amount of lysine is also detected. Cell-wall acyl type is glycolyl. Cell-wall sugar is galactose. Major menaquinones are MK-12 and MK-13. Major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, an unidentified glycolipid, and an unidentified phosphoglycolipid. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Type strain produces α-D-arabinofuranosidase (Kotani et al., 1972; Misaki et al., 1977).

Source: the type strain was isolated from soil (Kotani et al., 1972).

DNA G+C content (mol%): 69.3 (HPLC; type strain).

Type strain: ATCC 51926, CIP 103814, DSM 8611, JCM 9171, LMG 16469, NBRC 14344, VKM Ac-1943.

Sequence accession no. (16S rRNA gene): Y17228.

7. **Microbacterium arborescens** (*ex* Frankland and Frankland 1889) Imai, Takeuchi and Banno 1985, 535[VP] (Effective publication: Imai, Takeuchi and Banno 1984, 283.) ["*Flavobacterium arborescens*" (Frankland and Frankland 1889) Bergey, Harrison, Breed, Hammer and Huntoon 1923]

ar.bo.res′cens. L. part. adj. *arborescens* becoming a tree.

Motile rods, 0.5 by 2.5 µm (Breed et al., 1957). Growth on nutrient agar is poor; addition of 0.5% brain heart infusion (BHI) gives good growth. Color of colonies is orange. Aerobic. Good growth is shown at 28–37°C. Gelatin is hydrolyzed but Tweens 20, 40, and 80 are not. Hydrolysis of Tween 60 is weak. Production of H_2S is positive. Nitrate is not reduced. Voges–Proskauer test is negative. Arginine dihydrolase-negative. Acid is produced from D-xylose, sucrose, L-arabinose, and trehalose (weak reaction), but not from raffinose or inulin (Imai et al., 1984; Yokota et al., 1993b). Acetate and fumarate are assimilated but lactate, malate, and propionate are not (Yokota et al., 1993b).

Cell-wall peptidoglycan contains lysine as the diamino acid. The molar ratio of amino acids, alanine, glycine, lysine, glutamic acid with 3-hydroxyglutamic acid, and homoserine indicates that the peptidoglycan structure is type B1β (Figure 174). Cell-wall acyl type is glycolyl. Cell-wall sugars are mannose, galactose, and 6-deoxytalose. Major menaquinones are MK-11 and MK-12. Major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and unidentified glycolipids (Yokota et al., 1993b). Cellular fatty acids are predominantly $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso (Yokota et al., 1993b).

Source: isolated from river and lake water (Breed et al., 1957).

DNA G+C content (mol%): 71 (type strain; Weeks, 1974), 71.0 (HPLC; Yokota et al., 1993b).

Type strain: ATCC 4358, CIP 55.81, DSM 20754, HAMBI 1892, JCM 5884, LMG 4009, NBRC 3750, VKM Ac-1944.

Sequence accession no. (16S rRNA gene): X77443.

8. **Microbacterium aurantiacum** Takeuchi and Hatano 1998a, 978[VP]

au.ran.ti′a.cum. N.L. n. *aurantium* specific name of the orange; L. neut. suff. *-acum* adjectival suffix used with the sense of belonging to; N.L. neut. adj. *aurantiacum* orange-colored.

Cells are nonmotile, irregular, short rods, 0.2–0.5 × 0.6–2.0 µm in size, arranged at angles; V forms but no branching or rod–coccus cycle are observed. Colonies are 2–4 mm in diameter, orange-pigmented, circular, low convex with entire margins, opaque, and moist. Growth occurs at 37°C (optimal at 28°C). Grows in 5% NaCl but weak growth is observed in 6.5% NaCl. Starch, and Tweens 20, 40, 60, and 80 are hydrolyzed but gelatin is not. H_2S is produced. Methyl red and Voges–Proskauer tests are negative. Arginine dihydrolase is not produced. Acid is produced from mannose and sucrose; acid production is variable from glucose and xylose and negative from L-arabinose, galactose, inulin, melezitose, raffinose, rhamnose, ribose, and trehalose. The following compounds are assimilated: maltose, mannose, mannitol, fumarate, gluconate, and propionate. Assimilation of arabinose, lactate, and malate is variable. *N*-Acetylglucosamine, acetate, adipate, caprate, citrate, and phenylacetate are not assimilated.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid (and hydroxyglutamic acid), glycine, and alanine corresponding to peptidoglycan type B2β (Figure 174). Cell-wall sugars are rhamnose, galactose, and fucose. Major menaquinone is MK-12. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{15:0}$ iso, and $C_{16:0}$ iso.

Source: the type strain was isolated from sewage.

DNA G+C content (mol%): 70.1–70.3 (HPLC).

Type strain: ATCC 49090, CIP 105730, DSM 12506, JCM 9177, NCFB 2288, NBRC 15234, VKM Ac-2075.

Sequence accession no. (16S rRNA gene): AB004726.

9. **Microbacterium aurum** Yokota, Takeuchi and Weiss 1993b, 552[VP]

au′rum. L. n. *aurum* gold.

Cells are nonmotile, small, slender rods arranged at angles; V forms are observed but no branching. In older cultures, rods become shorter but no rod–coccus cycle is shown. Colonies are 1–2 mm in diameter, golden yellow-pigmented, circular, low convex with entire margins, opaque, and moist. Aerobic. Optimum temperature for growth is approximately 30°C. Esculin, starch, and Tween 60 are hydrolyzed but gelatin and Tweens 20, 40 and 80 are not. Urease-negative. H_2S is produced. Voges–Proskauer test is negative. Arginine is not decarboxylated. Acid is produced weakly from glucose, mannose, fructose, maltose, cellobiose, mannitol, galactose, L-rhamnose, sucrose, trehalose, raffinose, starch, and inulin but not from D-xylose, L-arabinose, D-arabinose, glycerol, arbutin, esculin, salicin, ethanol, butanol, melibiose, melezitose, ribose, L-sorbose, xylitol, erythritol, adonitol, dulcitol, sorbitol, inositol, methanol, or methyl α-D-glucoside. Acetate, 2-oxoglutarate, and succinate are assimilated but pyruvate, lactate, malate, maleate, formate, butyrate, oxalate, pimelate, glycolate, glyoxylate, gluconate, propionate, and hippurate are not.

Cell-wall peptidoglycan contains lysine as the diamino acid and conforms to type B1β (Figure 174). Cell-wall acyl type is glycolyl. Cell-wall sugars are fucose, galactose, and glucose. Major menaquinones are MK-11 and MK-12. The polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and dimannosyldiacylglycerol. Cellular fatty acids are predominantly $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from corn steep liquor.

DNA G+C content (mol%): 69.2 (HPLC; type strain).

Type strain: H-5, ATCC 51345, CIP 103994, DSM 8600, JCM 9179, NBRC 15204, VKM Ac-1950.

Sequence accession no. (16S rRNA gene): Y17229.

10. **Microbacterium awajiense** Kageyama, Matsuo, Kasai, Shizuri, Ōmura and Takahashi 2008b, 2471[VP] (Effective publication: Kageyama, Matsuo, Kasai, Shizuri, Ōmura and Takahashi, 2008a, 4.)

awa.ji.en′se. N.L. neut. adj. *awajiense* of or pertaining to Awaji Island, Hyogo, Japan, where the strain was isolated.

Cells are irregular rods, 0.5–0.8 × 0.7–1.2 µm in size. Nonmotile. Colony color is light yellow. Catalase-positive, aerobic. Grows at pH 6–11 and 13–38°C. Grows in up to 5% NaCl. D-Galactose, D-glucose, maltose, D-mannitol, D-mannose, raffinose, L-rhamnose, trehalose, and xylose are assimilated. Sucrose is not assimilated. Alkaline phosphatase, esterase (C4), esterase, lipase (C8), lipase (C14), leucine arylamidase, valine arylamidase, cystine arylamidase, chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, and α-fucosidase are detected by the API ZYM enzyme assay; trypsin, α-galactosidase, β-glucuronidase, and α-mannosidase are negative. β-Galactosidase reaction is weak.

The peptidoglycan contains ornithine as the diagnostic amino acid. Cell-wall acyl type is glycolyl. The major menaquinones are MK-12, MK-13, and MK-14. Predominant cellular fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso, followed by $C_{16:0}$ iso and $C_{15:0}$ iso.

Source: the type strain was isolated from sediment collected from the shore of Yura, Awaji Island, Japan.

DNA G+C content (mol%): 70 (HPLC) for type strain.

Type strain: YM13-414, DSM 18907, MBIC08276, NBRC 103565.

Sequence accession no. (16S rRNA gene): AB286027.

11. **Microbacterium azadirachtae** Madhaiyan, Poonguzhali, Lee, Lee, Saravanan and Santhanakrishnan 2010, 1690[VP]

a.za.di.rach′ta.e. N.L. n. *Azadirachta* a botanical genus name; N.L. gen. n. *azadirachtae* of *Azadirachta* isolated from *Azadirachta indica*.

Cells are motile, short rods, approximately 0.3–0.4 µm wide and 0.6–0.7 µm long, occurring singly or in pairs. Colonies are 1–2 mm in diameter, smooth, circular, and light-yellow after 48 h at 28°C on R2A agar. Growth is observed at 0–5.5% NaCl, pH 5.0–10.0, and 10–37°C, with optimal growth at 0–1% NaCl, pH 7.0–8.0, and 28°C.

Strictly aerobic. Catalase-positive and oxidase-negative. Nitrate is not reduced to nitrite. Esculin, casein, and tributyrin are hydrolyzed. Starch, gelatin, and urea are not hydrolyzed. No growth on MacConkey agar. Tolerates up to 1 mM $NiCl_2$ and 0.5 mM $CdCl_2$. The type strain tolerates bacitracin, cephalosporin, nalidixic acid, and polymyxin B (all at 500 µg/ml). Acid is produced from glucose and rhamnose. The following carbon substrates are oxidized (Biolog GP2 MicroPlates): β-cyclodextrin, dextrin, Tween 40, Tween 80, *N*-acetyl-D-galactosamine, *N*-acetyl-β-D-mannosamine, amygdalin, L-arabinose, D-arabitol, arbutin, cellobiose, D-fructose, L-fucose, D-galactose, gentiobiose, D-gluconic acid, α-D-glucose, *myo*-inositol, maltose, maltotriose, D-mannitol, D-mannose, melezitose, methyl β-D-glucoside, palatinose, D-psicose, L-rhamnose, salicin, D-sorbitol, sucrose, D-tagatose, trehalose, turanose, acetic acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, α-ketobutyric acid, D-lactic acid methyl ester, L-lactic acid, D-malic acid, L-malic acid, pyruvic acid methyl ester, pyruvic acid, succinamic acid, succinic acid, *N*-acetyl-L-glutamic acid, L-alaninamide, D-alanine, L-alanine, L-alanyl glycine, L-asparagine, L-glutamic acid, glycyl L-glutamic acid, L-serine, putrescine, glycerol, adenosine, 2′-deoxyadenosine, inosine, thymidine, uridine, and adenosine-5′-monophosphate. Negative for assimilation of α-cyclodextrin, glycogen, inulin, mannan, D-galacturonic acid, lactose, lactulose, melibiose, methyl α-D-galactoside, methyl β-D-galactoside, 3-methyl-D-glucose, methyl α-D-glucoside, methyl α-D-mannoside, raffinose, D-ribose, sedoheptulosan, stachyose, xylitol, D-xylose, α-hydroxybutyric acid, α-ketovaleric acid, lactamide, succinic acid monomethyl ester, propionic acid, L-pyroglutamic acid, 2,3-butanediol, thymidine-5′-monophosphate, uridine-5′-monophosphate, D-fructose 6-phosphate, α-D-glucose 1-phosphate, D-glucose 6-phosphate, and DL-α-glycerol phosphate.

The cell-wall peptidoglycan is of type B2β containing ornithine (Figure 174). Cell-wall acyl type is glycolyl. The predominant quinones are MK-12 and MK-13. Major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

The type strain shows plant-growth-promoting traits including indole-3-acetic acid production, phosphate-solubilization, 1-aminocyclopropane-1-carboxylate deaminase activity, and sulfur oxidation in plate assays, but is negative for siderophore production (Madhaiyan et al., 2010).

Source: the type strain was isolated from the rhizoplane of neem seedlings at Tamilnadu Agricultural University (TNAU), Coimbatore, Tamilnadu, India.

DNA G+C content (mol%): 69.5 (HPLC; type strain).

Type strain: AI-S262, JCM 15681, KCTC 19668, LMG 24772.

Sequence accession no. (16S rRNA gene): EU912487.

12. **Microbacterium barkeri** (Collins, Jones, Keddie, Kroppenstedt and Schleifer 1983a) Takeuchi and Hatano 1998b, 745[VP] (*Aureobacterium barkeri* Collins, Jones, Keddie, Kroppenstedt and Schleifer 1983a, 249; "*Corynebacterium barkeri*" Dias, Bilimoria and Bhat 1962, 66)

bar′ker.i. N.L. gen. masc. n. *barkeri* of Barker; named for H.A. Barker, an American biochemist.

The following characteristics are based mainly on Schleifer and Kandler (1972), Collins et al. (1983a), Suzuki and Komagata (1983), and Yokota et al. (1993a).

Cells are motile, small, slender rods, arranged at angles; V forms are observed in young cultures but no branching. In older cultures, rods become shorter but no rod–coccus cycle is seen. Good growth is observed on nutrient agar. Colonies are 1–3 mm in diameter, low convex, circular with entire margins, shiny, and moist. Colonies are yellow in color. Obligately aerobic. Catalase-positive. Optimum temperature for growth is 30°C. Esculin, starch, hippurate, and Tweens 20, 40 and 60 are hydrolyzed. Tween 80 is not hydrolyzed. Urease-negative. Arginine dihydrolase is positive. Nitrate is reduced. H_2S is produced. Voges–Proskauer test is negative but methyl red test is positive. Tellurite (0.05%) is reduced. Acid is produced slowly and weakly from glucose oxidatively. Acetate, malate, succinate, and fumarate are assimilated. Propionate and hippurate are assimilated weakly. Formate, citrate, DL-lactate, and oxalate are not assimilated.

Cell-wall peptidoglycan contains D-ornithine as the diamino acid and conforms to type B2β: [L-Hsr]–D-Glu–Gly–D-Orn (Figure 174). Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose, galactose, and glucose. Major menaquinones are MK-11 and MK-12. The polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and a diglycosyldiacylglycerol. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: the type strain was isolated from raw domestic sewage.

DNA G+C content (mol%): 68.7 (HPLC; type strain).

Type strain: ATCC 15954, CCM 1928, CCUG 33090, BCRC 11642, CIP 102692, DSM 20145, HAMBI 1894, IAM 12585, IMET 10688, JCM 1343, LMG 16341, NBRC 15036, NCIMB 9658, VKM Ac-1020.

Sequence accession no. (16S rRNA gene): X77446.

13. **Microbacterium binotii** Clermont, Diard, Bouchier, Vivier, Bimet, Motreff, Welker, Kallow and Bizet 2009, 1020[VP]

bi.no′ti.i. N.L. gen. masc. n. *binotii* of Binot, named in honor of Jean Binot (1867–1909), who created the Collection de l'Institut Pasteur.

Aerobic, nonmotile, short rods. Colonies are yellow, circular, and 1–2 mm in diameter after 48 h culture on

trypto-casein-soy agar at 30°C. Catalase-positive and oxidase-negative. Growth occurs at 15–37°C and in 0–6% NaCl. Nitrate is not reduced to nitrite. Starch is decomposed but gelatin and casein are not. Voges–Proskauer and indole production tests are negative. Positive for esterase, acid phosphatase, α- and β-galactosidases, *N*-acetyl-β-glucosaminidase, and α- and β-glucosidases. Negative for ornithine decarboxylase, arginine dihydrolase, lysine decarboxylase, urease, trypsin, β-glucuronidase, α-mannosidase, and α-fucosidase. Acid is produced from glycerol, L-arabinose, D-xylose, galactose, D-glucose, D-fructose, D-mannose, mannitol, arbutin, esculin, salicin, cellobiose, maltose, lactose, sucrose, trehalose, starch, β-gentiobiose, turanose, and gluconate.

The diamino acid of peptidoglycan is ornithine associated with alanine, glycine, homoserine, glutamic acid, and hydroxyglutamic acid, and conforms to type B2β. The cell-wall sugars are galactose, mannose, and rhamnose. The predominant menaquinones are MK-10, MK-11, and MK-12. Main polar lipids are diphosphatidylglycerol, phosphatidylglycerol, an unknown glycolipid, and an unknown phospholipid. Major cellular fatty acid is $C_{17:0}$ anteiso; $C_{15:0}$ anteiso and $C_{16:0}$ iso are also found.

Source: the type strain was isolated from human blood.

DNA G+C content (mol%): 70–72 (HPLC), 71.7 (type strain).

Type strain: CIP 101303, DSM 19164, JCM 16365.

Sequence accession no. (16S rRNA gene): EF567306.

Further comments: CIP 102116 is a reference strain.

14. **Microbacterium chocolatum** Takeuchi and Hatano 1998a, 979[VP]

cho.co.la′tum. N.L. neut. adj. *chocolatum* chocolate-colored, derived from the Mexican *chocolatl*, chocolate.

Cells are nonmotile, irregular, short rods, 0.2–0.5 × 0.6–2.0 µm in size, arranged at angles; V forms but no branching or rod–coccus cycle are observed. Colonies are 2–4 mm in diameter, orange or dull orange in color, circular, low convex with entire margins, opaque, and moist. Growth occurs at 37°C (optimal at 28°C). Weak growth occurs in 2% NaCl but not in 5% NaCl. Starch, and Tweens 20, 40, 60, and 80 are hydrolyzed but gelatin is not. H_2S is produced. Methyl red and Voges–Proskauer tests are negative. Arginine dihydrolase is not produced. Acid is produced from mannose, sucrose, and xylose but not from L-arabinose, galactose, glucose, inulin, melezitose, raffinose, rhamnose, ribose, or trehalose. Maltose and gluconate are assimilated; mannose and mannitol are weakly assimilated; and arabinose, *N*-acetylglucosamine, acetate, adipate, caprate, citrate, fumarate, lactate, malate, phenylacetate, and propionate are not assimilated.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid (and hydroxyglutamic acid), glycine, and alanine, corresponding to peptidoglycan type B2β (Figure 174). Cell-wall sugars are rhamnose and galactose, with small proportion of mannose and xylose. Major menaquinone is MK-12. Cellular fatty acids are composed of $C_{17:0}$ anteiso, $C_{15:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from culture contamination.

DNA G+C content (mol%): 69.5 (HPLC).

Type strain: BUCSAV 207, CIP 105729, DSM 12507, JCM 12412, NCIMB 8181, NBRC 3758, VKM Ac-2078.

Sequence accession no. (16S rRNA gene): AB004725.

Further comments: The type strain was originally isolated by M.H. Knutsen and named "*Chromobacterium chocolatum*" Knutsen (1944) (Clise, 1948), although the name does not appear in the Approved Lists of Bacterial Names.

15. **Microbacterium deminutum** Kageyama, Takahashi and Ōmura 2006, 2115[VP]

de.mi.nu′tum. L. part. neut. adj. *deminutum* diminutive.

Cells are nonmotile, irregular rods, 0.3–0.7 × 0.5–0.9 µm. Colony color is pale yellow. Aerobic and catalase-positive. Growth occurs at pH 6–9 and 17–31°C. Tolerates up to 4% NaCl on 5× diluted nutrient agar medium. D-Glucose, D-galactose, maltose, D-mannose, L-rhamnose, and sucrose are assimilated, but arabinose, fructose, mannitol, raffinose, trehalose, and xylose are not. Esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, and *N*-acetyl-β-glucosamidase are detected with the API ZYM enzyme assay; α-fucosidase is not detected. Reactions for alkaline phosphatase, lipase (C14), and α-mannosidase are weak.

The peptidoglycan contains ornithine as the diagnostic amino acid. Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose, fucose, galactose, glucose, and xylose. The quinone system contains predominantly menaquinone MK-13, with moderate amounts of MK-12 and MK-14. Major cellular fatty acids are $C_{17:0}$ anteiso and $C_{15:0}$ anteiso.

The type strain was isolated by adding superoxide dismutase and catalase to the culture medium to scavenge oxygen radicals.

Source: the type strain was isolated from soil from Aoyama Cemetery, Tokyo, Japan.

DNA G+C content (mol%): 69 (HPLC; type strain).

Type strain: KV-483, NBRC 101278, NRRL B-24453.

Sequence accession no. (16S rRNA gene): AB234026.

16. **Microbacterium dextranolyticum** Yokota, Takeuchi and Weiss 1993b, 551[VP]

dex.tra.no.ly′ti.cum. N.L. n. *dextranum* dextran, polysaccharide produced by bacteria; N.L. neut. adj. *lyticum* (from Gr. neut. adj. *lutikon*) able to loosen, able to dissolve; N.L. neut. adj. *dextranolyticum* dextran dissolving.

Cells are nonmotile, small, slender rods arranged at angles; V forms are observed but no branching. In older cultures, rods become shorter but no rod–coccus cycle is seen. Colonies are 2–4 mm in diameter, yellow-pigmented, circular, low convex with entire margins, opaque, and moist. Aerobic. Optimum temperature for growth is 30°C. Esculin, and Tweens 20, 40, 60, and 80 are hydrolyzed but gelatin and starch are not. Urease-negative. H_2S production and Voges–Proskauer test are positive. Arginine is not decarboxylated. Acid is produced weakly from glucose, mannose, fructose, maltose, cellobiose, mannitol, xylose, L-arabinose, galactose, sucrose, lactose, trehalose, raffinose, inulin, arbutin, esculin, ethanol, butanol, melibiose, and melezitose but not from ribose, D-arabinose, L-sorbose, xylitol, erythritol,

adonitol, dulcitol, sorbitol, inositol, methanol, methyl α-D-glucoside, L-rhamnose, starch, glycerol, or salicin. Pyruvate, fumarate, and succinate are assimilated but acetate, lactate, malate, 2-oxoglutarate, maleate, formate, butyrate, oxalate, pimelate, glycolate, glyoxylate, gluconate, propionate, and hippurate are not.

Cell-wall peptidoglycan contains L-lysine as the diamino acid, conforming to type B1α (Figure 174). Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose, 6-deoxytalose, galactose, and glucose. Major menaquinones are MK-11 and MK-12. The polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and dimannosyldiacylglycerol. In addition, an unknown monoglycosyldiacylglycerol and phosphoglycolipid are also present. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{16:0}$ iso.

The type strain is known to produce a dextran-α-1,2-debranching enzyme (Kobayashi et al., 1978; Mitsuishi et al., 1979).

Source: the type strain was isolated from soil.

DNA G+C content (mol%): 68.3 (HPLC; type strain).

Type strain: M-73, ATCC 51344, CCUG 38517, CIP 103993, DSM 8607, JCM 9180, NBRC 14592, NRRL B-23242, VKM Ac-1940.

Sequence accession no. (16S rRNA gene): AB007417.

17. **Microbacterium esteraromaticum** (Omelianski 1923) Takeuchi and Hatano 1998b, 745[VP] ("*Bacterium esteraromaticum*" Omelianski 1923; *Flavobacterium esteraromaticum* Bergey, Harrison, Breed, Hammer and Huntoon 1930, 150; *Aureobacterium esteraromaticum* Yokota, Takeuchi, Sakane and Weiss 1993a, 560)

es.ter.a.ro.ma′ti.cum. N.L. n. *ester* ester; L. neut. adj. *aromaticum* aromatic, fragrant; N.L. neut. adj. *esteraromaticum* smelling sweet due to esters.

The following characteristics are based mainly on the data of Yokota et al. (1993a).

Cells are rods arranged at angles; V forms are observed but no branching. Motile with lateral flagella. Colonies are 1–3 mm in diameter, yellow-pigmented, circular, low convex with entire margins, opaque, and moist. Aerobic. Optimum temperature for growth is 28°C. No growth occurs in the presence of 2% NaCl. Oxidative. Starch, and Tweens 40, 60, and 80 are hydrolyzed but hydrolysis of gelatin and Tween 20 is variable depending on strain. Nitrate is not reduced. Methyl red and Voges–Proskauer tests are negative. Urease-negative. Positive for production of H_2S. Arginine decarboxylase-negative. Acetate, malate, succinate, oxalate (weak reaction), fumarate, DL-lactate, propionate, and hippurate are assimilated but formate and citrate are not.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid (and hydroxyglutamic acid), glycine, and alanine, conforming to type B2β (Figure 174). Cell-wall acyl type is glycolyl. Cell-wall sugars are galactose and glucose. Major menaquinones are MK-12 and MK-13. The polar lipids are diphosphatidylglycerol and phosphatidylglycerol. An unidentified glycolipid is also present. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: the type strain was isolated from soil (Omelianski, 1923).

DNA G+C content (mol%): 69 (T_m) (Weeks, 1974), 68.8 (HPLC; type strain).

Type strain: ATCC 8091, CIP 103916, DSM 8609, JCM 9172, LMG 4020, NBRC 3751, VKM Ac-1942.

Sequence accession no. (16S rRNA gene): Y17231.

18. **Microbacterium flavescens** (Lochhead 1958) Takeuchi and Hatano 1998b, 745[VP] (*Arthrobacter flavescens* Lochhead 1958, 170; *Aureobacterium flavescens* Collins, Jones, Keddie, Kroppenstedt and Schleifer 1983a, 247)

fla.ves′cens. L. v. *flavesco* to become golden yellow; L. part. adj. *flavescens* becoming yellow.

The following characteristics are based mainly on Lochhead (1958), Collins et al. (1983a), and Yokota et al. (1993a).

Small, irregular, nonmotile rods. Cells in young cultures are 0.4–0.6 × 1.0–6.0 µm in size, arranged at angles; V forms are observed but no branching. In older cultures, coccoid forms, 0.5 µm in diameter, are observed but no rod–coccus cycle is seen. Nutritionally exacting; terregens factor, biotin, and thiamine are required for growth. Colonies are 0.2–0.5 mm in diameter, low convex, and circular with entire edge. A yellow non-diffusible pigment is produced. Obligately aerobic. Catalase-positive. Oxidase is weakly positive. Optimum temperature for growth is 25°C. Growth occurs at 10°C but not at 37°C. Soil extract is required for growth. Gelatin, starch, and DNA are hydrolyzed. Tweens 20, 40, 60, and 80 are hydrolyzed. Urease-negative. Arginine is not decarboxylated. Nitrate is reduced. H_2S is produced. The terregens factor may be replaced by other siderophores such as coprogen and ferrichrome. When supplied with terregens factor, vitamins, and glucose as carbon plus energy source, ammonium salts or nitrates are utilized as nitrogen source. Acid is produced slowly from D-glucose, galactose, and few other sugars. Acetate is assimilated. Succinate, fumarate, DL-lactate, propionate, and hippurate are assimilated weakly. Formate, citrate, malate, and oxalate are not assimilated.

Cell-wall peptidoglycan contains D-ornithine as the diamino acid and L-homoserine, conforming to type B2β (Figure 174). Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose, galactose, and glucose. Major menaquinones are MK-13 and MK-14. The polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and diglycosyldiacylglycerol. Cellular fatty acids are predominantly $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from soil.

DNA G+C content (mol%): 66.9 (HPLC; type strain).

Type strain: ATCC 13348, CCUG 29000, CIP 102401, DSM 20643, HAMBI 1909, JCM 11568, JCM 3877, LMG 3028, NCIMB 9221, NBRC 15039, VKM Ac-1415.

Sequence accession no. (16S rRNA gene): Y17232.

19. **Microbacterium flavum** Kageyama, Takahashi, Matsuo, Adachi, Kasai, Shizuri and Ōmura 2008c, 529[VP] (Effective publication: Kageyama, Takahashi, Matsuo, Adachi, Kasai, Shizuri and Ōmura 2007a, 57.)

fla′vum. L. neut. adj. *flavum* yellow.

Cells are nonmotile, irregular rods, 0.5–0.8 × 0.7–1.1 µm. Colony color is lemon yellow. Aerobic. Growth occurs at pH

5–11 and 5–37°C. Tolerates up to 7% NaCl on 5× diluted nutrient agar medium. D-Glucose, fructose, D-galactose, maltose, D-mannose, raffinose, L-rhamnose, sucrose (strong reaction), and trehalose are assimilated, but arabinose, mannitol, and xylose are not. Esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase are detected by the API ZYM enzyme assay; α-galactosidase, β-glucuronidase, α-mannosidase, and α-fucosidase are negative. Reactions for alkaline phosphatase, lipase (C14), chymotrypsin, and β-glucosidase are weak.

The cell-wall peptidoglycan contains lysine as the diagnostic amino acid. Cell-wall acyl type is glycolyl. The major menaquinones are MK-11 and MK-12. Predominant cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from the ascidian *Didemnum moseleyi* collected from near the Nomazaki Peninsula, Nagasaki, Japan.

DNA G+C content (mol%): 70 (HPLC; type strain).

Type strain: YM18-098, DSM 18909, JCM 15574, MBIC08278, NBRC 103923.

Sequence accession no. (16S rRNA gene): AB286029.

20. **Microbacterium fluvii** Kageyama, Matsuo, Kasai, Shizuri, Ōmura and Takahashi 2008b, 2471[VP] (Effective publication: Kageyama, Matsuo, Kasai, Shizuri, Ōmura and Takahashi, 2008a, 4.)

flu'vi.i. L. gen. n. *fluvii* of a river.

Cells are irregular rods, 0.4–0.6 × 0.6–1.2 µm. Nonmotile. Colony color is pale yellow. Catalase-positive, aerobic. Grows at pH 6–11 and 16–36°C. Grows in up to 3% NaCl. D-Galactose, D-glucose, maltose, D-mannitol, D-mannose, and L-rhamnose are assimilated. Raffinose, sucrose, and xylose are not assimilated. Esterase (C4), esterase lipase (C8), lipase (C14), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-glucosidase, and *N*-acetyl-β-glucosaminidase are detected by the API ZYM enzyme assay; α-galactosidase, β-glucuronidase, α-glucosidase, α-mannosidase, and α-fucosidase are negative. Weak reaction for alkaline phosphatase and β-galactosidase.

The peptidoglycan contains ornithine as the diagnostic amino acid. Cell-wall acyl type is glycolyl. The major menaquinones are MK-11 and MK-12. Predominant cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from driftwood collected at the estuary of Maera River in Iriomote Island, Japan.

DNA G+C content (mol%): 70 (HPLC; type strain).

Type strain: YSL3-15, DSM 18908, MBIC08277, NBRC 105003.

Sequence accession no. (16S rRNA gene): AB286028.

21. **Microbacterium foliorum** Behrendt, Ulrich and Schumann 2001, 1273[VP]

fo.li.o'rum. L. pl. gen. neut. n. *foliorum* of the leaves.

Cells are irregularly shaped rods. In older cultures, rods are shorter, but a marked rod–coccus cycle does not occur. Motile by means of a single polar or lateral flagellum. Colonies are yellow, shiny, slightly convex, and round with entire margins. Strictly aerobic. Optimum growth temperature is approximately 25°C. Growth occurs in the presence of 2% (w/v) NaCl. Catalase-positive and oxidase-negative. Nitrate is not reduced to nitrite. β-Galactosidase is positive. Esculin, DNA, and gelatin are hydrolyzed. Urease, arginine dihydrolase, Voges–Proskauer test, H_2S production, and indole production are negative. Starch is weakly utilized. Casein and Tween 80 are not hydrolyzed. Hydrolysis of Tween 60 is strain-dependent. Acid is produced from amygdalin, L-arabinose, arbutin, cellobiose, D-fructose, galactose, glycerol, maltose, mannitol, D-mannose, salicin, sucrose, trehalose, and D-xylose but not from adonitol, D-arabitol, dulcitol, D-fucose, erythritol, gluconate, 2-ketogluconate, 5-ketogluconate, inositol, L-sorbose, D-tagatose, xylitol, or L-xylose. Acid production from D-arabinose, methyl α-D-glucoside, L-fucose, β-gentiobiose, glycogen, inulin, lactose, methyl α-D-mannoside, melibiose, melezitose, raffinose, rhamnose, ribose, sorbitol, starch, and methyl β-xyloside is variable between strains. Negative for the fermentative and oxidative production of acid from glucose by the method of Hugh and Leifson (1953) but positive for oxidative acid production by using API 20NE and API50CH.

The cell-wall peptidoglycan is type B2β containing ornithine, [L-Hsr]–D-Glu–Gly–D-Orn. The cell-wall acyl type is glycolyl. The cell-wall sugars are galactose, rhamnose, and mannose. The major menaquinones are MK-12, MK-11, and MK-10. Cellular fatty acids contain $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: strains are isolated from the phyllosphere of grasses and from the litter layer after mulching of the sward. The type strain was isolated from phyllosphere of grasses.

DNA G+C content (mol%): 67 (HPLC; type strain).

Type strain: P 333/02, CIP 107137, DSM 12966, JCM 11569, LMG 19580, NBRC 103072.

Sequence accession no. (16S rRNA gene): AJ249780.

22. **Microbacterium ginsengisoli** Park, Kim, Kim, Im, Yi, Kim, Soung and Yang 2008, 430[VP]

gin.seng.i.so'li. N.L. n. *ginsengum* ginseng; L. n. *solum* soil; N.L. gen. n. *ginsengisoli* of soil of a ginseng field, the source of type strain.

Cells are short rods, 0.3–0.4 × 0.6–0.8 µm in size. Nonmotile. Colonies are yellow, smooth, circular, convex, and transparent after 2 d cultivation on R2A agar. Aerobic. Catalase and oxidase are positive. Growth occurs at 18–30°C, at pH 5–9, and in up to 4% (w/v) NaCl. Nitrate is not reduced to nitrite. Esculin and DNA are hydrolyzed but starch, xylan, gelatin, chitin, cellulose, and skim milk are not. Urease and arginine dihydrolase are absent. In the API 50CH tests, acid is produced from D-fructose, cellobiose, D-mannose, L-rhamnose, sucrose, trehalose, turanose, D-xylose, glycerol, and mannitol. Acid is not produced from gluconate, 2-ketogluconate, 5-ketogluconate, D- and L-arabinose, D- and L-fucose, galactose, gentiobiose, lactose, D-lyxose, melezitose, melibiose, raffinose, ribose, sorbose, D-tagatose, L-xylose, methyl α-D-glucoside, methyl α-D-mannoside, methyl β-D-xyloside, adonitol, D- and L-arabitol, dulcitol, erythritol, inositol, sorbitol, xylitol, *N*-acetylglucosamine, starch, amygdalin,

arbutin, inulin, salicin, or glycogen. The carbon sources utilized in the API 20NE and API 32GN systems are D-glucose, maltose, D-mannose, rhamnose, sucrose, inositol, mannitol, L-alanine, L-proline, L-serine, 3-hydroxybutyrate, acetate, gluconate, malate, propionate, and valerate. Negative for utilization of the following substrates: L-arabinose, L-fucose, melibiose, D-ribose, D-sorbitol, L-histidine, *N*-acetylglucosamine, salicin, glycogen, 2-ketogluconate, 5-ketogluconate, 3-hydroxybenzoate, 4-hydroxybenzoate, adipate, caprate, citrate, itaconate, D- and L-lactate, malonate, phenylacetate, and suberate. In API ZYM assays, esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, trypsin, acid phosphatase, β-galactosidase, α-glucosidase, β-glucosidase, and *N*-acetyl-β-glucosaminidase activities are present, but alkaline phosphatase, lipase (C14), cystine arylamidase, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-glucuronidase, α-mannosidase, and α-fucosidase are absent.

The peptidoglycan contains ornithine. The cell-wall sugar is rhamnose. The predominant menaquinone is MK-12, followed by MK-11. Major cellular fatty acids are $C_{17:0}$ anteiso, $C_{15:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from soil from a ginseng field in Pocheon in the Republic of Korea.

DNA G+C content (mol%): 69.4 (HPLC; type strain).

Type strain: Gsoil 259, DSM 18659, JCM 15304, KCTC 19189.

Sequence accession no. (16S rRNA gene): AB271048.

23. **Microbacterium ginsengiterrae** Kim, Kim, Bui, Kim, Srinivasan and Yang 2010, 2811[VP]

gin.seng.i.ter′ra.e. N.L. n. *ginsengum* ginseng; L. n. *terra* soil; N.L. gen. n. *ginsengiterrae* of soil of a ginseng field, the source of the type strain.

Cells are nonmotile and rod-shaped, 0.5–0.7 µm in diameter and 1.5–2.0 µm in length. Colonies are circular with regular edges, yellow, and translucent with a diameter of 2–3 mm after 2 d incubation on R2A agar. Strictly aerobic. Grows at 15–45°C and pH 5–9, with optimal growth at 30°C and pH 7.0. Slightly halophilic. Grows poorly in the absence of NaCl and at concentrations greater than 8% NaCl. Catalase, oxidase, and DNase are positive. In the API ZYM kit, α-glucosidase, β-glucosidase, esterase (C4), esterase lipase (C8), naphthol-AS-BI-phosphohydrolase, and α-mannosidase activities are positive, whereas alkaline phosphatase, lipase (C14), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, and α-fucosidase activities are negative. In the API 20NE kit, arginine dihydrolase and urease reactions are positive, but the following reactions are negative: reduction of nitrate to nitrite, reduction of nitrate to nitrogen, indole production, protease, β-galactosidase, glucose acidification, and assimilation of L-arabinose, D-mannitol, *N*-acetylglucosamine, maltose, potassium gluconate, capric acid, adipic acid, malic acid, trisodium citrate, and phenylacetic acid. In the API 32GN kit, the following substrates are assimilated: D-ribose, L-rhamnose, sucrose, 3-hydroxybenzoic acid, and 4-hydroxybenzoic acid. The following substrates are not assimilated: glucose, inositol, itaconic acid, suberic acid, sodium malonate, sodium acetate, L-alanine, glycogen, L-serine, salicin, melibiose, L-fucose, D-sorbitol, propionic acid, capric acid, valeric acid, L-histidine, 3-hydroxybutyric acid, and L-proline.

The cell-wall peptidoglycan is of type B2β: (L-Hsr)–D-Glu–Gly–D-Orn. Major whole-cell sugars are ribose, xylose, and galactose. The predominant quinones are MK-12 and MK-13. The polar lipids contain one unknown glycolipid and aminolipids, in addition to diphosphatidylglycerol and phosphatidylglycerol. Major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from soil of a ginseng field in the Republic of Korea.

DNA G+C content (mol%): 64.5 (HPLC; type strain).

Type strain: DCY37, JCM 15516, KCTC 19526.

Sequence accession no. (16S rRNA gene): EU873314.

24. **Microbacterium gubbeenense** Brennan, Brown, Goodfellow, Ward, Beresford, Vancanneyt, Cogan and Fox 2001, 1974[VP]

gub.be.en.en′se. N.L. neut. adj. *gubbeenense* of or belonging to Gubbeen House, County Cork, Ireland, where the cheese containing the organism is produced.

Cells are small, slender rods, 0.5 to 2.0 µm in length, showing typical coryneform morphology with cells arranged at angles to V-shapes. No primary branching or rod–coccus cycle are observed. Colonies on peptone-yeast extract agar are irregular, cream, matt, slightly raised, and 1–5 mm in diameter.

Facultatively anaerobic. Catalase-positive and oxidase-negative. Growth occurs at 30°C but not at 37°C. Tolerates up to 12% (w/v) NaCl. Nitrate is reduced to nitrite. Starch, gelatin, urea, and Tweens 20, 40, 60, and 80 are not hydrolyzed. H_2S production, methyl red test, and Voges–Proskauer test are negative. Indole is not produced. β-Galactosidase is produced, but arginine dihydrolase is not. Acid is produced from arabinose, mannose, glucose, galactose, trehalose, and lactose and not from rhamnose, melezitose, xylose, inulin, raffinose, or ribose. Gluconate, mannose, malate, citrate, propionate, and fumarate are assimilated but adipate, caprate, phenylacetate, acetate, and lactate are not. The organism produces alkaline phosphatase, esterase (2-naphthyl butyrate as substrate), esterase lipase (2-naphthyl caprylate as substrate), leucine arylamidase (L-leucine 2-naphthylamide as substrate), acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, and *N*-acetylglucosaminidase. The organism does not produce lipase (2-naphthyl myristate as substrate), valine arylamidase, cystine arylamidase, trypsin, β-glucuronidase, chymotrypsin, α-mannosidase, α-fucosidase, or arginine dihydrolase.

The peptidoglycan contains lysine, conforming to type B1. The cell-wall acyl type is glycolyl. The cell-wall sugars are rhamnose and galactose. The menaquinone is composed of MK-11 and MK-12. The presence of phosphatidylglycerol mannosides in the polar lipids of this species, in addition to diphosphatidylglycerol and phosphatidylinositol, has been reported (Brennan et al., 2001). Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from surface of Gubbeen, Irish farmhouse smear-ripened cheese.

DNA G+C content (mol%): 69–75 (HPLC).

Type strain: DPC 5286, JCM 12075, LMG S-19263, NBRC 103073, NCIMB 30129.

Sequence accession no. (16S rRNA gene): AF263563.

Further comments: phosphatidylglycerol mannosides are reported in the polar lipid profile of this species in addition to diphosphatidylglycerol and phosphatidylinositol. There are no other species of the genus *Microbacterium* that have a similar polar lipid profile. If the identification of these lipids is correct and not originating from a contaminant, this is the distinctive characteristic of this species.

25. **Microbacterium halophilum** Takeuchi and Hatano 1998a, 980[VP]

ha.lo′phi.lum. Gr. n. *hals halos* salt; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*), friend, loving; N.L. neut. adj. *halophilum* salt-loving.

Cells are nonmotile, irregular short rods, 0.2–0.5 × 0.6–2.0 μm in size, arranged at angles; V forms but no branching or rod–coccus cycle are observed. Colonies are 2–4 mm in diameter, yellowish white in color, circular, low convex with entire margins, opaque, and moist. Growth occurs at 37°C (optimal at 28°C). Good growth is observed in 2 to 6.5% NaCl. Starch, and Tweens 40, 60, and 80 are hydrolyzed and gelatin and Tween 20 are weakly hydrolyzed. Methyl red test is positive. Voges–Proskauer test, production of H_2S, and arginine dihydrolase are negative. Acid is produced from glucose, mannose, and rhamnose but not from L-arabinose, galactose, inulin, melezitose, raffinose, ribose, sucrose, trehalose, or xylose. Maltose, mannose, mannitol, and gluconate are assimilated whereas arabinose, *N*-acetylglucosamine, acetate, adipate, caprate, citrate, fumarate, lactate, malate, phenylacetate, and propionate are not.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid (and hydroxyglutamic acid), glycine, and alanine, corresponding to peptidoglycan type B2β (Schleifer and Kandler, 1972). Cell-wall sugars are mannose, galactose, and glucose. Major menaquinones are MK-11, MK-12, and MK-13. Cellular fatty acid profile is composed of almost equal amounts of $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso, followed by $C_{17:0}$ anteiso and $C_{17:0}$ iso.

Source: the type strain was isolated from mangrove rhizosphere soil.

DNA G+C content (mol%): 67.2 (HPLC; type strain).

Type strain: No. 76, DSM 12508, JCM 12077, NBRC 16062, VKM Ac-2080.

Sequence accession no. (16S rRNA gene): AB004714.

26. **Microbacterium halotolerans** Li, Chen, Kim, Park, Tang, Lee, Xu and Jiang 2005a, 69[VP]

ha.lo.to′le.rans. Gr. n. *hals halos* salt; L. part. adj. *tolerans* tolerating; N.L. part. adj. *halotolerans* salt-tolerating, referring to the ability of the organism to tolerate high salt concentrations.

Cells are nonmotile, short rods. Colonies are white, circular, convex with entire margins, shiny, moist, and 1–2 mm in diameter after 2–3 d incubation. Grows optimally at 28–30°C and pH 7.0–8.0. Tolerant to salts; grows in 0–15% NaCl, 0–20% KCl, and 0–30% $MgCl_2 \cdot H_2O$, with optimal growth at 5% NaCl, 5–10% KCl, and 10% $MgCl_2 \cdot H_2O$. Catalase-positive and oxidase-negative. Tweens 20 and 80, gelatin, casein, and starch are not decomposed. Voges–Proskauer test, H_2S production, and indole production are negative. Nitrate is not reduced to nitrite. Acid is produced from glucose, mannitol, mannose, ribose, fructose, maltose, and xylose. Uses the following compounds as sole carbon and energy sources: glucose, mannitol, mannose, ribose, fructose, sucrose, maltose, galactose, arabinose, starch, cellobiose, lactose, and xylose. Amygdalin, salicin, dextrin, galacturonate, 5-ketogluconate, L-arabitol, trehalose, rhamnose, inositol, sorbitol, malonate, and adonitol cannot be assimilated. Positive for lipase and β-galactosidase. Negative for ornithine decarboxylase, arginine dihydrolase, lysine decarboxylase, urease, α-galactosidase, *N*-acetyl-β-glucosaminidase, β-glucuronidase, and L-aspartic arylamidase. In the original description, the species is described as being both positive and negative for α-maltosidase and β-glucosidase.

Cell-wall peptidoglycan is type B2β: [Gly]–L-Hsr–D-Glu(Hyg)–Gly–D-Orn. The acyl type is glycolyl. Cell-wall sugars are ribose, galactose, glucose, and trace amounts of xylose. Predominant menaquinones are MK-10 and MK-11. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from saline soil collected from Qinghai Province in the west China.

DNA G+C content (mol%): 63.8 (T_m; type strain) [66.5 mol% is reported by Li et al. (2005a)].

Type strain: YIM 70130, CIP 108071, JCM 13013, KCTC 19017.

Sequence accession no. (16S rRNA gene): AY376165.

27. **Microbacterium hatanonis** Bakir, Kudo and Benno 2008, 656[VP]

ha.ta.no′nis. N.L. gen. masc. n. *hatanonis* of Hatano, in honor of Dr Kazunori Hatano, for his contribution to the understanding of the genus *Microbacterium*.

Cells are nonmotile rods, approximately 0.8 μm wide and 1.7 μm long. Colonies are light yellow, circular, convex with entire margins, moist, and shiny. Aerobic. Catalase-positive and oxidase-negative. Growth occurs at 10–37°C and pH 6.0–9.0, with optimal growth at 30°C and pH 7.0. No growth occurs at 2% NaCl; optimum growth is seen in the absence of NaCl. Nitrate is not reduced. Arginine dihydrolase, urease, gelatin hydrolysis, indole production, and D-glucose fermentation are negative. Esculin hydrolysis and β-galactosidase are positive. Arabinose, D-Glucose, D-mannose, mannitol, maltose, and potassium gluconate are assimilated. Malate is assimilated weakly. *N*-Acetylglucosamine, capric acid, adipic acid, trisodium citrate, and phenylacetic acid are not utilized. In the API ZYM test system, positive for the production of esterase, esterase lipase, leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, and α-fucosidase; negative for alkaline phosphatase, lipase, α-chymotrypsin, and α-mannosidase.

The cell-wall peptidoglycan contains ornithine as the diagnostic diamino acid. Cell-wall sugars are rhamnose and galactose. The major menaquinones are MK-12 and MK-11,

with moderate amounts of MK-10. Predominant cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from a contaminant of hairspray.

DNA G+C content (mol%): 69.0 (HPLC; type strain).

Type strain: FCC-01, DSM 19179, JCM 14558.

Sequence accession no. (16S rRNA gene): AB274908.

28. **Microbacterium hominis** Takeuchi and Hatano 1998a, 980[VP]

ho′mi.nis. L. masc. n. *homo -inis* man; L. gen. masc. n. *hominis* of man.

Cells are nonmotile, irregular, short rods, 0.2–0.5 × 0.6–2.0 µm, arranged at angles; V forms but no branching or rod–coccus cycle are observed. Colonies are 2–4 mm in diameter, yellowish white in color, circular, low convex with entire margins, opaque, and moist. Growth occurs at 37°C (optimal growth at 28°C). Good growth is observed in the presence of 2% NaCl but only weak growth is observed at 5 and 6.5% NaCl. H_2S is formed. Methyl red and Voges–Proskauer tests are positive. Tweens 20, 40, 60, and 80 are hydrolyzed but starch and gelatin are not. Acid is produced from L-arabinose, galactose, glucose, mannose, melezitose, sucrose, and trehalose but not from inulin, raffinose, rhamnose, ribose, or xylose. Arabinose, maltose, mannose, mannitol, *N*-acetylglucosamine, acetate, citrate, fumarate, gluconate, lactate, malate, and propionate are assimilated but not adipate, caprate, or phenylacetate.

Cell-wall peptidoglycan contains lysine, glutamic acid (and hydroxyglutamic acid), glycine, and alanine. Cell-wall sugars are rhamnose, 6-deoxy-L-talose, galactose, and mannose. Major menaquinones are MK-11 and MK-12. Cellular fatty acids are composed of $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from lung aspirate.

DNA G+C content (mol%): 71.2 (HPLC; type strain).

Type strain: CIP 105731, DSM 12509, JCM 12413, LCDC 84-209, NBRC 15708, VKM Ac-2081.

Sequence accession no. (16S rRNA gene): AM181504.

29. **Microbacterium humi** Young, Busse, Langer, Chu, Schumann, Arun, Shen, Rekha and Kämpfer 2010, 859[VP]

hu′mi. L. gen. n. *humi* of earth, soil, of soil, the source of the type strain.

Cells are short rods, about 1–1.2 µm in width and 2–3 µm in length. Aerobic. Catalase and oxidase are positive. Good growth occurs on nutrient agar and R2A agar (Oxoid) at 25–30°C and yellow colonies appear in 3 d.

Acid is produced from D-mannitol and sucrose. Acid is produced weakly from glucose and lactose but not from adonitol, L-arabinose, cellobiose, D-mannose, D-xylose, D-arabitol, dulcitol, erythritol, maltose, melibiose, methyl D-glucoside, raffinose, rhamnose, salicin, sorbitol, or trehalose. Esculin, pNP-α-D-glucopyranoside, pNP-β-D-glucopyranoside, oNP-β-D-galactopyranoside, pNP-β-D-glucuronide, pNP-β-D-xylopyranoside, bis-pNP-phosphate, pNP-phenylphosphate, and L-alanine-pNA are hydrolyzed but pNP-phosphoryl-choline, 2-deoxythymidine-5′-pNP-phosphate, L-glutamate-γ-3-carboxy-pNA, and L-proline-pNA are not hydrolyzed. Cellobiose, D-fructose, D-glucose, DL-lactate, D-mannose, maltose, D-mannitol, L-proline, sucrose, trehalose, *N*-acetyl-D-glucosamine, L-arabinose, D-galactose, α-melibiose, L-rhamnose, D-ribose, D-xylose, maltitol, D-sorbitol, fumarate, L-malate, oxoglutarate, pyruvate, and L-aspartate are assimilated but *N*-acetyl-D-galactosamine, *p*-arbutin, gluconate, salicin, adonitol, i-inositol, putrescine, acetate, propionate, *cis*-aconitate, citrate, *trans*-aconitate, adipate, 4-aminobutyrate, azelate, glutarate, DL-3-hydroxybutyrate, itaconate, L-leucine, mesaconate, phenylacetate, L-phenylalanine, suberate, L-tryptophan, L-alanine, β-alanine, L-histidine, L-ornithine, L-serine, 3-hydroxybenzoate, and 4-hydroxybenzoate are not assimilated.

The cell-wall peptidoglycan is of type B2α with an interpeptide bridge D-Glu–Gly–D-Orn. The predominant quinones are MK-11 and MK-10, with MK-12 as a minor component. The polar lipid profile is composed of diphosphatidylglycerol, phosphatidylglycerol, and one unknown glycolipid. Major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. Predominant polyamines are spermidine and spermine.

Source: isolated from the stalk of the edible mushroom *Agaricus blazei* cultivated in the laboratory.

DNA G+C content (mol%): not known.

Type strain: CC-12309, CCM 7687, DSM 21799.

Sequence accession no. (16S rRNA gene): FJ865215.

30. **Microbacterium hydrocarbonoxydans** Schippers, Bosecker, Spröer and Schumann 2005, 657[VP]

hy.dro.car.bon.ox′y.dans. N.L. n. *hydrocarbonum* hydrocarbon; N.L. part. adj. *oxydans* oxidizing; N.L. part. adj. *hydrocarbonoxydans* oxidizing hydrocarbons.

Cells are motile, irregular rods, 0.3–1.5 µm in size. Colonies are circular, smooth, translucent, and yellow-pigmented with a maximum diameter of 5 mm after 2 weeks of cultivation. Obligately aerobic. Growth occurs at 30–37°C and in 2–4% NaCl. Catalase-positive and oxidase-negative. Arginine is not hydrolyzed. Urease-negative. H_2S is not produced and the Voges–Proskauer reaction is negative. Acid is produced from rhamnose, sucrose, and xylose but not from D-glucose, adonitol, inositol, or sorbitol. The following compounds are utilized as a sole carbon sources: *N*-acetyl-D-glucosamine, L-arabinose, cellobiose, D-fructose, D-galactose, gluconate, D-glucose, glycogen, maltose, D-mannose, L-rhamnose, D-ribose, sucrose, salicin, trehalose, L-xylose, D-mannitol, acetate, propionate, citrate, fumarate, DL-lactate, L-malate, pyruvate, L-alanine, L-aspartate, L-histidine, L-hydroxyproline, L-proline, L-serine, putrescine, phenylacetate, and *N*-acetyl-D-galactosamine. α-D-Galacturonate, α-D-melibiose, adonitol, i-inositol, sorbitol, *trans*-aconitate, adipate, DL-3-hydroxybutyrate, suberate, 3-hydroxybenzoate, 4-hydroxybenzoate, and L-ornithine are not utilized. The following are hydrolyzed: pNP-*N*-acetyl-β-D-galactosaminide, pNP-*N*-acetyl-β-D-glucosaminide, pNP-α-L-arabinopyranoside, pNP-β-D-cellopyranoside, pNP-β-D-galactopyranoside, pNP-α-D-glucopyranoside, pNP-β-D-glucopyranoside, pNP-β-D-lactoside, pNP-α-D-mannoside, pNP-α-D-maltoside, pNP-β-D-xyloside, bis-pNP-phosphate, benzolphosphonacid-pNP ester, pNP-phosphoryl-choline, 2-deoxythymidine-5′-pNP-phosphate, L-alanine-pNA, glycine-pNA, L-leucine-pNA, L-lysine-pNA, and L-proline-pNA.

The following are not hydrolyzed: pNP-β-D-glucuronide, γ-L-glutamate-pNA, L-glutamate-γ-3-carboxy-pNA, and L-valine-pNA. Crude oil is used as a substrate for growth.

The cell-wall peptidoglycan contains L-ornithine as the diagnostic diamino acid, conforming to type B2β: [L-HSr]–D-Glu(Hyg)–Gly–D-Orn. The predominant menaquinones are MK-11 and MK-12.

The type strain was isolated by enrichment with medium containing 1–5% crude oil.

Source: the type strain was isolated from oil-contaminated soil in Germany.

Type strain: BNP48, DSM 16089, JCM 14340, NBRC 103074, NCIMB 14002.

Sequence accession no. (16S rRNA gene): AJ698726.

31. **Microbacterium imperiale** (Steinhaus 1941) Collins, Jones and Kroppenstedt 1983b, 672[VP] (Effective publication: Collins, Jones and Kroppenstedt 1983c, 75.) ("*Bacterium imperiale*" Steinhaus 1941, 777; *Brevibacterium imperiale* Breed 1953, 13)

im.pe.ri.a′le. L. neut. adj. *imperiale* imperial, from the specific epithet of name of insect host (*Eacles imperialis* Dru).

The following characteristics are based mainly on Steinhaus (1941), Schleifer and Kandler (1972), Yamada and Komagata (1972b), Jones (1975), Collins et al. (1983c), and Yokota et al. (1993b).

Cells are small, slender rods, arranged at angles; V forms are observed but no branching. In older culture, rods become shorter but no rod–coccus cycle is seen. Very weak motility is observed. A few cells may be motile by means of one (Steinhaus, 1941), two, or three (Jones, 1975) flagella. Colonies are 1–4 mm in diameter, circular, low-convex with entire margins, opaque, and moist. Mucoid growth occurs on solid media containing glucose or lactose. Reddish orange pigment is produced. Aerobic and weak anaerobic growth is shown (Jones, 1975). Catalase-positive. Oxidase-negative. Optimum temperature for growth is 25–30°C. Growth occurs at 10°C and 37°C, but not at 45°C. Does not survive heating at 60°C for 30 min. Hydrolysis of starch and gelatin is negative or weakly positive. Tweens 40 and 60 are weakly hydrolyzed, whereas Tweens 20 and 80 are not hydrolyzed. Urease-negative. Arginine is not decarboxylated. Acid is produced from L-arabinose, glucose, fructose, mannose, galactose, sucrose, trehalose, cellobiose, and esculin, but not from rhamnose, sorbose, maltose, starch, inulin, glycerol, erythritol, adonitol, mannitol, dulcitol, sorbitol, inositol, arbutin, or methyl α-glucoside. Slow, weak acid production from lactose, xylose, salicin, raffinose, and dextrin is observed. The following organic acids are assimilated: acetate, pyruvate, L-lactate, D-lactate, malate, succinate, fumarate, 2-oxoglutarate, citrate, and propionate. The following organic acids are not assimilated: formate, butyrate, oxalate, malonate, glutarate, adipate, pimelate, glycolate, glyoxylate, gluconante, hippurate, and uriate.

Cell-wall peptidoglycan contains L-lysine as the diamino acid, conforming to type B1β (Figure 174). Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose, mannose, and galactose. Major menaquinones are MK-12 and MK-11. The polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and dimannosyldiacylglycerol. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: the type strain was isolated from alimentary tract of the imperial moth *Eacles imperialis*.

DNA G+C content (mol%): 71–75.4 (T_m) (Yokota et al., 1993b).

Type strain: ATCC 8365, CIP 82.108, DSM 20530, HAMBI 117, HAMBI 1891, JCM 1378, NCIMB 9888, NBRC 12610, VKM Ac-1447.

Sequence accession no. (16S rRNA gene): X77442.

32. **Microbacterium indicum** Shivaji, Bhadra, Rao, Chaturvedi, Pindi and Raghukumar 2007, 1821[VP]

in.di′cum. L. neut. adj. *indicum* pertaining to India.

Cells are rod-shaped. Colonies are circular and pale yellow with an entire margin on yeast extract-peptone agar after 2 d incubation at 22°C. Growth occurs between 8°C and 30°C but not at 5°C or 37°C. Growth occurs between pH 5 and 9. Tolerates up to 6% (w/v) NaCl at pH 6.8. Catalase- and oxidase-negative. Negative for Voges–Proskauer reaction, indole production, and methyl red test. Ornithine decarboxylase, lysine decarboxylase, phenylalanine deaminase, and urease are also negative. Esculin is hydrolyzed. Nitrate is reduced. Acid is produced from D-glucose, fructose, L-arabinose, D-arabinose, D-xylose, cellobiose, maltose, trehalose, melezitose, and sucrose but not from D-galactose, L-rhamnose, mannose, or sorbitol. The following compounds are used as sole carbon sources: D-glucose, D-fructose, D-galactose, L-arabinose, cellobiose, lactose, maltose, sucrose, acetate, L-serine, L-arginine, L-lysine, D-xylose, L-xylose, raffinose, D-ribose, melezitose, inositol, mannitol, malonate, and L-asparagine but not L-rhamnose, mannose, D-glucuronate, citrate, or L-alanine. Sensitive to amikacin (30 μg), cefuroxime (30 μg), rifampin (25 μg), bacitracin (10 μg), roxithromycin (30 μg), tobramycin (15 μg), gentamicin (30 μg), erythromycin (15 μg), ciprofloxacin (30 μg), chloramphenicol (30 μg), penicillin (10 μg), and kanamycin (30 μg), but resistant to ampicillin (25 μg) and nalidixic acid (30 μg).

The cell-wall peptidoglycan contains D-ornithine as the diagnostic amino acid and has possible structure B2β (Figure 174). Whole-cell sugars are rhamnose, galactose, and glucose. The menaquinones are MK-11 and MK-12. Predominant cellular fatty acids are $C_{16:0}$ iso, $C_{15:0}$ anteiso, $C_{16:0}$, and $C_{17:0}$ anteiso. In addition to phosphatidylglycerol, the presence of phosphatidylinositol was reported by Shivaji et al. (2007) in the polar lipid profile of this species. These authors also reported the same result in *Microbacterium barkeri*, which had not been reported previously. However, the presence of phosphatidylinositol is an uncommon trait among species of this genus.

Source: the type strain was isolated from deep-sea sediment of the Chagos Trench at a depth of 5904 m.

DNA G+C content (mol%): 65.5 (T_m; type strain).

Type strain: BBH6, IAM 15355, JCM 21800, LMG 23459.

Sequence accession no. (16S rRNA gene): AM158907.

33. **Microbacterium insulae** Yoon, Schumann, Kang, Lee, Lee and Oh 2009, 1741[VP]

in.su′la.e. L. fem. gen. n. *insulae* of an island, where the type strain was isolated.

Cells are nonmotile rods to cocci (0.2–0.5 × 0.5–1.8 µm). Colonies are yellow, circular, convex, smooth, glistening, and 1.5–2.0 mm in diameter after 7 d culture at 30°C on TSA. Grows at 20–38°C, at pH 5.5–8.0, and in up to 5% (w/v) NaCl; optimal growth is at 30°C, at pH 6.5 and 7.0, and in 0.5–1.0% NaCl. Anaerobic growth does not occur on TSA or on TSA supplemented with nitrate. Catalase-negative and oxidase-positive. Negative reaction for H_2S and indole production and hydrolysis of urea, casein, hypoxanthine, tyrosine, and xanthine. Positive for hydrolysis of gelatin, esculin, starch, and Tweens 20, 40, 60, and 80. Utilizes glycerol, L-arabinose, D-xylose, galactose, glucose, fructose, mannose, mannitol, rhamnose, amygdalin, esculin, salicin, cellobiose, maltose, lactose, sucrose, trehalose, melezitose, starch, gentiobiose, turanose, methyl α-D-glucoside, and gluconate; utilization of glycogen is weak; negative for utilization of D-arabinose, D-ribose, methyl β-D-xyloside, inositol, *N*-acetylglucosamine, arbutin, melibiose, raffinose, D-lyxose, L-fucose, 2-ketogluconate, 5-ketogluconate, citrate, malate, phenylacetate, erythritol, L-xylose, adonitol, sorbose, dulcitol, sorbitol, methyl α-D-mannoside, inulin, xylitol, D-tagatose, D-fucose, D-arabitol, L-arabitol, caprate, and adipate. Negative for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase activities.

In the API ZYM test, positive for leucine arylamidase, β-glucosidase, α-glucosidase, and *N*-acetyl-β-glucosaminidase, weakly positive for esterase (C4) and esterase lipase (C8), but negative for acid phosphatase, alkaline phosphatase, lipase (C14), valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, α-mannosidase, β-glucuronidase, and α-fucosidase. Susceptible to ampicillin, carbenicillin, cephalothin, chloramphenicol, lincomycin, novobiocin, oleandomycin, penicillin G, streptomycin, and tetracycline but not to gentamicin, kanamycin, neomycin, or polymyxin B.

Cell-wall peptidoglycan is type B2β: [L-HSr]–D-Glu(Hyg)–Gly–D-Orn. The acyl type is glycolyl. Cell-wall sugars are galactose, ribose, and rhamnose. Predominant menaquinone is MK-13; MK-12 and MK-14 are present in moderate amounts. Major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, an unidentified phospholipid, and an unidentified glycolipid. Major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{17:0}$ iso, and $C_{16:0}$ iso.

Source: the type strain was isolated from soil of Dokdo, Korea.

DNA G+C content (mol%): 69.9 (T_m; type strain).

Type strain: DS-66, CCUG 54523, KCTC 19247.

Sequence accession no. (16S rRNA gene): EU239498.

34. **Microbacterium invictum** Vaz-Moreira, Lopes, Faria, Spröer, Schumann, Nunes and Manaia 2009, 2039[VP]

in.vic′tum. L. neut. adj. *invictum* invincible, powerful, that survives composting, also an ancient and popular designation attributed to Oporto city.

Cells are motile, short rods (0.5–0.6 µm long by 0.7–0.8 µm). Colonies are white and convex in 2-d-old cultures, turning yellowish in 4–6 d. Grows at 10–37°C, at pH 6.0–9.5, and in up to 5% NaCl. Catalase-positive and oxidase-negative. Nitrate is reduced to nitrite. Citrate is not used and H_2S and indole are not produced. Anaerobic growth is observed in the presence of nitrate. Voges–Proskauer test is positive. Gelatin, esculin, starch (weakly), and ε-poly-caprolactone (weakly) are hydrolyzed. Acid is produced from *N*-acetylglucosamine, amygdalin, L-arabinose, arbutin, cellobiose, D-fructose, D-glucose, D-mannitol, D-mannose, L-rhamnose, and salicin, with weak reactions observed for D-galactose, D-sorbitol, and D-xylose, but not from D-adonitol, D-arabinose, D- and L-arabitol, dulcitol, erythritol, D- and L-fucose, gentiobiose, gluconate, 2- and 5-ketogluconate, glycerol, glycogen, inositol, inulin, lactose, D-lyxose, maltose, melezitose, melibiose, raffinose, D-ribose, L-sorbose, starch, sucrose, D-tagatose, trehalose, turanose, xylitol, L-xylose, methyl α-D-glucopyranoside, methyl α-D-mannopyranoside, or methyl β-D-xylopyranoside. The following compounds are oxidized (API 20E) and assimilated: L-arabinose, D-glucose, D-mannitol, L-rhamnose, and D-sorbitol. In addition, assimilates *N*-acetylglucosamine, cellobiose, D-fructose, gentiobiose, potassium gluconate, potassium 2-ketogluconate, maltose, D-mannose, turanose, xylitol (weakly), and D-xylose, but not phenylacetate, D-adonitol, adipate, esculin, amygdalin, D-arabinose, D- and L-arabitol, caprate, citrate, dulcitol, erythritol, D- and L-fucose, D-galactose, potassium 5-ketogluconate, glycerol, glycogen, inositol, inulin, lactose, D-lyxose, malate, melezitose, melibiose, raffinose, D-ribose, salicin, L-sorbose, starch, sucrose, D-tagatose, trehalose, L-xylose, methyl α-D-glucopyranoside, methyl α-D-mannopyranoside, or methyl β-D-xylopyranoside. Glucose fermentation is weak and slow. Alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, β-glucuronidase, α- and β-glucosidase, and *N*-acetyl β-glucosamidase are produced, but not arginine dihydrolase, lysine and ornithine decarboxylases, urease, tryptophan deaminase, lipase (C14), cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, α-mannosidase, or α-fucosidase. Growth occurs in the presence of (µg/l) sulfamethoxazole/trimethoprim (23.75/1.25), meropenem (10), and ceftazidime (30).

Cell-wall peptidoglycan type is B1α containing lysine, glycine, alanine, and glutamic acid but not homoserine or hydroxyglutamic acid. The acyl type is glycolyl. Predominant menaquinones are MK-11 and MK-12 (approx. 40% each). Major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: the type strain was isolated from homemade compost.

DNA G+C content (mol%): 70.1 ± 0.3 (HPLC; type strain).

Type strain: DC-200, DSM 19600, LMG 24557.

Sequence accession no. (16S rRNA gene): AM949677.

35. **Microbacterium keratanolyticum** (Yokota, Takeuchi, Sakane and Weiss 1993a) Takeuchi and Hatano 1998b, 745[VP] (*Aureobacterium keratanolyticum* Yokota, Takeuchi, Sakane and Weiss 1993a, 561)

ker.a.ta.no.ly′ti.cum. N.L. n. *keratanum* keratan, sulfur-containing polysaccharide produced by mammals; N.L. neut. adj. *lyticum* (from Gr. neut. adj. *lutikon*) able to loosen, able to dissolve; N.L. neut. adj. *keratanolyticum* keratan dissolving.

The following characteristics are based mainly on the data of Yokota et al. (1993a).

Cells are motile rods arranged at angles; V forms are observed. Colonies are 1–3 mm in diameter, circular, low convex with entire margins, opaque, and moist. Yellow pigment is produced. Aerobic. Optimum temperature for growth is 28°C. Growth occurs in presence of 2% NaCl. Oxidative. Esculin and gelatin are hydrolyzed. Starch, and Tweens 20, 40, 60, and 80 are not hydrolyzed. Nitrate is reduced. Negative for the methyl red test and urease. Arginine decarboxylase-positive. Produces H_2S. Acetate, DL-lactate, malate, succinate, oxalate, fumarate, propionate, and hippurate are assimilated. Citrate is assimilated weakly but formate is not.

Cell-wall peptidoglycan contains ornithine, glutamic acid (and hydroxyglutamic acid), glycine, and alanine but not homoserine, conforming to peptidoglycan type B2α (Figure 174). A small amount of lysine is also detected. Cell-wall acyl type is glycolyl. Cell-wall sugar is galactose. Major menaquinones are MK-12 and MK-13. The polar lipids are diphosphatidylglycerol and phosphatidylglycerol. An unidentified glycolipid is also present. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Type strain is reported to produce keratansulfate endo-β-galactosidase (EC 3.2.1.103).

Source: the type strain was isolated from soil (Nakazawa et al., 1975; Nakazawa and Suzuki, 1975).

DNA G+C content (mol%): 66.5 (HPLC; type strain).

Type strain: ATCC 35057, CIP 103815, DSM 8606, JCM 9173, LMG 16470, NBRC 13309, VKM Ac-1958.

Sequence accession no. (16S rRNA gene): AB004717.

36. **Microbacterium ketosireducens** Takeuchi and Hatano 1998a, 980[VP]

ke.to.si.re.du′cens. N.L. n. *ketosum* ketose; L. part. adj. *reducens* reducing (deoxidizing); N.L. part. adj. *ketosireducens* ketose-deoxidizing.

Cells are nonmotile, irregular short rods of 0.2–0.5 × 0.6–2.0 µm in size, arranged at angles; V forms but no branching or rod–coccus cycle are observed. Colonies are 2–4 mm in diameter, yellow in color, circular, low convex with entire margins, opaque, and moist. Optimal growth occurs at 28°C; no growth at 37°C. Good growth occurs in 2% NaCl but not at 6.5%. H_2S is formed and methyl red test is positive. Voges–Proskauer test is negative. Nitrate is reduced to nitrite. Arginine dihydrolase is negative. Starch, gelatin, and Tweens 20, 40, 60, and 80 are hydrolyzed. Acid is produced from L-arabinose, glucose, mannose, sucrose, and xylose; variable from galactose and inulin; and negative from melezitose, raffinose, rhamnose, ribose, and trehalose. Arabinose, maltose, mannose, mannitol, and gluconate are assimilated; acetate, fumarate, and lactate are weakly assimilated; citrate assimilation is variable; and *N*-acetylglucosamine, adipate, caprate, malate, phenylacetate, and propionate are not assimilated.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid (and hydroxyglutamic acid), glycine, and alanine, corresponding to peptidoglycan type B2β (Figure 174). Major menaquinone is MK-13. Cellular fatty acids are mainly composed of $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso.

Strains of this species have the ability to reduce 2,5-diketo-D-gluconic acid (2,7-anhydro-β-arabino-2,5-hepto-diulo-pyranose) to 2-keto-gulonic acid (2,7-anhydro-β-D-ido-heptulopyranose).

Source: the type strain was isolated from soil.

DNA G+C content (mol%): 69.7–69.8 (HPLC; type strain).

Type strain: CIP 105732, DSM 12510, JCM 12078, NBRC 14548, VKM Ac-2082.

Sequence accession no. (16S rRNA gene): AB004724.

37. **Microbacterium kitamiense** Matsuyama, Kawasaki, Yumoto and Shida 1999, 1356[VP]

kita.mi.en′se. N.L. neut. adj. *kitamiense* of or belonging to Kitami, a city in Hokkaido, Japan, where the organism was isolated.

Cells are nonmotile, irregular rods, 0.5–0.8 × 1.0–2.0 µm in size. Colonies grown on TSA for 5 d at 25°C are round, capitate, smooth, orange in color, glistening, and about 1.5 to 3.0 mm in diameter. Strictly aerobic. Catalase-positive and oxidase-negative. Growth occurs between 15 and 37°C and between pH 6.0 and 9.0. Tolerates up to 7% NaCl. Nitrate reduction is variable depending on strain. Indole is not formed and production of H_2S is negative. Positive for hydrolysis of gelatin and starch. Hydrolysis of casein, urea, DNA, and Tweens 20, 40, 60, and 80 is negative. Tyrosine is decomposed. Acid is produced from glucose, fructose, galactose, mannose, maltose, arabinose, sucrose, xylose, trehalose, glycerol, mannitol, and raffinose but not from inositol, sorbose, lactose, ribose, salicin, sorbitol, melibiose, or adonitol. Utilization of citrate, succinate, fumarate, and propionate is negative.

The peptidoglycan contains D-ornithine as the diagnostic diamino acid. Cell-wall acyl type is glycolyl. The predominant menaquinone is MK-11, followed by MK-12. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

The strains of *Microbacterium kitamiense* were isolated in the course of screening of producers of exopolysaccharide. The strains produce soluble and insoluble polysaccharides (yields of 0.5 to 5.0 g/l) containing glucose, galactose, mannose, and rhamnose.

Source: the type strain was isolated from wastewater of a sugar-beet factory in Kitami City, Hokkaido, Japan.

DNA G+C content (mol%): 69.2 (HPLC; type strain).

Type strain: Kitami C2, CIP 106320, DSM 13237, JCM 10270, NBRC 16414.

Sequence accession no. (16S rRNA gene): AB013907.

38. **Microbacterium koreense** Lee, Lee and Park 2006, 426[VP]

ko.re.en′se. N.L. neut. adj. *koreense* of or pertaining to Korea, where the type strain was isolated.

Cells are nonmotile, short rods, approximately 0.7 µm in diameter and 3.0 to 4.0 µm in length. Cells of old cultures become shorter or spherical. Colonies are circular, convex with entire margins, moist, shiny, and light yellow in color. Aerobic. Catalase-positive. Oxidase-negative. Growth occurs at 20–37°C (optimum at 30°C), pH 6.0–8.0 (optimum at pH 7.0). Grows at 5% NaCl but not at 10% (w/v) or higher. Optimum growth is observed without addition of NaCl to the medium. H_2S is not produced and indole is not formed. Esculin is hydrolyzed but gelatin is not. Nitrate is not reduced to nitrite. Arginine dihydrolase, urease, and β-galactosidase

are negative. Acid is produced from glucose, fructose, mannose, rhamnose, mannitol, *N*-acetylglucosamine, cellobiose, maltose, sucrose, and starch and produced weakly from D-xylose, galactoside, trehalose, glycogen, and D-turanose. Acid is not produced from glycerol, erythritol, D-arabinose, L-arabinose, ribose, L-xylose, adonitol, methyl β-D-xyloside, sorbose, dulcitol, inositol, sorbitol, methyl α-D-mannoside, methyl α-D-glucoside, amygdalin, arbutin, salicin, lactose, melibiose, inulin, melezitose, raffinose, xylitol, gentiobiose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, 2-ketogluconate, or 5-ketogluconate.

The diamino acid of peptidoglycan is lysine. The cell-wall sugars are galactose and xylose. The predominant menaquinones are MK-11 and MK-12. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. The polar lipids consist of diphosphatidylglycerol and phosphatidylglycerol.

Source: the type strain was isolated from seawater in the South Sea of Korea.

DNA G+C content (mol%): 68 (HPLC; type strain).

Type strain: JS53-2, CCUG 50754, CIP 108696, JCM 15305, KCTC 19074.

Sequence accession no. (16S rRNA gene): AY962574.

39. **Microbacterium kribbense** Dastager, Lee, Ju, Park and Kim 2008b, 2539[VP]

krib.ben′se. N.L. neut. adj. *kribbense* of or belonging to KRIBB, arbitrary adjective formed from the acronym of the Korea Research Institute of Bioscience and Biotechnology, KRIBB, where the taxonomic studies on the type strain were performed.

Cells are irregular rods, 0.4–0.6 × 0.5–0.8 µm in size. Nonmotile. Colonies are pale to lemon yellow. Aerobic but catalase-negative. Growth occurs at 20–37°C (optimum at 28°C), at pH 7–11 (optimum at pH 7.2–7.4), and in up to 3% (w/v) NaCl. Nitrate is reduced to nitrite. Esculin, starch, and Tween 80 are hydrolyzed but cellulose, gelatin, and urea are not. Arabinose, galactose, glucose, maltose, mannitol, mannose, melibiose, raffinose, rhamnose, sucrose, and trehalose are assimilated but ribose, fructose, and xylose are not. Esterase (C4), esterase lipase (C8), leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase and *N*-acetyl-β-glucosaminidase are detected with the API ZYM enzyme assay; alkaline phosphatase, lipase (C14), valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, β-galactosidase, α-mannosidase, and α-fucosidase are negative.

The peptidoglycan contains lysine. The cell-wall acyl type is glycolyl. The cell-wall sugars detected are ribose, galactose, glucose, and xylose. The major menaquinones are MK-11 and MK-12. Main polar lipids are diphosphatidylglycerol and phosphatidylglycerol. Cellular fatty acids contain a large proportion of $C_{18:1}$ ω7*c* in addition to $C_{15:0}$ anteiso and $C_{16:0}$ iso.

Source: the type strain was isolated from soil collected from Bigeum Island, Korea.

DNA G+C content (mol%): 71.0 (T_m; type strain).

Type strain: MSL-04, DSM 19265, KCTC 19269.

Sequence accession no. (16S rRNA gene): EF466125.

Further comments: although the diamino acid of the species is lysine in the description, in the text of the same reference, peptidoglycan is type B2β containing ornithine, alanine, glycine, homoserine, and hydroxyglutamic acid (Dastager et al., 2008b).

There are no other species of the genus *Microbacterium* that have a large proportion of $C_{18:1}$ ω7*c* in the cellular fatty acids. If the identification of this fatty acid is correct and not originating from a contaminant, this is the distinctive characteristic of this species.

40. **Microbacterium lacus** Kageyama, Takahashi, Matsuo, Adachi, Kasai, Shizuri and Ōmura 2008c, 529[VP] (Effective publication: Kageyama, Takahashi, Matsuo, Adachi, Kasai, Shizuri and Ōmura 2007a, 57.)

la′cus. L. gen. n. *lacus* of a lake.

Cells are nonmotile, irregular rods, 0.6–0.7 × 0.9–1.5 µm. Colony color is pale yellow. Aerobic. Growth occurs at pH 6–11 and 13–33°C. Tolerates up to 2% NaCl on 5× diluted nutrient agar medium. D-Glucose, D-galactose, maltose, and sucrose are assimilated, but arabinose, fructose, mannitol, D-mannose, raffinose, L-rhamnose, trehalose, and xylose are not. Esterase (C4), esterase lipase (C8), lipase (C14), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, α-glucosidase, and *N*-acetyl-β-glucosaminidase are detected by the API ZYM enzyme assay; β-galactosidase, β-glucuronidase, β-glucosidase, α-mannosidase, and α-fucosidase are negative. Reaction for alkaline phosphatase is weak.

The cell-wall peptidoglycan contains ornithine as the diagnostic amino acid. Cell-wall acyl type is glycolyl. The major menaquinones are MK-12 and MK-13. Predominant cellular fatty acids are $C_{17:0}$ anteiso, $C_{15:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from sediments collected at the shore of Lake Shinjiko, Shimane, Japan (salinity of the sample and the depth of the site were approximately 0.5% and 2 m, respectively).

DNA G+C content (mol%): 69 (HPLC; type strain).

Type strain: A5E-52, DSM 18910, JCM 15575, MBIC08279, NBRC 103566.

Sequence accession no. (16S rRNA gene): AB286030.

41. **Microbacterium laevaniformans** (*ex* Dias and Bhat 1962) Collins, Jones and Kroppenstedt 1983b, 673[VP] (Effective publication: Collins, Jones and Kroppenstedt 1983c, 75.) ("*Corynebacterium laevaniformans*" Dias and Bhat 1962, 68.)

la.e.van.i.for′mans. N.L. n *laevanum* laevan, levan polysaccharide; L. part. adj. *formans* forming; N.L. part. adj. *laevaniformans* levan forming.

The following characteristics are based mainly on Dias and Bhat (1962, 1964), Schleifer and Kandler (1972), Collins et al. (1983c), Yokota et al. (1993b), and Takeuchi and Hatano (1998a).

Cells are nonmotile, small, slender rods, arranged at angles; V forms are observed but no branching. In older cultures, rods become shorter but no rod–coccus cycle is seen. Colonies are 1–3 mm in diameter, circular, low convex with entire margins, opaque, and moist. Produces a

yellow pigment. Aerobic. Optimum temperature for growth is 30°C. Survives heating at 60°C. Catalase-positive. H_2S is formed. Methyl red and Voges–Proskauer tests are positive. Nitrate is not reduced. Starch and gelatin are hydrolyzed. Tweens 20, 40, 60, and 80 are not hydrolyzed. Urease-negative. Arginine is decarboxylated. Acid is produced from glucose, galactose, fructose, mannose, lactose, maltose, cellobiose, dextrin, sorbitol, mannitol, glycerol, and glycogen. Acid production is variable from rhamnose, raffinose, sucrose, and trehalose (Takeuchi and Hatano, 1998a). Acid is not produced from *N*-acetylglucosamine, xylose, arabinose, inulin, inositol, salicin, arbutin sorbose, dulcitol, ribose, melibiose, or melezitose. Maltose, mannose, mannitol, gluconate, acetate, lactate, malate, fumarate, and propionate are assimilated; citrate assimilation is variable but phenylacetate, caprate, and adipate are not assimilated. Biotin, thiamine, and pantothenic acid are required for growth.

Cell-wall peptidoglycan contains L-lysine as the diamino acid, conforming to type B1α (Figure 174). Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose, mannose, galactose, and xylose. Major menaquinones are MK-11 and MK-12. The polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and dimannosyldiacylglycerol. In addition, an unknown monoglycosyldiacylglycerol is sometimes present. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: the type strain was isolated from activated sludge.

DNA G+C content (mol%): 70–73.7 (T_m).

Type strain: ATCC 15953, CIP 100934, DSM 20140, JCM 9181, NCIMB 9659, NBRC 14471, VKM Ac-1138.

Sequence accession no. (16S rRNA gene): Y17234.

42. **Microbacterium lindanitolerans** Lal, Gupta, Schumann and Lal 2010, 2637[VP]

lin.da.ni.to′le.rans. N.L. n. *lindanum* lindane; L. part. adj. *tolerans* tolerating; N.L. part. adj. *lindanitolerans* lindane-tolerating.

Cells are rod-shaped and not flagellated. Colonies are smooth, circular, 1.0–1.5 mm in diameter, and yellow after incubation on LB agar at 28°C for 3 d. Growth occurs at 25–37°C, pH 6–11, with optimal growth at 28–37°C and pH 7–8. Optimal growth is shown in the presence of 0–2% NaCl. No growth in 5% NaCl. Catalase-positive and oxidase-negative. Nitrate is reduced to nitrite. Hydrolysis of esculin and starch is positive. Xanthine and hypoxanthine are hydrolyzed after 3 weeks. Urease, DNase, gelatin hydrolysis, H_2S production, and Voges–Proskauer reaction are negative.

Acid production is observed from L-arabinose, D-glucose, raffinose, sucrose, and D-mannitol, but not from adonitol, lactose, *myo*-inositol, D-ribose, D-sorbitol, or D-xylose. As sole carbon sources, cellobiose, D-fructose, D-galactose, D-glucose, lactose, D-mannose, raffinose, sucrose, D-sorbitol, and trehalose are utilized, but adonitol, L-arabinose, citrate, D-mannitol, *myo*-inositol, D-ribose, and D-xylose are not. Hexachlorocyclohexane (CHC, lindane) is not degraded.

The peptidoglycan is of the B type of cross-linkage containing ornithine as the diagnostic diamino acid and glycolyl residues, but not homoserine or hydroxyglutamic acid. The whole-cell sugars include ribose and galactose. The menaquinones are MK-12, MK-11, MK-13, and MK-10, in an approximate molar ratio of 45:40:13:3. The polar lipids comprise diphosphatidylglycerol, phosphatidylglycerol, and two unknown polar lipids. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso.

Source: the type strain was isolated from soil contaminated with hexachlorocyclohexane (HCH, a herbicide called lindane) in North India.

DNA G+C content (mol%): 65.3 (HPLC; type strain).

Type strain: MNA2, CCM 7585, DSM 22422.

Sequence accession no. (16S rRNA gene): EU873539.

43. **Microbacterium liquefaciens** (Collins, Jones, Keddie, Kroppenstedt and Schleifer 1983a) Takeuchi and Hatano 1998b, 745[VP] ("*Microbacterium liquefaciens*" Orla-Jensen (1919); *Aureobacterium liquefaciens* Collins, Jones, Keddie, Kroppenstedt and Schleifer 1983a, 246)

li.que.fa′ciens. L. part. adj. *liquefaciens* dissolving.

The following characteristics are based mainly on Orla-Jensen (1919), Schleifer and Kandler (1972), Collins et al. (1983a), Yokota et al. (1993a), and Buczolits et al. (2008a).

Aureobacterium liquefaciens is the type species of the genus *Aureobacterium.*

Cells are nonmotile, small, slender rods arranged at angles; V forms are observed in young cultures but no branching. In older cultures, rods become shorter but no rod–coccus cycle is seen. Colonies are 1–3 mm in diameter, convex, circular with entire margins, opaque, and glistening. A bright yellow pigment is produced. Obligately aerobic. Catalase-positive. Optimum temperature for growth is 30°C. Growth occurs at pH 10, and at 4 and 37°C but not at 42°C. Weak growth is observed in 7% (w/v) NaCl. H_2S is produced. Arginine, gelatin, esculin, and casein are hydrolyzed. Starch, hippurate, and Tweens 20, 40, 60, and 80 are not hydrolyzed. Nitrate is reduced. Voges–Proskauer test is negative. Methyl red test, urease, and arginine dihydrolase are positive. Tellurite (0.05%) is not reduced. B vitamins are required. Acid is produced slowly from D-glucose, galactose, and few other sugars. Acetate, malate, succinate, fumarate, propionate, and hippurate are assimilated. Oxalate and DL-lactate are weakly assimilated. Formate and citrate are not assimilated.

Cell-wall peptidoglycan contains D-ornithine as the diamino acid, conforming to type B2β: [L-Hsr]–D-Glu–Gly–D-Orn. Cell-wall acyl type is glycolyl. Cell-wall sugar is rhamnose. Major menaquinones are MK-11 and MK-12. Moderate amounts of MK-10 or MK-13 may occur. The polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and diglycosyldiacylglycerol. Additionally, an unidentified glycolipid and three unidentified polar lipids may occur. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: milk, cheese, dairy products, and dairy equipment.

DNA G+C content (mol%): 68.6 (HPLC; type strain).

Type strain: ATCC 43647, BCRC 14859, CCUG 33091, CIP 102402, DSM 20638, HAMBI 1895, JCM 3879, LMG 16342, NBRC 15037, NCIMB 11509, VKM Ac-1018.

Sequence accession no. (16S rRNA gene): X77444.

44. **Microbacterium luteolum** (Yokota, Takeuchi, Sakane and Weiss 1993a) Takeuchi and Hatano 1998b, 745[VP] (*Aureobacterium luteolum* Yokota, Takeuchi, Sakane and Weiss 1993a, 562)

lu.te.o′lum. L. neut. adj. *luteolum* yellowish.

The following characteristics are based mainly on the data of Yokota et al. (1993a) and Buczolits et al. (2008a).

Cells are nonmotile rods arranged at angles; V forms are observed. Colonies are 1–3 mm in diameter, circular, low convex with entire margins, opaque, and moist. Yellow pigment is produced. Aerobic. Optimum temperature for growth is 28°C. Weak growth occurs at 4°C but no growth is seen at 37°C. No growth occurs in the presence of 2% NaCl. Oxidative. Gelatin, starch, and Tweens 20, 40, 60, and 80 are not hydrolyzed. Nitrate is reduced. Methyl red test and urease are positive. Arginine decarboxylase-negative. Produces H_2S. Acetate, DL-lactate, malate, succinate, fumarate, propionate, and hippurate are assimilated. Formate and citrate are not assimilated. Oxalate is assimilated weakly.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid with hydroxyglutamic acid, glycine, and alanine, corresponding to type B2β (Figure 174). A small amount of lysine is also detected. Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose, galactose, and glucose. Major menaquinone is MK-12. Menaquinones MK-11 and MK-13 are found in moderate amounts. The polar lipids are diphosphatidylglycerol and phosphatidylglycerol. One or two unidentified glycolipids and three unidentified polar lipids are also present. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: the type strain was isolated from soil.

DNA G+C content (mol%): 70.6 (HPLC; type strain).

Type strain: ATCC 51474, CIP 102086, DSM 20143, JCM 9174, LMG 16207, NBRC 15074.

Sequence accession no. (16S rRNA gene): AB004718.

45. **Microbacterium luticocti** Vaz-Moreira, Lopes, Falsen, Schumann, Nunes and Manaia 2008a, 1703[VP]

lu.ti.coc′ti. L. neut. n. *lutum* mud, sludge; L. part. adj. *coctus -a -um* digested; N.L. gen. n. *luticocti* of digested sludge.

Cells are short rods, 0.4–0.6 × 1.3–1.9 µm in size. Motile. Colonies are white, opaque, and circular (1–2 mm diameter) on BHI agar. Aerobic but catalase and oxidase are negative. Growth occurs between 27 and 45°C (optimally 36°C), between pH 5.5 and 9.7 (optimally pH 8), and in NaCl up to 10% (optimally 1–3%). Nitrate is reduced to nitrite. Starch, gelatin, and esculin are hydrolyzed. Urease is produced. Acid is produced from D-arabitol, D-fructose, D-mannitol, L-rhamnose, sucrose, and trehalose. Acid is produced weakly from cellobiose, L-fucose, D-galactose, maltose, D-mannose, potassium 5-ketogluconate, and turanose. The carbon sources assimilated are *N*-acetylglucosamine, amygdalin, D-arabinose, cellobiose, D-fructose, L-fucose, D-galactose, gentiobiose, D-lactose, maltose, D-mannitol, D-mannose, potassium gluconate, L-rhamnose, D-ribose, salicin, and trehalose. Negative for Tweenase, arginine dihydrolase, lysine and ornithine decarboxylases, citrate utilization, and indole and acetoin production. In the original description, the species is described as being both positive and negative for β-galactosidase.

Growth on glucose as a single carbon source is poor. The following compounds are not assimilated: L-arabinose, caprate, adipate, malate, citrate, phenylacetate, glycerol, erythritol, D-xylose, L-xylose, D-adonitol, methyl β-D-xylopyranoside, L-sorbose, dulcitol, inositol, D-sorbitol, methyl α-D-mannopyranoside, methyl α-D-glucopyranoside, arbutin, melibiose, sucrose, inulin, melezitose, raffinose, starch, glycogen, xylitol, turanose, D-lyxose, D-tagatose, D-fucose, D-arabitol, L-arabitol, potassium 2-ketogluconate, or potassium 5-ketogluconate. Does not produce acid from glycerol, erythritol, D-arabinose, L-arabinose, D-ribose, D-xylose, L-xylose, D-adonitol, methyl β-D-xylopyranoside, D-glucose, L-sorbose, dulcitol, inositol, D-sorbitol, methyl α-D-mannopyranoside, methyl α-D-glucopyranoside, *N*-acetylglucosamine, amygdalin, arbutin, salicin, D-lactose, melibiose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, D-lyxose, D-tagatose, D-fucose, L-arabitol, potassium gluconate, or potassium 2-ketogluconate. Cannot ferment or oxidize (API 20E) D-glucose, D-mannitol, inositol, D-sorbitol, sucrose, melibiose, amygdalin, or L-arabinose. Growth occurs in the presence of ciprofloxacin (5 µg), meropenem (10 µg), ceftazidime (30 µg), colistin sulfate (50 µg), and sulfamethoxazole (25 µg). Unable to grow in the presence of amoxycillin (25 µg), gentamicin (10 µg), tetracycline (30 µg), SXT (sulfamethoxazole/trimethoprim, 23.5/1.25 µg), cephalothin (30 µg), streptomycin (10 µg), or ticarcillin (75 µg).

The peptidoglycan is type B2β, containing ornithine, homoserine, glycine, alanine, and glutamic acid (and hydroxyglutamic acid). Cell-wall acyl type is glycolyl. The cell-wall sugar is mannose, with a trace amount of xylose. The major menaquinone is MK-12, with MK-11 as a moderate component. Predominant cellular fatty acids are $C_{17:0}$ anteiso and $C_{15:0}$ anteiso, with moderate amounts of $C_{15:0}$ iso and $C_{16:0}$ iso.

Source: the type strain was isolated from municipal sewage sludge compost.

DNA G+C content (mol%): 72±0.3 (HPLC; type strain).

Type strain: SC-087B, CCUG 54537, DSM 19459, JCM 15576.

Sequence accession no. (16S rRNA gene): AM747814.

46. **Microbacterium marinilacus** Kageyama, Takahashi, Matsuo, Kasai, Shizuri and Ōmura 2007b, 2358[VP]

mari.ni.la′cus. L. adj. *marinus* marine; L. n. *lacus -us* lake; N.L. gen. n. *marinilacus* of a marine lake.

Rod-shaped cells are variable in size, 0.4–0.6 × 0.9–1.4 µm. Colony color is lemon yellow. Catalase-positive, aerobic. Grows between pH 6 and 11, and at 12°C and 38°C. Grows in the presence of up to 8% NaCl. L-Arabinose, D-fructose, D-glucose, maltose, D-mannitol, D-mannose, L-rhamnose, trehalose, and D-xylose are assimilated. D-Galactose, raffinose, and sucrose are not assimilated. Esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, naphthol-AS-BI-phosphohydrolase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, and α-fucosidase are detected by the API ZYM enzyme assay; alkaline phosphatase, α-galactosidase, β-galactosidase, β-glucuronidase, and α-mannosidase are negative. Reactions for lipase (C14), chymotrypsin, acid phosphatase, and trypsin are weak.

The peptidoglycan contains ornithine as the diagnostic amino acid. Cell-wall acyl type is glycolyl. The major menaquinones are MK-11 and MK-12. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from an unidentified hydroid collected from the Sano Marine Lake, Republic of Palau.

DNA G+C content (mol%): 71.6 (HPLC; type strain).

Type strain: YM11-607, DSM 18904, MBIC07778, NBRC 104188.

Sequence accession no. (16S rRNA gene): AB286020.

47. **Microbacterium maritypicum** corrig. (ZoBell and Upham 1944) Takeuchi and Hatano 1998a, 981[VP] (*Flavobacterium marinotypicum* ZoBell and Upham 1944, 268)

ma.ri.ty′pi.cum. L. n. *mare* the sea; L. neut. adj. *typicum* typical; N.L. neut. adj. *maritypicum* typical of the sea.

Cells are irregular short rods of 0.2–0.5 × 0.6–2.0 µm in size, arranged at angles; V forms but no branching or rod–coccus cycle are observed. Motile with peritrichous flagella. Colonies are 2–4 mm in diameter, light yellow in color, circular, low convex with entire margins, opaque, and moist. Growth occurs at 28°C (optimal) and 37°C. Good growth occurs in 2% and 5% NaCl, but growth is weak in 6.5% NaCl. H_2S formation, methyl red test, and Voges–Proskauer test are negative. Arginine dihydrolase is not produced. Gelatin, and Tweens 20, 40, 60, and 80 are hydrolyzed but starch is not. Acid is produced from glucose and mannose and weakly from sucrose but not from L-arabinose, galactose, inulin, melezitose, raffinose, rhamnose, ribose, trehalose, or xylose. Maltose, mannose, mannitol, *N*-acetylglucosamine, citrate, gluconate, malate, and phenylacetate are assimilated but arabinose, acetate, adipate, caprate, fumarate, lactate, and propionate are not.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid (plus hydroxyglutamic acid), glycine, and alanine, corresponding to peptidoglycan type B2β (Figure 174). Cell-wall sugar is galactose. Major menaquinone is MK-12. Predominant cellular fatty acids are $C_{15:0}$ anteiso and $C_{16:0}$ iso; $C_{15:0}$ iso and $C_{17:0}$ anteiso are present in small amounts.

Source: the type strain was isolated from seawater and marine mud.

DNA G+C content (mol%): 71.6 (HPLC; type strain).

Type strain: ATCC 19260, CIP 105733, DSM 12512, JCM 11570, LMG 8374, NCIMB 559, NBRC 15779, VKM Ac-2079.

Sequence accession no. (16S rRNA gene): AJ853910.

Further comments: The specific epithet *marinotypicum* (*sic*) was corrected by Takeuchi and Hatano (1998a).

48. **Microbacterium natoriense** Liu, Nakayama, Hemmi, Asano, Tsuruoka, Shimomura, Nishijima and Nishino 2005, 664[VP]

na.to.ri.en′se. N.L. neut. adj. *natoriense* of or belonging to Natori, Miyagi, Japan, where the type strain was isolated.

Cells are nonmotile rods, 0.5–0.6 × 1.5 µm in size. Colonies are yellow in color. Obligately aerobic. Growth occurs at 10 to 40°C (optimum at 30°C) and pH 5 to 9 (optimum at pH 5–7). Grows in 6% (w/v) NaCl. Catalase-positive and oxidase-negative. Pyradinamidase, alkaline phosphatase, β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, β-glucosidase, and gelatinase are positive. Casein hydrolysis, nitrate reduction, pyrrolidonyl arylamidase, β-glucuronidase, and urease are negative.

Acid is produced from glycerol, L-arabinose, D-xylose, D-galactose, D-glucose, D-fructose, D-mannose, methyl α-D-glucopyranoside, *N*-acetyl-D-glucosamine, amygdalin, arbutin, esculin, salicin, cellobiose, maltose, melibiose, sucrose, trehalose, inulin, melezitose, raffinose, starch, glycogen, and D-turanose. Acid production is not observed from erythritol, D-arabinose, D-ribose, L-xylose, D-adonitol, methyl β-D-xylopyranoside, L-sorbose, L-rhamnose, dulcitol, inositol, D-mannitol, D-sorbitol, lactose, xylitol, gentiobiose, D-tagatose, D-fucose, D-arabitol, L-arabitol, potassium gluconate, potassium 2-ketogluconate, or potassium 5-ketogluconate.

The cell-wall peptidoglycan contains ornithine as the diagnostic amino acid. The menaquinones are MK-9, MK-10, MK-11, and MK-12. Cellular fatty acids are composed of $C_{15:0}$ anteiso, $C_{15:0}$ iso, and $C_{17:0}$ anteiso.

The type strain was isolated by using a selective medium containing 0.1% (w/v) *N*-acetyl-D-phenylalanine to screen for the activity of *N*-acyl-D-amino acid amidohydrolase (D-aminoacylase).

Source: the type strain was isolated from soil obtained at Natori, Miyagi, Japan.

DNA G+C content (mol%): 69.1 (HPLC; type strain).

Type strain: TNJL143-2, ATCC BAA-1032, JCM 12611.

Sequence accession no. (16S rRNA gene): AY566291.

49. **Microbacterium oleivorans** Schippers, Bosecker, Spröer and Schumann 2005, 657[VP]

o.le.i.vo′rans. L. n. *oleum* oil; L. part. adj. *vorans* devouring; N.L. part. adj. *oleivorans* oil-devouring, capable of utilizing oil (hydrocarbons).

Cells are nonmotile, irregular rods, 0.3–1.1 µm in size. Colonies are circular, smooth, translucent, and orange-pigmented with a maximum diameter of 3 mm after 2 weeks of cultivation. Obligately aerobic. Growth occurs at 30–37°C and in 2–4% (w/v) NaCl. Catalase-positive and oxidase-negative. Arginine is not hydrolyzed. Urease-negative. H_2S is not produced and the Voges–Proskauer test is negative. Acid is produced from sucrose and xylose but not from D-glucose, rhamnose, adonitol, inositol, or sorbitol. The following compounds are utilized as sole sources of carbon: L-arabinose, cellobiose, D-fructose, D-galactose, gluconate, D-glucose, maltose, D-mannose, α-D-melibiose, L-rhamnose, D-ribose, sucrose, salicin, trehalose, L-xylose, D-mannitol, sorbitol, fumarate, DL-lactate, L-malate, pyruvate, L-aspartate, L-histidine, putrescine, and 4-hydroxybenzoate. The following are not utilized: *N*-acetyl-D-glucosamine, α-D-galacturonate, glycogen, adonitol, i-inositol, acetate, propionate, *trans*-aconitate, adipate, citrate, DL-3-hydroxybutyrate, suberate, L-alanine, L-hydroxyproline, L-proline, L-serine, 3-hydroxybenzoate, phenylacetate, *N*-acetyl-D-galactosamine, and L-ornithine. Crude oil is used as a substrate for growth. The following are hydrolyzed: esculin, pNP-*N*-acetyl-β-D-galactosaminide, pNP-*N*-acetyl-β-D-glucosaminide, pNP-α-L-arabinopyranoside, pNP-β-D-cellobioside, pNP-β-D-galactopyranoside, pNP-α-D-glucopyranoside, pNP-β-D-glucopyranoside, pNP-α-D-mannoside, pNP-α-D-maltoside,

pNP-β-D-xyloside, bis-pNP-phosphate, benzolphosphonacid-pNP ester, L-alanine-pNA, glycine-pNA, L-leucine-pNA, L-lysine-pNA, and L-proline-pNA. The following are not hydrolyzed: pNP-β-D-glucuronide, pNP-β-D-lactoside, pNP-phosphoryl-choline, 2-deoxythymidine-5′-pNP-phosphate, γ-L-glutamate-pNA, L-glutamate-γ-3-carboxy-pNA, and L-valine-pNA.

The cell-wall peptidoglycan contains L-lysine as the diagnostic diamino acid, conforming to type B1γ: [L-Glu]–D-Glu(Hyg)–Gly_{1-2}–L-Lys. The menaquinones are predominantly MK-11 and MK-12.

The type strain was isolated by enrichment with medium containing 1–5% crude oil.

Source: the type strain was isolated from oil storage cavern 126 near Etzel, Germany.

Type strain: BAS69, DSM 16091, JCM 14341, NBRC 103075, NCIMB 14003.

Sequence accession no. (16S rRNA gene): AJ698725.

50. **Microbacterium oxydans** (Chatelain and Second 1966) Schumann, Rainey, Burghardt, Stackebrandt and Weiss 1999, 176[VP] (*Brevibacterium oxydans* Chatelain and Second 1966, 642)

o′xy.dans. N.L. part. adj. *oxydans* oxidizing.

The following description is based mainly on Schumann et al. (1999) and Buczolits et al. (2008a).

Cells are motile rods, 1–2 µm in length, occurring singly or in random groups. Colonies cultured on nutrient agar at 30°C for 24 h are very small, round with entire edges, and produce a yellow color within 2–3 d. Grows at 20 and 37°C, with optimum growth at 30°C. Growth is also observed at 4°C, pH 10, and in the presence of 7% (w/v) NaCl. Aerobic. Catalase-positive and oxidase-negative. Nitrate is not reduced to nitrite. Gelatin is liquefied and most strains peptonize milk. Esculin is hydrolyzed. β-Galactosidase is produced. H_2S is produced. Methyl red test is negative. Acetylmethylcarbinol is not produced. Lysine decarboxylase is not produced. Urease-negative. Cellulose is not attacked. Acid is produced from glucose, fructose, galactose, mannose, sucrose, maltose, mannitol, glycerol, salicin, and dextrin but not from inositol. Acid production from xylose, arabinose, rhamnose, lactose, and sorbitol is variable between strains. The type strain utilizes caprylate, citrate, 4-hydroxybenzoate, D-gluconate, and D-ribose as carbon sources.

The cell-wall peptidoglycan contains D-ornithine as the diagnostic amino acid and is possibly type B2β, [L-Hsr]-D-Glu–Gly D-Orn. Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose, mannose, glucose, and galactose. The menaquinones are mainly MK-11 and MK-12, with MK-9 and MK-10 as minor components. Polar lipids detected are diphosphatidylglycerol and phosphatidylglycerol, as well as one or two unknown glycolipids. In addition, three unidentified polar lipids are also found (Buczolits et al., 2008a). Predominant cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: contaminated hospital material, habitat unknown.

DNA G+C content (mol%): 70–71 (HPLC; type strain).

Type strain: CIP 66.12, DSM 20578, JCM 12414, NBRC 15586, NCIMB 9944, VKM Ac-2116.

Sequence accession no. (16S rRNA gene): Y17227.

51. **Microbacterium paludicola** Park, Kim, Jin and Lee 2006, 536[VP]

pa.lu.di′co.la. L. n. *palus -udis* swamp; L. suff. *-cola* from L. masc. or fem. n. *incola* inhabitant; N.L. masc. or fem. n. *paludicola* inhabitant of a swamp.

Cells are nonmotile, short rods, 0.8–1.0 × 1.0–2.5 µm in size. Colonies are lemon yellow, translucent, and circular with entire edges. Aerobic. Growth occurs at 15–37°C (optimum at 25–30°C), pH 6–9 (optimum at pH 6–8), and in up to 6.5% (w/v) NaCl. Catalase- and oxidase-positive. Nitrate is not reduced to nitrite. Xylan, starch, and esculin are hydrolyzed but casein, cellulose, and gelatin are not. Arginine dihydrolase and urease are produced, but ornithine and lysine decarboxylases are not produced. Methyl red and Voges–Proskauer tests are negative. Acid is produced from glycerol, L-arabinose, D-xylose, galactose, glucose, fructose, mannose, rhamnose, mannitol, methyl α-D-mannoside, esculin, salicin, cellobiose, maltose, sucrose, trehalose, melezitose, starch, glycogen, and D-turanose, but not from erythritol, D-arabinose, ribose, L-xylose, adonitol, methyl β-D-xylose, sorbose, dulcitol, inositol, sorbitol, methyl α-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, lactose, melibiose, inulin, raffinose, xylitol, gentiobiose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, 2-ketogluconate, or 5-ketogluconate. The following compounds are utilized as sole carbon sources: mannose, gluconate, adipate, mannitol, D-glucose, salicin, L-arabinose, propionate, valerate, 2-ketogluconate, rhamnose, D-sucrose, maltose, DL-lactate, 5-ketogluconate, and glycogen. The following carbon sources are not utilized: malate, phenylacetate, melibiose, L-fucose, D-sorbitol, caprate, citrate, histidine, 3-hydroxybutyrate, 4-hydroxybenzoate, L-proline, *N*-acetylglucosamine, D-ribose, inositol, itaconate, suberate, malonate, acetate, L-alanine, glycogen, 3-hydroxybenzoate, and L-serine. According to the results from the API ZYM test, 2-naphthyl butyrate, 2-naphthyl caprylate, 2-naphthyl myristate, L-leucyl 2-naphthylamide, L-valyl 2-naphthylamide, 2-naphthyl phosphate (pH 5.4), naphthol-AS-BI-phosphate, 2-naphthyl α-D-glucopyranoside, and 6-bromo-2-naphthyl α-D-mannopyranoside are hydrolyzed, but 2-naphthyl phosphate (pH 8.5), L-cystyl 2-naphthylamide, *N*-benzoyl-DL-arginine 2-naphthylamide, *N*-glutaryl-phenylalanine 2-naphthylamide, 6-bromo-2-naphthyl α-D-galactopyranoside, 2-naphthyl β-D-galactopyranoside, naphthol-AS-BI-β-D-glucuronide, 6-bromo-2-naphthyl β-D-glucopyranoside, 1-naphthyl *N*-acetyl-β-D-glucosaminide, and 2-naphthyl α-L-fucopyranoside are not hydrolyzed.

The peptidoglycan is type B2β: [L-Hsr]–D-Glu–Gly–D-Orn. The cell-wall acyl type is glycolyl. The cell-wall sugars detected are glucose, galactose, and mannose, with trace amounts of rhamnose and fucose. The menaquinones are predominantly MK-11 and MK-12, with small amounts of MK-13. Main polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and unknown polar lipids including glycolipids and phospholipids. Cellular fatty acids contain a large proportion of $C_{15:0}$ anteiso, followed by $C_{17:0}$ anteiso and $C_{16:0}$ iso.

The type strain was isolated by the enrichment culture for xylan degradation.

Source: the type strain was isolated from swamp forest soil in Ulsan, Korea.

DNA G+C content (mol%): 66.5 (HPLC; type strain).

Type strain: US15, DSM 16915, JCM 14308, KCTC 19080.

Sequence accession no. (16S rRNA gene): AJ853909.

52. **Microbacterium paraoxydans** Laffineur, Avesani, Cornu, Charlier, Janssens, Wauters and Delmée 2003b, 936[VP] (Effective publication: Laffineur, Avesani, Cornu, Charlier, Janssens, Wauters and Delmée 2003a, 2244.) emend. Buczolits, Schumann, Valens, Rosselló-Mora and Busse 2009, 1559 (Effective publication: Buczolits, Schumann, Valens, Rosselló-Mora and Busse 2008a, 249.)

pa.ra.o′xy.dans. Gr. prep. *para* beside, alongside of, near, like; N.L. part. adj. *oxydans* a bacterial specific epithet; N.L. part. adj. *paraoxydans* like (*Microbacterium*) *oxydans*, because the organism resembles to *Microbacterium oxydans*.

Coryneform rods. Motile by peritrichous flagella. Growth occurs under aerobic and microaerobic conditions, but not anaerobically. Growth occurs between 20 to 40°C on blood agar and at 15–42°C but not at 4°C on PYES agar (0.3% peptone from casein, 0.3% yeast extract, 0.1% succinic acid, pH 7.2). Optimum growth is observed between 25 and 37°C. Growth is observed at pH 10 and in the presence of 7% (w/v) NaCl. Colonies are bright yellow in color, smooth, sometimes sticky, and reach a diameter of 2 mm after 48 h of incubation at 37°C. On PYES agar after 48 h incubation at 28°C, colonies are 4–6 mm in diameter. Catalase-positive and oxidase-negative. Negative for urease, H_2S production, and nitrate reduction. Acid is produced from glucose, sucrose, maltose, galactose, fructose, mannose, D-ribose, and mannitol but not from salicin, D-arabinose, L-arabinose, DL-lactose, or raffinose. Acid production from melibiose, L-rhamnose, and D-xylose is variable. The following compounds are assimilated (API 50CH test): glycerol, D-arabinose, ribose, glucose, galactose, fructose, mannose, rhamnose, mannitol, methyl α-D-glucoside, *N*-acetylglucosamine, esculin, salicin, cellobiose, maltose, lactose, sucrose, trehalose, melezitose, gentiobiose, D-turanose, L-fucose, and gluconate. Assimilation is variable for sorbose, sorbitol, amygdalin, xylitol, and D-fucose.

The peptidoglycan is type B2β containing the amino acids D-ornithine, glycine, alanine, glutamic acid, hydroxyglutamic acid, and homoserine. Muramic acid residues are glycolylated. Major menaquinones are MK-12 and MK-11; MK-13 and MK-10 are present in minor amounts. The polar lipid profile is composed of diphosphatidylglycerol, phosphatidylglycerol, two unidentified glycolipids, one unknown phospholipid, and four unidentified polar lipids. Main cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. Phylogenetically, closely related to *Microbacterium luteolum*, *Microbacterium oxydans*, and *Microbacterium saperdae* based on 16S rRNA gene sequences.

Source: the type strain was isolated from human blood (of a patient of bacteremia).

DNA G+C content (mol%): 69.9 (HPLC; type strain).

Type strain: CF36, CCUG 46601, DSM 15019, JCM 12372, NBRC 103076.

Sequence accession no. (16S rRNA gene): AJ491806, AJ581908.

Further comments: C57-33 (=DSM 15461) is a reference strain.

53. **Microbacterium phyllosphaerae** Behrendt, Ulrich and Schumann 2001, 1273[VP]

phyl.lo.sphae′rae. Gr. n. *phullon* leaf; L. fem. n. *sphaera* ball, sphere; N.L. fem. n. *phyllosphaera*, phyllosphere; N.L. gen. fem. n. *phyllosphaerae* of the phyllosphere.

Cells are irregularly shaped rods. In older cultures, rods are shorter, but a marked rod–coccus cycle does not occur. Motile by means of a single polar or lateral flagellum. Colonies are yellow, shiny, slightly convex, and round with entire margins. Strictly aerobic. Optimum growth temperature is approximately 25°C. Growth occurs in the presence of 2% (w/v) NaCl. Catalase-positive and oxidase-negative. Nitrate is not reduced to nitrite. β-Galactosidase is positive. Esculin, DNA, and gelatin are hydrolyzed. Urease, arginine dihydrolase, Voges–Proskauer test, H_2S production, and indole production are negative. Hydrolysis of starch, casein, and Tween 80 is variable between strains. Acid is produced from amygdalin, arbutin, cellobiose, D-fructose, galactose, β-gentiobiose, glycerol, maltose, mannitol, D-mannose, rhamnose, salicin, sucrose, and trehalose and but not from adonitol, D-arabitol, dulcitol, D-fucose, erythritol, gluconate, 2-ketogluconate, 5-ketogluconate, L-sorbose, D-tagatose, or L-xylose. Acid production from L-arabinose, D-arabinose, methyl α-D-glucoside, L-fucose, glycogen, inositol, inulin, lactose, methyl α-D-mannoside, melibiose, melezitose, raffinose, ribose, sorbitol, starch, xylitol, D-xylose, and methyl β-xyloside is variable between strains. Oxidative production of acid from glucose is observed by using API 20NE. Assimilation of citrate is negative.

The cell-wall peptidoglycan is type B2β: [L-Hsr]–D-Glu–Gly–D-Orn. The cell-wall acyl type is glycolyl. The cell-wall sugars are galactose and rhamnose. The major menaquinones are MK-12, MK-11, and MK-10. Cellular fatty acids contain $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{15:0}$ iso, and $C_{17:0}$ anteiso.

Source: strains are isolated from the phyllosphere of grasses and from the litter layer after mulching of the sward. The type strain was isolated from phyllosphere of grasses.

DNA G+C content (mol%): 64 (HPLC; type strain).

Type strain: P 369/06, CIP 107138, DSM 13468, JCM 11571, LMG 19581, NBRC 103077.

Sequence accession no. (16S rRNA gene): AJ277840.

54. **Microbacterium profundi** Wu, Wu, Wang, Wang, Yang, Oren and Xu 2008, 2932[VP]

pro.fun′di. L. gen. n. *profundi* of the depths of the sea, of the deep-sea.

Cells are short rods, 0.4–0.6 × 1.0–2.0 µm in size, occurring singly or in pairs. Colonies are 1–2 mm in diameter, smooth, circular, elevated, and yellow in color after 48 h at 28°C. Aerobic. Growth occurs at 4–35°C (optimum at 28°C) and pH 6–9.5 (optimum at pH 7–8). Grows in 0–7.5% (w/v) NaCl, but optimum growth is observed in 1% NaCl or less. Catalase-positive and oxidase-negative. Nitrate is not reduced to nitrite. Esculin, DNA, and gelatin are hydrolyzed but casein, starch, Tweens 20 and 80, and tyrosine are not. Urease, arginine dihydrolase, gluconate oxidation, β-galactosidase, and lecithinase are negative. Acid is produced (API 50CH) from D- and L-arabinose, arbutin, cellobiose, erythritol, esculin, ferric citrate, D-galactose,

D-glucose, D- fructose, L-fucose, glycerol, D-lactose, maltose, D-mannitol, D-mannose, methyl β-D-glucoside, L-rhamnose, D-ribose, salicin, and D-xylose. Negative for the production of acid from sucrose and trehalose, but positive when tested according to the method of Leifson (1963). The substrates utilized as sole carbon source are acetate, L-arabinose, L-arginine, L-aspartate, cellobiose, D-fructose, fumarate, D-galactose, D-glucose, glycerol, isoleucine, lactate, lactose, lysine, malate, maltose, D-mannitol, D-mannose, propionate, pyruvate, raffinose, rhamnose, ribose, salicin, L-serine, succinate, sucrose, trehalose, L-valine, and xylose but not *N*-acetylglucosamine, adipic acid, L-alanine, capric acid, citrate, L-cysteine, ethanol, formate, glycine, L-histidine, *myo*-inositol, malonate, L-methionine, potassium gluconate, phenylacetic acid, sorbitol, sorbose, or trisodium citrate. Susceptible to ampicillin (10 µg), bacitracin (0.04 IU), carbenicillin (100 µg), cefalexin (30 µg), cefoxitin (30 µg), ceftriaxone (30 µg), chloramphenicol (30 µg), erythromycin (15 µg), gentamicin (10 µg), minocycline (30 µg), neomycin (30 µg), novobiocin (30 µg), penicillin (10 µg), polymyxin B (300 IU), rifampin (5 µg), streptomycin (10 µg), and tetracycline (30 µg), but not to kanamycin (30 µg), nitrofurantoin (300 µg), nystatin (100 µg), or tobramycin (10 µg).

The purified peptidoglycan contains ornithine, alanine, and glycine, plus two unidentified amino acids. The menaquinones are MK-12 and MK-13. Cellular fatty acids contain $C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso.

Source: the type strain was isolated from deep-sea sediment collected from a polymetallic nodule region in the East Pacific Ocean.

DNA G+C content (mol%): 66.8 (T_m; type strain).

Type strain: Shh49, CGMCC 1.6777, JCM 14840.

Sequence accession no. (16S rRNA gene): EF623999.

55. **Microbacterium pseudoresistens** Young, Busse, Langer, Chu, Schumann, Arun, Shen, Rekha and Kämpfer 2010, 859[VP]

pseu.do.re.sis′tens. Gr. adj. *pseudês* false; L. part adj. *resistens* resisting and also a bacterial specific epithet; N.L. part. adj. *pseudoresistens* the false *Microbacterium resistens*.

Cells are short rods, about 1–1.2 µm in width and 2–3 µm in length. Aerobic. Catalase and oxidase are positive. Good growth occurs on nutrient agar and R2A agar (Oxoid) at 25–30°C and yellow colonies appear in 3 d.

Does not produce acid from D-arabitol, adonitol, dulcitol, erythritol, D-mannitol, L-arabinose, D-xylose, glucose, cellobiose, lactose, maltose, D-mannose, sucrose, melibiose, methyl D-glucoside, raffinose, rhamnose, salicin, sorbitol, or trehalose. Esculin, pNP-α-D-glucopyranoside, pNP-β-D-glucopyranoside, pNP-phenyl-phosphate, L-alanine-pNA, and L-proline-pNA are hydrolyzed but oNP-β-D-galactopyranoside, pNP-β-D-glucuronide, pNP-β-D-xylopyranoside, bis-pNP-phosphate, pNP-phosphoryl-choline, 2-deoxythymidine-5′-pNP-phosphate, and L-glutamate-γ-3-carboxy-pNA are not hydrolyzed. Cellobiose, D-fructose, D-glucose, DL-lactate, D-mannose, maltose, D-mannitol, L-proline, sucrose, trehalose, *N*-acetyl-D-glucosamine, D-ribose, salicin, and fumarate (weak reaction) are assimilated but L-arabinose, *p*-arbutin, D-galactose, gluconate, α-melibiose, L-rhamnose, D-xylose, adonitol, *i*-inositol, maltitol, D-sorbitol, putrescine, *N*-acetyl-D-galactosamine, acetate, propionate, *cis*-aconitate, citrate, L-malate, oxoglutarate, pyruvate, *trans*-aconitate, adipate, 4-aminobutyrate, azelate, glutarate, DL-3-hydroxybutyrate, itaconate, L-leucine, mesaconate, phenylacetate, L-phenylalanine, suberate, L-tryptophan, L-alanine, β-alanine, L-aspartate, L-histidine, L-ornithine, L-serine, 3-hydroxybenzoate, and 4-hydroxybenzoate are not assimilated.

The cell-wall peptidoglycan is of type B2α with an interpeptide bridge D-Glu–D-Orn. The predominant quinone is MK-13, with MK-12 and MK-14 as minor components. The polar lipid profile is composed of diphosphatidylglycerol, phosphatidylglycerol, and one unknown glycolipid. Trace amounts of three unknown lipids are also found. Major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. Predominant polyamines are spermidine and spermine.

Source: isolated from the stalk of the edible mushroom *Agaricus blazei* cultivated in the laboratory.

DNA G+C content (mol%): Not known.

Type strain: CC-5209, CC-005209, CCM 7688, DSM 22185.

Sequence accession no. (16S rRNA gene): FJ865214.

56. **Microbacterium pumilum** Kageyama, Takahashi and Ōmura 2006, 2115[VP]

pu′mi.lum. L. neut. adj. *pumilum* dwarfish, diminutive, little.

Cells are nonmotile, irregular rods, 0.2–0.6 × 0.4–1.2 µm. Colony color is pale yellow. Aerobic and catalase-positive. Growth occurs at pH 7–10 and 17–32°C. Tolerates up to 2% NaCl on 5× diluted nutrient agar medium. D-Glucose, arabinose, D-galactose, maltose, D-mannose, and sucrose are assimilated, but fructose, mannitol, raffinose, L-rhamnose, trehalose, and xylose are not. Alkaline phosphatase, esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosamidase, and α-fucosidase are detected with the API ZYM enzyme assay; α-mannosidase is not detected. Reactions for esterase (C4) and lipase (C14) are weak.

The peptidoglycan contains ornithine as the diagnostic amino acid. Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose and galactose. The predominant menaquinones are MK-13 and MK-12, with minor amounts of MK-14. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso.

The type strain was isolated by cultivation with superoxide dismutase and catalase in the isolation medium to scavenge oxygen radicals.

Source: the type strain was isolated from soil from Aoyama Cemetery, Tokyo, Japan.

DNA G+C content (mol%): 71 (HPLC; type strain).

Type strain: KV-488, JCM 14902, NBRC 101279, NRRL B-24452.

Sequence accession no. (16S rRNA gene): AB234027.

57. **Microbacterium pygmaeum** Kageyama, Matsuo, Kasai, Shizuri, Ōmura and Takahashi 2008b, 2471[VP] (Effective

publication: Kageyama, Matsuo, Kasai, Shizuri, Ōmura and Takahashi 2008a, 5.)

pyg.ma′e.um. L. neut. adj. *pygmaeum* dwarf.

Cells are nonmotile, irregular rods, 0.3–0.4 × 0.5–0.9 µm. Colony color is pale yellow. Catalase-positive, aerobic. Grows between pH 5 and 9, and 17°C and 31°C. Grows in up to 5% NaCl. Galactose, glucose, maltose, mannitol, mannose, raffinose, sucrose, and trehalose are assimilated. L-Rhamnose and xylose are not assimilated. Esterase (C4), esterase lipase (C8), leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-glucosidase, β-glucosidase, and *N*-acetyl-β-glucosaminidase are detected by the API ZYM enzyme assay; phosphatase alkaline, lipase (C4), cystine arylamidase, trypsin, chymotrypsin, α-galactosidase, α-galactosidase, β-glucuronidase, α-mannosidase, and α-fucosidase are negative. Weak reaction for valine arylamidase.

The peptidoglycan contains ornithine as the diagnostic amino acid. Cell-wall acyl type is glycolyl. The major menaquinones are MK-11, MK-12, and MK-13. The major cellular fatty acids are $C_{17:0}$ anteiso and $C_{15:0}$ anteiso.

Source: the type strain was isolated from soil collected from Aoyama Cemetery, Japan.

DNA G+C content (mol%): 68 (HPLC; type strain).

Type strain: KV-490, JCM 15925, NBRC 101800, NRRL B-24469.

Sequence accession no. (16S rRNA gene): AB248875.

58. **Microbacterium radiodurans** Zhang, Zhu, Yuan, Yao, Tang, Lin, Yang, Li and Chen 2010, 2668[VP]

ra.di.o.du′rans. L. n. *radius* a beam or ray; N.L. pref. *radio-* pertaining to radiation; L. part. adj. *durans* enduring; N.L. part. adj. *radiodurans* resisting radiation.

Cells are weakly motile, short rods, about 0.4–0.6 µm wide and 0.5–0.8 µm long. Colonies grown on nutrient agar at 28°C for 2 d are smooth, nearly circular, convex, transparent, and white. Growth occurs at 18–30°C, at pH 6.0–10.0, and with <7% (w/v) NaCl. Catalase is weakly positive and oxidase is negative. Strictly aerobic and heterotrophic. Nitrate reduction is negative. Gelatin is not hydrolyzed. With the Biolog GP2 MicroPlate system, β-cyclodextrin, cellobiose, gentiobiose, α-D-glucose, D-xylose, D-fructose, maltose, D-mannose, salicin, D-sorbitol, inositol, maltotriose, D-mannitol, trehalose, 3-methyl D-glucose, α-keto-glutaric acid, valerate, succinic acid monomethyl ester, pyruvic acid methyl ester, glycyl L-glutamic acid, uridine, uridine 5′-monophosphate, putrescine, and α-D-glucose 1-phosphate are oxidized but the following compounds are not utilized: L-arabinose, sucrose, raffinose, L-rhamnose, D-tagatose, xylitol, α-cyclodextrin, dextrin, glycogen, D-galacturonic acid, sedoheptulosan, methyl α-D-glucoside, *N*-acetylglucosamine, acetate, adipate, L-lactate, D-malate, L-malate, propionic acid, citrate, 3-hydroxybutyrate, phenylacetate, Tweens 40 and 80, L-alanine, *N*-acetyl-L-glutamic acid, L-serine, L-proline, L-alaninamide, L-pyroglutamic acid, L-glutamic acid, lactamide, D-lactic acid methyl ester, and adenosine 2′-deoxyadenosine.

The diagnostic diamino acid of the cell-wall peptidoglycan is ornithine. The cell-wall acyl type is glycolyl. The cell-wall sugar is rhamnose. The major menaquinones are MK-11, MK-12, and MK-10. The major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, an unidentified phospholipid, and an unidentified glycolipid. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso.

The type strain shows high resistance to UV radiation (254 nm, 200 mW/cm^2, 5 min) compared to *Microbacterium arborescens*, *Microbacterium imperiale*, and *Escherichia coli* K-12 (Zhang et al., 2010).

Source: the type strain was isolated from the upper sand layer of the Gobi desert, Xinjiang, China.

DNA G+C content (mol%): 67.7 (HPLC; type strain).

Type strain: GIMN 1.002, CCTCC M208212, NRRL B-24799.

Sequence accession no. (16S rRNA gene): GQ329713.

59. **Microbacterium resistens** (Funke, Lawson, Nolte, Weiss and Collins 1998) Behrendt, Ulrich and Schumann 2001, 1275[VP] (*Aureobacterium resistens* Funke, Lawson, Nolte, Weiss and Collins 1998, 91)

re.sis′tens. L. pres. part. *resistens* being resistant, referring to the vancomycin resistance which is very unusual for coryneform bacteria.

The following characteristics are taken from Funke et al. (1998) and Behrendt et al. (2001).

Cells are nonmotile, small, slim rods, 1–2 µm in length. Colonies are up to 1.5 mm in diameter after 24 h incubation, glistening, convex, of creamy consistency, and exhibit yellow pigment. Grows in 2% NaCl. Catalase-positive. DNase activity is present. Arginine dihydrolase and Voges–Proskauer reactions are negative. Nitrate is not reduced. Esculin, tyrosine, casein, and DNA are hydrolyzed but not urea or starch. Acid is produced from glucose, maltose, and sucrose but not from mannitol or xylose. The following carbon compounds are utilized: glycerol, ribose, galactose, D-fructose, D-mannose, rhamnose, *N*-acetylglucosamine, amygdalin, salicin, cellobiose, lactose, trehalose, xylitol, D-turanose, D-lyxose, gluconate, 2-keto-gluconate, and 5-keto-gluconate. The following are not utilized: erythritol, L-arabinose, adonitol, methyl β-xyloside, L-sorbose, dulcitol, sorbitol, methyl α-D-mannoside, methyl α-D-glucoside, melibiose, inulin, melezitose, raffinose, starch, glycogen, D-fucose, D-arabitol, and L-arabitol. Activities of pyrazinamidase, esterase (C4), esterase lipase (C8), leucine arylamidase, cystine arylamidase, acid phosphatase, phosphoamidase, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-glucosaminidase, α-mannosidase, and α-fucosidase are present whereas pyrrolidonyl arylamidase, chymotrypsin, α-galactosidase, and β-glucuronidase activities are not detected.

Cell-wall peptidoglycan contains ornithine in both D and L forms as diamino acid and is possibly type B2α: [L-Orn]–D-Glu–D-Orn. Cell-wall acyl type is glycolyl. Major menaquinones are MK-12 and MK-13. Major cellular fatty acids are $C_{17:0}$ anteiso, $C_{15:0}$ anteiso, and $C_{16:0}$ iso.

Strains of this species are resistant to vancomycin but susceptible to teicoplanin.

Source: human clinical specimens. The type strain was isolated from a corneal ulcer of a 14-year-old female wearing contact lenses

DNA G+C content (mol%): 64 (HPLC; type strain).

Type strain: CCUG 38312, DMMZ 1710, DSM 11986, JCM 11686, NBRC 103078.

Sequence accession no. (16S rRNA gene): Y14699.

60. **Microbacterium saperdae** (Lysenko 1959) Takeuchi and Hatano 1998b, 745[VP] (*Brevibacterium saperdae* Lysenko 1959, 41; *Curtobacterium saperdae* Yamada and Komagata 1972a, 425; *Aureobacterium saperdae* Collins, Jones, Keddie, Kroppenstedt and Schleifer 1983a, 248)

sa.per′da.e. N.L. gen. nov. *saperdae* of *Saperda* (scientific name for a genus of insects), isolated from *Saperda caracharias*.

The following characteristics are based mainly on Yamada and Komagata (1972b), Schleifer and Kandler (1972), Collins et al. (1980, 1983a), Suzuki and Komagata (1983), Yokota et al. (1993a), and Buczolits et al. (2008a).

Cells are motile, small, slender rods arranged at angles; V forms are observed in young cultures but no branching. In older cultures, rods become shorter but no rod–coccus cycle is seen. Good growth on nutrient agar. Colonies are 1–3 mm in diameter, convex, circular with entire margins, opaque, glistening, and yellow in color. Obligately aerobic. Catalase-positive. Optimum temperature for growth is 30°C. Growth is also observed at 4°C but not at 37°C, pH 10, or in the presence of 7% (w/v) NaCl. H_2S is produced. Arginine, esculin, starch, and Tweens 20, 40, 60 and 80 are hydrolyzed. Gelatin and hippurate are not hydrolyzed. Urease-positive. Arginine dicarboxylase is positive. Nitrate is not reduced. Tellurite (0.05%) is not reduced. Acid is produced weakly from L-arabinose, xylose, rhamnose, glucose, fructose, mannose, galactose, sucrose, maltose, cellobiose, dextrin, mannitol, arbutin, esculin, and salicin, but not from sorbose, lactose, trehalose, raffinose, starch, inulin, glycerol, erythritol, adonitol, dulcitol, sorbitol, inositol, or methyl α-glucoside.

The following organic acids are assimilated: acetate, pyruvate, L-lactate, D-lactate, malate, succinate, fumarate, 2-oxoglutarate, propionate, butyrate, glycolate, glyoxylate and hippurate. The following organic acids are not assimilated: citrate, malonate, glutarate, adipate, pimelate, gluconate, and uriate.

Cell-wall peptidoglycan contains D-ornithine as the diamino acid, conforming to type B2β: [Hsr]–D-Glu–Gly–D-Orn (Figure 174). Cell-wall acyl type is glycolyl. Cell-wall sugars are galactose and glucose. Major menaquinones are MK-11 and MK-12. The polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and diglycosyldiacylglycerol. In addition, an unidentified glycolipid and three unidentified polar lipids may found (Buczolits et al., 2008a). Cellular fatty acids are predominantly $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from body cavity of dead insects (*Saperda caracharias*).

DNA G+C content (mol%): 69.1 (HPLC; type strain).

Type strain: ATCC 19272, BCRC 12119, CCEB 366, CCUG 33092, CIP 104420, DSM 20169, HAMBI 1890, IAM 12547, IMET 11076, JCM 1352, LMG 16343, NBRC 15038, NRRL B-14833, VKM Ac-1414.

Sequence accession no. (16S rRNA gene): AB004719.

61. **Microbacterium schleiferi** (Yokota, Takeuchi, Sakane and Weiss 1993a) Takeuchi and Hatano 1998b, 745[VP] (*Aureobacterium schleiferi* Yokota, Takeuchi, Sakane and Weiss 1993a, 563)

schlei′fer.i. N.L. gen. masc. n. *schleiferi* of Schleifer, referring to K.H. Schleifer, a German microbiologist who contributed to the elucidation of the primary structure of peptidoglycan and to taxonomic studies of the strains belonging to this species.

The following characteristics are based mainly on the data of Yokota et al. (1993a).

Cells are nonmotile rods arranged at angles; V forms are observed. Colonies are 1–3 mm in diameter, circular, low convex with entire margins, opaque, and moist. Yellow pigment is produced. Aerobic. Optimum temperature for growth is 28°C. Growth occurs in the presence of 2% NaCl. Oxidative. Gelatin and starch are not hydrolyzed. Tween 40 is hydrolyzed but hydrolysis of Tweens 20, 60, and 80 is strain-dependent. Nitrate is not reduced. Voges–Proskauer test is positive. Methyl red test, urease, and production of H_2S are negative. Formate, acetate, citrate, malate, succinate, oxalate, fumarate, DL-lactate, propionate, and hippurate are not assimilated.

Cell-wall peptidoglycan contains ornithine with hydroxylornithine, homoserine, glutamic acid with hydroxyglutamic acid, glycine, and alanine, corresponding to peptidoglycan type B2β (Figure 174). A small amount of lysine is also detected. Cell-wall acyl type is glycolyl. Cell-wall sugars are 6-deoxytalose, mannose, and galactose. Major menaquinones are MK-11 and MK-12; MK-10 is also found in moderate amounts. The polar lipids are diphosphatidylglycerol and phosphatidylglycerol; an unidentified glycolipid is also present. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: the type strain was isolated from soil.

DNA G+C content (mol%): 66.9 (HPLC; type strain).

Type strain: ATCC 51473, CIP 102087, DSM 20489, JCM 9175, LMG 16153, NBRC 15075, VKM Ac-1946.

Sequence accession no. (16S rRNA gene): Y17237.

62. **Microbacterium sediminicola** Kageyama, Takahashi, Matsuo, Kasai, Shizuri and Ōmura 2007b, 2357[VP]

se.di.mi.ni′co.la. L. n. *sedimen -inis* sediment; L. suff. *-cola* inhabitant dweller; N.L. n. *sediminicola* sediment-dweller.

Rod-shaped cells, variable in size, 0.4–0.7 × 0.8–1.5 µm. Colony color is pale yellow. Catalase-positive, aerobic. Grows between pH 6 and 11 and between 19°C and 35°C. Grows in the presence of up to 7% NaCl. L-Arabinose, D-galactose, D-glucose, maltose, D-mannitol, D-mannose, L-rhamnose, trehalose, and D-xylose are assimilated. D-Fructose, raffinose, and sucrose are not assimilated. Esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, acid phosphatase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, and *N*-acetyl-β-glucosaminidase are detected by the API ZYM enzyme assay; alkaline phosphatase, chymotrypsin, naphthol-AS-BI-phosphohydrolase, β-glucuronidase, α-mannosidase, and α-fucosidase are negative. Reactions for lipase (C14) and trypsin are weak.

The peptidoglycan contains ornithine as the diagnostic diamino acid. Cell-wall acyl type is glycolyl. The major menaquinones are MK-10 and MK-11. Predominant cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from sediment collected from the mouth of the Samambula River, Fiji.

DNA G+C content (mol%): 67.8 (HPLC; type strain).

Type strain: YM10-847, DSM 18905, JCM 15577, MBIC 08264.

Sequence accession no. (16S rRNA gene): AB286021.

63. **Microbacterium soli** Srinivasan, Kim, Sathiyaraj, Kim, Jung, In and Yang 2010, 482[VP]

so′li. L. gen. n. *soli* of soil, the source of the first strains.

Cells are nonmotile and rod-shaped, approximately 0.2–0.5 µm wide and 0.5–0.9 µm long after growth on R2A agar (Difco) at 30°C for 5 d. Colonies are circular and pale yellow on R2A agar after 5 d of incubation at 30°C. Growth occurs at 25–42°C, with optimal growth at 30°C on R2A agar. Aerobic. Catalase-positive and oxidase-negative. Nitrate is not reduced to nitrite or nitrogen gas. Positive for production of acid phosphatase, cysteine arylamidase, α-galactosidase, α-glucosidase, β-galactosidase, β-glucosidase (esculin hydrolysis), leucine arylamidase, α-mannosidase, and valine arylamidase, but negative for production of arginine dihydrolase, α-fucosidase, β-glucuronidase, lipase (C14), protease (gelatin hydrolysis), and urease. Acid is produced from cellobiose, esculin, and trehalose but not from D-adonitol, D- or L-arabitol, dulcitol, erythritol, D- or L-fucose, glycerol, glycogen, inositol, inulin, 2-ketogluconate, D-lyxose, methyl α-D-mannoside, raffinose, L-rhamnose, sorbitol, L-sorbose, starch, D-tagatose, L-xylose, or xylitol. *N*-Acetyl-D-glucosamine, L-arabinose, gluconate, glucose, maltose, mannitol, mannose, phenylacetate, L-proline, salicin, and sucrose are assimilated. Acetate, adipate, L-alanine, caprate, citrate, L-fucose, glycogen, L-histidine, 3-hydroxybenzoate, 3-hydroxy-DL-butyrate, inositol, itaconate, 2-ketogluconate, 5-ketogluconate, DL-lactate, L-malate, malonate, melibiose, propionate, L-rhamnose, D-ribose, L-serine, sorbitol, suberate, and n-valerate are not assimilated.

The possible cell-wall peptidoglycan structure is of type B2β, (L-Hsr)–D-Glu–Gly–D-Orn with glycolyl resides. Cell-wall sugar is galactose, with traces of an unknown sugar. The predominant quinones are MK-12, MK-11, and MK-13. The major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, an unidentified phospholipid, and an unidentified glycolipid. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso.

Four strains were also isolated from the same source and classified in this species based on the results of DNA–DNA hybridization experiments (Srinivasan et al., 2010).

Source: soil of a ginseng field in Daejeon, Republic of Korea.

DNA G+C content (mol%): 68.9–73.5 (HPLC), 70.2 (type strain).

Type strain: DCY 17, JCM 17024, KCTC 19237, LMG 24010.

Sequence accession no. (16S rRNA gene): EF593038.

Further comments: although the results of peptidoglycan analysis give Orn, Gly, Ala and Asp, the description shown in the text, B2α with [L-Orn]–D-Glu–D-Orn is more likely.

64. **Microbacterium terrae** (Yokota, Takeuchi, Sakane and Weiss 1993a) Takeuchi and Hatano 1998b, 745[VP] (*Aureobacterium terrae* Yokota, Takeuchi, Sakane and Weiss 1993a, 562[VP])

ter′ra.e. L. n. *terra* soil; L. gen. n. *terrae* of soil.

The following characteristics are based mainly on the data of Yokota et al. (1993a).

Cells are nonmotile rods arranged at angles; V forms are observed. Colonies are 1–3 mm in diameter, circular, low convex with entire margins, opaque, and moist. Yellow pigment is produced. Aerobic. Optimum temperature for growth is 28°C. Growth occurs in presence of 2% NaCl. Oxidative. Gelatin, starch, and Tweens 40, 60, and 80 are hydrolyzed. Hydrolysis of Tween 20 is variable. Nitrate is reduced. Voges–Proskauer and methyl red tests are negative. Urease-positive. Arginine decarboxylase-negative. Produces H_2S. Acetate, fumarate, and DL-lactate are assimilated. Malate, succinate, and hippurate are assimilated weakly. Oxalate, formate, and citrate are not assimilated. Propionate assimilation is variable.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid with hydroxyglutamic acid, glycine, and alanine, corresponding to type B2β (Figure 174). A small amount of lysine is also detected. Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose, galactose, and glucose. Major menaquinones are MK-13 and MK-14. The polar lipids are diphosphatidylglycerol and phosphatidylglycerol. Unidentified phosphoglycolipids are also present. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: the type strain was isolated from soil.

DNA G+C content (mol%): 70.7 (HPLC; type strain).

Type strain: ATCC 51476, CIP 103816, DSM 8610, JCM 9176, LMG 16471, NBRC 15300, VKM Ac-1945.

Sequence accession no. (16S rRNA gene): AB004720.

65. **Microbacterium terregens** (Lochhead and Burton 1953) Takeuchi and Hatano 1998b, 745[VP] (*Arthrobacter terregens* Lochhead and Burton 1953, 254; *Aureobacterium terregens* Collins, Jones, Keddie, Kroppenstedt and Schleifer 1983a, 247)

ter.re′gens. L. n. *terra* soil; L. part. adj. *egens* requiring; N.L. part. adj. *terregens* soil-requiring.

The following characteristics are based mainly on Lochhead and Burton (1953), Schleifer and Kandler (1972), Collins et al. (1983a), Suzuki and Komagata (1983), and Yokota et al. (1993a).

Cells are nonmotile, small, irregular rods, 0.6–0.8 × 1.0–5.0 µm in size, arranged at angles; V forms are observed in young cultures but no branching. In older cultures, shorter coccoid forms are observed but no rod–coccus cycle is seen. Yellowish brown colonies are 1–2 mm in diameter, low convex, and circular with entire edges on soil extract agar. A yellow non-diffusible pigment is produced. Obligately aerobic. Catalase-positive. Oxidase-negative. Optimum temperature for growth is 20 to 26°C. Growth occurs at 10°C but not at 37°C. Soil extract is required for growth. Starch, casein, gelatin, cellulose, and Tweens 20, 40, 60, and 80 are not hydrolyzed. Urease-negative. Arginine dihydrolase-negative. Nitrate is reduced to nitrite. H_2S is not produced. Voges–Proskauer test is negative but methyl red test is positive. Terregens factor, biotin, thiamine, pantothenic acid, and methionine are required for growth. Good growth is

not observed without supplementation with a source of terregens factor or similar factors and, preferably, yeast extract. The terregens factor is replaceable by other siderophores such as coprogen and ferrichrome. Acetate, malate, succinate, fumarate, and propionate are assimilated. Hippurate is assimilated weakly. Formate, citrate, oxalate, and DL-lactate are not assimilated.

Cell-wall peptidoglycan contains D-ornithine as the diamino acid, conforming to type B2β: [Hsr]–D-Glu–Gly–D-Orn. Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose, 6-deoxytalose, and galactose. Major menaquinones are MK-12 and MK-13, with a minor amount of MK-14. The polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and diglycosyldiacylglycerol. Cellular fatty acids are predominantly $C_{17:0}$ anteiso, and $C_{15:0}$ anteiso.

Source: the type strain was isolated from soil.

DNA G+C content (mol%): 68.6 (HPLC; type strain).

Type strain: ATCC 13345, CCUG 23845, CIP 103038, DSM 20449, JCM 1342, LMG 17311, NBRC 12961, NCIMB 8909, NRRL B-1824, VKM Ac-2083.

Sequence accession no. (16S rRNA gene): AB004721.

66. **Microbacterium terricola** corrig. Kageyama, Takahashi and Ōmura 2007d, 1372[VP] (Effective publication: Kageyama, Takahashi and Ōmura 2007c, 3.)

te.rri.co′la. L. n. *terricola* dweller in soil.

Irregular rods, 0.2–0.5 × 0.3–0.7 µm in size. Nonmotile. Colony color is yellow. Catalase-positive. Grows between pH 6 and 11, and at 10 and 35°C but not at 37°C. Grows in up to 4% NaCl. Assimilates glucose, galactose, maltose, mannose, raffinose, sucrose, and trehalose. In the API ZYM enzyme assay, alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine, arylamidase, valine arylamidase, cystine arylamidase, trypsin, acid phosphatase, β-galactosidase, α-glucosidase, β-glucosidase, and *N*-acetyl-β-glucosaminidase are positive whereas chymotrypsin, β-glucuronidase, α-mannosidase, and α-fucosidase are negative. Weak reaction for lipase (C14) and variable reactions for naphthol-AS-BI-phosphohydrolase and α-galactosidase are observed.

The peptidoglycan contains ornithine, alanine, glycine, homoserine, and glutamic acid (partially substituted by hydroxyglutamic acid). Cell-wall acyl type is glycolyl. The major menaquinones are MK-12 and MK-13. Predominant cellular fatty acid is $C_{15:0}$ anteiso, followed by $C_{17:0}$ anteiso and $C_{16:0}$ iso.

The strains of this species were isolated by selective medium supplemented by superoxide dismutase and catalase (Takahashi et al., 2003).

Source: the type strain was isolated from soil collected from Aoyama Cemetery, Tokyo, Japan.

DNA G+C content (mol%): 70 (HPLC; type strain).

Type strain: KV-448, NBRC 101801, NRRL B-24468.

Sequence accession no. (16S rRNA gene): AB234025.

Further comments: the specific epithet *Microbacterium terricolae* (*sic*) has been corrected on validation according to Rule 61.

67. **Microbacterium testaceum** (Komagata and Iizuka, 1964) Takeuchi and Hatano 1998b, 745[VP] (*Brevibacterium testaceum* Komagata and Iizuka 1964, 497; *Curtobacterium testaceum* Yamada and Komagata 1972a, 425; *Aureobacterium testaceum* Collins, Jones, Keddie, Kroppenstedt and Schleifer 1983a, 249)

tes.ta′ce.um. L. neut. adj. *testaceum* brick-colored.

The following characteristics are based mainly on Yamada and Komagata (1972b, 1972a), Collins et al. (1980, 1983a), Suzuki and Komagata (1983), Yokota et al. (1993a), and Zlamala et al. (2002b).

Cells are motile, small, slender rods arranged at angles; V forms are observed in young cultures but no branching. In older cultures, rods become shorter but no rod–coccus cycle is seen. Good growth on nutrient agar. Colonies are 1–3 mm in diameter, low convex, circular with entire margins, shiny, and moist. Colonies are orange in color. Obligately aerobic. Catalase-positive. Optimum temperature for growth is 30°C. Gelatin, casein, arginine, and Tweens 20, 40, 60, and 80 are hydrolyzed. Starch is not hydrolyzed. Urease-positive. Arginine decarboxylation is strain-dependent. Nitrate is reduced. Tellurite (0.05%) is reduced. Acid is produced from xylose, glucose, fructose, mannose, sucrose, maltose, trehalose, cellobiose, raffinose, starch, and inulin, but not from L-arabinose, rhamnose, galactose, sorbose, lactose, dextrin, glycerol, erythritol, adonitol, mannitol, dulcitol, sorbitol, inositol, arbutin, esculin, salicin, or methyl α-glucoside. The following organic acids are assimilated: acetate, pyruvate, L-lactate, D-lactate, malate, succinate, fumarate, 2-oxoglutarate, propionate, butyrate, glycolate, gluconate, and hippurate. The following organic acids are not assimilated: malonate, glutarate, adipate, pimelate, glyoxylate, and uriate.

Cell-wall peptidoglycan contains D-ornithine as the diamino acid, conforming to type B2β (Figure 174). Cell-wall acyl type is glycolyl. Cell-wall sugars are rhamnose and galactose. In addition, some strains contain xylose. Major menaquinone is MK-11, with small amounts of MK-10 and MK-12. The polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and diglycosyldiacylglycerol. Cellular fatty acids are predominantly $C_{17:0}$ anteiso, $C_{15:0}$ anteiso, and $C_{16:0}$ iso.

Source: the type strain was isolated from rice paddy.

DNA G+C content (mol%): 67.7 (HPLC; type strain).

Type strain: ATCC 15829, BCRC 12120, CCM 2299, CCUG 23849, CIP 104324, DSM 20166, IAM 1561, IMET 10361, JCM 1353, LMG 16344, NBRC 12675, VKM Ac-1019.

Sequence accession no. (16S rRNA gene): X77445.

68. **Microbacterium thalassium** Takeuchi and Hatano 1998a, 981[VP]

tha.las′si.um. N.L. neut. adj. *thalassium* based on Gr. adj. *thalassios* pertaining to the sea.

Cells are nonmotile, irregular, short rods, 0.2–0.5 × 0.6–2.0 µm in size, arranged at angles; V forms but no branching or rod–coccus cycle are observed. Colonies are 2–4 mm in diameter, yellow or yellowish white in color, circular, low convex with entire margins, opaque, and moist. Growth occurs at 28°C (optimal) and but not at 37°C. Good growth occurs in the presence of 2% and 5% NaCl but only weakly in 6.5% NaCl. H_2S and arginine dihydrolase are not formed and Voges–Proskauer test is negative; methyl red

test is positive. Starch, and Tweens 40, 60, and 80 are hydrolyzed. Gelatin and Tween 20 are hydrolyzed weakly. Acid is produced from glucose, mannose, and xylose but is not produced from L-arabinose, galactose, inulin, melezitose, raffinose, rhamnose, ribose, sucrose, or trehalose. Maltose, mannose, mannitol, and gluconate are assimilated but arabinose, *N*-acetylglucosamine, acetate, adipate, caprate, citrate, fumarate, lactate, malate, phenylacetate, and propionate are not.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid (hydroxyglutamic acid), glycine, and alanine, corresponding to peptidoglycan type B2β (Schleifer and Kandler, 1972). Cell-wall sugars of the type strain are galactose and glucose, whereas those of another strain are rhamnose, mannose, galactose, and glucose. Major menaquinones are MK-11 and MK-12. Predominant cellular fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{15:0}$ iso, and $C_{17:0}$ anteiso.

Source: the type strain was isolated from soil from mangrove rhizosphere.

DNA G+C content (mol%): 69.1–69.7 (HPLC; type strain).

Type strain: CIP 105728, DSM 12511, JCM 12079, NBRC 16060, VKM Ac-2084.

Sequence accession no. (16S rRNA gene): AM181507.

69. **Microbacterium trichothecenolyticum** (Yokota, Takeuchi, Sakane and Weiss 1993a) Takeuchi and Hatano 1998b, 745[VP] (*Aureobacterium trichothecenolyticum* Yokota, Takeuchi, Sakane and Weiss 1993a, 562[VP])

tri.cho.the.ce.no.ly′ti.cum. N.L. n. *trichothecenum* trichothecene, a mycotoxin produced by the fungus *Trichothecium roseum*; N.L. neut. adj. *lyticum* (from Gr. neut. adj. *lutikon*) able to loosen, able to dissolve; N.L. neut. adj. *trichothecenolyticum* trichothecene decomposing.

The following characteristics are based mainly on the data of Yokota et al. (1993a).

Cells are nonmotile rods arranged at angles; V forms are observed. Colonies are 1–3 mm in diameter, circular, low convex with entire margins, opaque, and moist. Yellow pigment is produced. Aerobic. Optimum temperature for growth is 28°C. Weak growth occurs in the presence of 2% NaCl. Oxidative. Starch, and Tweens 20, 40, 60, and 80 are hydrolyzed. Gelatin is not hydrolyzed. Nitrate is reduced. Voges–Proskauer and methyl red tests are negative. Urease-positive and arginine decarboxylase-negative. Produces H_2S. Acetate, malate, succinate, and fumarate are assimilated. DL-Lactate, propionate, and hippurate are assimilated weakly. Formate, citrate, and oxalate are not assimilated.

Cell-wall peptidoglycan contains ornithine, homoserine, glutamic acid plus hydroxyglutamic acid, glycine, and alanine, corresponding to peptidoglycan type B2β (Figure 174). A small amount of lysine is also detected. Cell-wall acyl type is glycolyl. Cell-wall sugars are galactose and glucose. Major menaquinone is MK-13; MK-12 and MK-14 are present in moderate amounts. The polar lipids are diphosphatidylglycerol and phosphatidylglycerol. An unidentified glycolipid is also present. Cellular fatty acids are predominantly $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

The type strain is reported to decompose trichothecene mycotoxin (Nakayama et al., 1980).

Source: the type strain was isolated from soil.

DNA G+C content (mol%): 69.0 (HPLC; type strain).

Type strain: ATCC 51475, CIP 103817, DSM 8608, JCM 1358, LMG 16696, NBRC 15077, VKM Ac-1948.

Sequence accession no. (16S rRNA gene): Y17240.

70. **Microbacterium ulmi** Rivas, Trujillo, Sánchez, Mateos, Martínez-Molina and Velázquez 2004b, 516[VP]

ul′mi. L. gen. fem. n. *ulmi* of the elm tree.

Cells are nonmotile rods with coryneform morphology. Colonies are convex, smooth, opaque, white, and 1–3 mm in diameter within 7 d of cultivation at 28°C. Aerobic or facultatively anaerobic. Growth occurs between 15 and 37°C and between pH 5 and 8. Catalase- and oxidase-negative. Arginine dihydrolase, ornithine decarboxylase, lysine decarboxylase, tryptophan deaminase, and urease are not produced. Esculin, casein, and gelatin are hydrolyzed. Nitrate is not reduced. D-Arabinose, carboxymethylcellulose, cellobiose, D-fructose, gentiobiose, maltose, mannitol, D-mannose, phenylacetate, starch, and xylan are utilized as sole carbon sources. Does not utilize L-arabinose, malate, *N*-acetyl-D-galactosamine, or citrate as sole carbon sources.

The cell-wall peptidoglycan contains D-ornithine as the diagnostic amino acid and possible structure is type B2β (Figure 174). Cell-wall sugars are galactose, fucose, xylose, and rhamnose. The menaquinones are predominantly MK-12 and MK-13, with minor amounts of MK-11 and MK-14, and trace amounts of MK-10. Predominant cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

The type strain was isolated by enrichment in the medium containing 0.7% xylan. In addition to xylanolytic activity, this strain possesses phosphate-solubilizing activity (Rivas et al., 2004b).

Source: the type strain was isolated from sawdust of a decayed tree of *Ulmus nigra*.

DNA G+C content (mol%): 69 (T_m; type strain).

Type strain: XIL02, CECT 5976, JCM 14282, LMG 20991.

Sequence accession no. (16S rRNA gene): AY062021.

71. **Microbacterium xylanilyticum** Kim, Park, Park, Kim and Lee 2005, 2077[VP]

xy.la.ni.ly′ti.cum. N.L. n. *xylanum* xylan, a plant polymer; N.L. neut. adj. *lyticum* (from Gr. neut. adj. *lutikon*) able to loose, able to dissolve; N.L. neut. adj. *xylanilyticum* xylan-dissolving.

Cells are nonmotile rods showing primary branching. Colonies are yellowish, rough, slightly convex, and circular with irregular margins. Aerobic. Growth occurs at 15–37°C (optimum at 25–30°C), at pH 6–9 (optimum at pH 6–8), and in up to 4% (w/v) NaCl. Catalase- and oxidase-positive. Indole and H_2S are not produced. The methyl red test is negative, but the Voges–Proskauer test is positive. Nitrate is reduced to nitrite but nitrite is not reduced. Esculin, starch, and xylan are hydrolyzed but casein, cellulose, and urea are not. Acid is produced from glycerol, D-arabinose, L-arabinose, ribose, D-xylose, galactose, glucose, fructose, mannose, mannitol, methyl α-D-glucoside, amygdalin, esculin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, melezitose, raffinose, starch, glycogen, and D-turanose but not from erythritol, L-xylose, adonitol, methyl β-D-xyloside,

sorbose, rhamnose, dulcitol, inositol, sorbitol, methyl α-D-mannoside, *N*-acetylglucosamine, arbutin, inulin, xylitol, gentiobiose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, 2-ketogluconate, or 5-ketogluconate. The compounds utilized as sole carbon sources are mannitol, *N*-acetylglucosamine, D-glucose, D-ribose, D-melibiose, D-sucrose, maltose, L-arabinose, DL-lactate, histidine, glycogen, and L-proline but not rhamnose, salicin, inositol, L-fucose, D-sorbitol, itaconate, propionate, suberate, caprate, malonate, valerate, acetate, citrate, malate, L-alanine, 2-ketogluconate, 5-ketogluconate, 3-hydroxybutyrate, 4-hydroxybenzoate, 3-hydroxybenzoate, or L-serine. In the API ZYM assay, L-leucyl 2-naphthylamide, 2-naphthyl phosphate (pH 5.4), 6-bromo-2-naphthyl α-D-galactopyranoside, 2-naphthyl α-D-glucopyranoside, and 2-naphthyl α-L-fucopyranoside are hydrolyzed, but 2-naphthyl phosphate (pH 8.5), 2-naphthyl butyrate, 2-naphthyl caprylate, 2-naphthyl myristate, L-valyl 2-naphthylamide, L-cystyl 2-naphthylamide, *N*-benzoyl-DL-arginine 2-naphthylamide, *N*-glutaryl-phenylalanine 2-naphthylamide, naphthol-AS-BI-phosphate, 2-naphthyl β-D-galactopyranoside, naphthol-AS-BI-β-D-glucuronide, 6-bromo-2-naphthyl β-D-glucopyranoside, 1-naphthyl *N*-acetyl-β-D-glucosaminide, and 6-bromo-2-naphthyl α-D-mannopyranoside are not hydrolyzed.

The cell-wall peptidoglycan is type B2β: [L-Hsr]–D-Glu–Gly–D-Orn. The cell-wall acyl type is glycolyl. The cell-wall sugars are glucose and galactose. The major menaquinone is MK-12; MK-11 and MK-13 are present in moderate amounts. Main polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and unknown polar lipids including glycolipids and phospholipids. Cellular fatty acids contain a large proportion of $C_{15:0}$ anteiso, followed by $C_{16:0}$ iso and $C_{17:0}$ anteiso.

The type strain was isolated by enrichment culture for xylan degradation; cultivation was carried out on R2A agar supplemented with 2.5% (w/w) insoluble chromogenic xylan.

Source: the type strain was isolated from biofilm of a membrane bioreactor for wastewater treatment.

DNA G+C content (mol%): 69.7 (HPLC; type strain).

Type strain: S3-E, DSM 16914, JCM 13591, KCTC 19079.

Sequence accession no. (16S rRNA gene): AJ853908.

Genus II. **Agreia** Evtushenko, Dorofeeva, Dobrovolskaya, Streshinskaya, Subbotin and Tiedje 2001, 2077[VP]

Lyudmila I. Evtushenko

Ag.re′i.a. N.L. fem. n. *Agreia* named in honor of Nina S. Agre, a Russian microbiologist.

Irregular, slender rods (mean 0.4–0.6 × 1.5–2.5 µm). Some cells are arranged at an angle to each other to give V-formations. **Nonsporeforming**. **Gram-stain-positive** in terms of cell-wall composition, but the cells are **readily decolorized**. Non-acid-fast. **Chemo-organotrophs**, having a respiratory type of metabolism. **Obligately aerobic; catalase-positive**. Acid is produced from some carbohydrates oxidatively. Nutritionally fastidious. Growth is moderate to good on standard laboratory media based on peptone, yeast extract, and glucose at near neutral pH. Colonies are typically yellow or yellow-orange and may become red-orange or brown-orange with age. Mostly mesophilic with a growth optimum at ~24–26°C.

The cell-wall peptidoglycan **contains L-diaminobutyric acid and D-ornithine** as diamino acids; **glutamic acid is 3-hydroxylated to a high degree.** Glycan moiety of the peptidoglycan is acetylated. Menaquinones are the sole respiratory quinones; the major component is an unsaturated **menaquinone with 10 isoprene units (MK-10), followed by MK-11 and/or MK-9.** Predominant fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso; **1,1-dimethoxy-anteiso-pentadecane ($C_{15:0}$ anteiso DMA) is present.** Mycolic acids are lacking. The principal polar lipids detected are phosphatidylglycerol, diphosphatidylglycerol, and a characteristic glycolipid. Spermine is the single major compound in the polyamine pattern. Commonly associated with plants and related sources.

DNA G+C content (mol%): 65–67.

Type species: **Agreia bicolorata** Evtushenko, Dorofeeva, Dobrovolskaya, Streshinskaya, Subbotin and Tiedje 2001, 2077[VP].

Further descriptive information

The genus *Agreia* belongs to the family *Microbacteriaceae*, the order *Micrococcales*. Strains of the genus show the highest 16S rRNA gene sequence similarities (up to ~97%) with *Okibacterium* and *Subtercola*, and form a clade with *Subtercola* species. (Figure 173). The close relatedness of *Agreia* and *Subtercola* is also supported by results of housekeeping gene analyses (Stackebrandt et al., 2007). The type strains of two recognized *Agreia* species, *Agreia bicolorata* and *Agreia pratensis*, exhibit 99.6% 16S rRNA gene sequence similarity and 47.8% DNA–DNA relatedness (Schumann et al., 2003).

Visible growth is observed after 2–3 d on *Corynebacterium* medium CB (DSMZ medium 53), and modified *Corynebacterium* medium MCB (Casamino acids, 3 g; peptone, 5 g; beef extract, 2 g; yeast extract, 5 g; glucose, 5 g; NaCl, 5 g; agar, 15 g; tap water, 1 liter; pH 7.0) at 24–26°C. Colonies are round, glistening, opaque, and sometimes fluid on certain media due to production of abundant polysaccharide slime (*Agreia bicolorata*). The colony color is usually yellow to orange; *Agreia bicolorata* may become red-orange to brown-orange with age (5–7 d) on some media (e.g. MCB-agar). The determined pigment is of the carotenoid nature (Trutko et al., 2005). The inhibition of pigmentation by fosmidomycin at the concentration lower than those inhibitory for growth suggests the nonmevalonate pathway of pigment biosynthesis (Kuzuyama, 2002; Lichtenthaler, 2000; Trutko et al., 2005). Various carbon sources are used for growth and energy. None of the strains

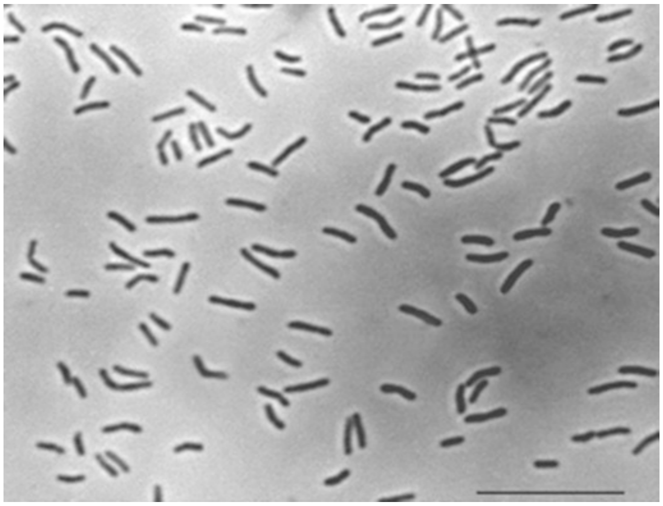

FIGURE 176. Cellular morphology of *Agreia bicolorata*, 2-d-old slide culture on CB agar. Phase-contrast microscopy. Bar = 10 µm. (Courtesy of N.E. Suzina.)

examined so far decompose starch, casein, gelatin, DNA, cellulose, hypoxanthine, and xanthine.

Cells are slender irregular rods under light microscopy, 0.4–0.6 µm in diameter × 1.5–2.5 µm or occasionally even longer, sometimes slightly curved. Some of the rods are arranged at an angle to each other giving V-formations (Figure 176). Branching forms occasionally occur, and longer cells might be composed of divided but not separated cells due to capsular material like that in *Rathayibacter* species. In older cultures, cells are usually shorter; they are single or may be arranged in pairs or short chains. Some cells show a weak but distinct motility, however, no flagella were observed. The electron microscopic study revealed the cell-wall structure typical of Gram-stain-positive bacteria, but the test with Gram-staining is indistinct or negative; KOH test also shows a reaction typical of Gram-stain-negative bacteria.

The unusual cell-wall peptidoglycan of group B-type contains two diamino acids, diaminobutyric acid (L-Dab) and D-ornithine (D-Orn), in equimolar amounts, along with alanine, glycine, glutamate, and 3-hydroxylated glutamate (Behrendt et al., 2002; Evtushenko et al., 2001; Schumann et al., 2003). The molar ratios of glutamate and 3-hydroxyglutamate vary in different strains or experiments, but 3-hydroxyglutamate always significantly predominates. The L-Dab supposedly occupies position 3 of the peptide subunit and D-Orn is present in the bridge (Schumann et al., 2003). Muramic acid residues of the peptidoglycans of both *Agreia pratensis* and *Agreia bicolorata* are acetylated (Schumann et al., 2003), as determined according to Uchida et al. (1999). Cell-wall sugars determined in three strains of *Agreia bicolorata* are rhamnose, mannose, and fucose.

Oxidase reaction applying tetramethyl-*p*-phenylenediamine varies between species or strains. Three terminal oxidases, the bb_3- and aa_3- type cytochrome oxidases and nonheme cyanide-resistant oxidase, were revealed in the respiratory chain of *Agreia bicolorata* in varying proportions depending on the strain, the growth medium, and growth phase at which biomass was harvested, and the oxygen concentration. Under oxygen deficiency, the *bd*-oxidase is additionally produced (Trutko et al., 2003). The major respiratory menaquinone is MK-10, with lower amounts of MK-11 and/or MK-9. The predominant fatty acids are $C_{15:0}$ anteiso (30–49%), $C_{17:0}$ anteiso (14–23%), and $C_{16:0}$ iso (17–41%) as determined for cells grown in different media. In addition, 1,1-dimethoxy-anteiso-pentadecane ($C_{15:0}$ anteiso-DMA) is present constituting more than 4% of the fatty compounds (Schumann et al., 2003). Principal polar lipids, as recently determined for *Agreia bicolorata*, include phosphatidylglycerol, diphosphatidylglycerol, and a characteristic glycolipid co-migrating with the glycolipid G_2 as designated by Collins and Jones (1980) and with the same staining characteristics. In addition, a few unknown α-naphthol-positive glycolipids in trace amounts were revealed. It is worth noting that the glycolipid G_2 was also found, along with other glycolipids, in representatives of several genera of the family *Microbacteriaceae* including *Agromyces*, *Clavibacter*, *Leifsonia*, *Rathayibacter* (Collins and Jones, 1980), and *Frigoribacterium* (Kämpfer et al., 2000). *Agreia bicolorata* exhibits a polyamine pattern with the single major compound spermine, which is quite an unusual feature (H.-J. Busse, unpublished results). Similar polyamine patterns have so far only been detected in representatives of the genera *Agrococcus* and *Plantibacter* species (Altenburger et al., 1997; Schumann et al., 2009; Wieser et al., 1999; Zlamala et al., 2002a).

Strains of *Agreia bicolorata* are sensitive to the following antibiotics (10 µg/ml): ampicillin, doxycycline, gentamicin, penicillin, rifampin, and tetracycline; they are resistant to neomycin and streptomycin. A representative of the genus, strain "*Subtercola pratensis*" beet 1-3-7 (AJ969075), was reported to possess antifungal activity against a plant pathogen, *Pythium ultimum* (Zachow et al., 2008).

Members of the genus *Agreia* are primarily associated with plants and plant-derived materials; some may be endophytes. Strains of *Agreia pratensis* were isolated from grass phyllosphere. *Agreia bicolorata* and some related strains were recovered from leaf galls induced by the plant parasitic gall-forming nematode *Heteroanguina graminophila* (the subfamily *Anguininae*) on the nematode plant host, *Calamagrostis neglecta*. A single *Agreia bicolorata* strain was also found in the stem gall induced by *Anguina agropyri* on *Elymus repens* sampled at the same site. The bacteria might be nematode-vectored like *Rathayibacter* species (Bird, 1981; Bradbury, 1986; Riley et al., 2001) or represent a secondary bacterial infection of galls, descending from phyllosphere or healthy plant tissue. Two yellow-pigmented bacteria, strains VKM Ac-2052 and VKM Ac-1783, which were isolated from plant galls induced by the nematode *Heteroanguina graminophila* on *Calamagrostis neglecta* and *Anguina agropiry* on *Elymus repens*, respectively (Evtushenko et al., 1994; Evtushenko and Takeuchi, 2006), most likely represent two novel species of the genus *Agreia*, as might be supposed from the 16S rRNA gene sequence comparison and phenotypic characteristics. A few strains belonging to the genus *Agreia* were isolated from internal parts of sugar beet body (Zachow et al., 2008), soil (Davis et al., 2005), permafrost (Vishnivetskaya et al., 2006), and some other environments. Information concerning these and several other environmental isolates is limited, but some might also prove to be representatives of novel species of the genus. No bacteria pathogenic for warm-blooded animals and humans or associated with clinical specimens have been identified within this genus up to now.

Enrichment and isolation procedures

Bacteria of the genus *Agreia* can be isolated on MCB agar, PYGV agar (Staley, 1968), R2A agar (Difco), and other media based on glucose, peptone, and yeast extract commonly used for isolation of plant-associated actinobacteria. Various approaches and techniques, e.g. described by Dunleavy (1989), Behrendt et al. (1997), Zinniel et al. (2002), might be applied. For isolation of bacteria from plant galls, the following procedure may be used. The galls are detached from a plant with a sterile scalpel, treated by a detergent or/and surface sterilized, rinsed by sterile water, and pre-incubated in water or in tenfold-diluted nutrient broth (e.g. MCB broth) for 1–2 h. Then the galls are cut into pieces, transferred to 1–2 ml of 0.85% solution of NaCl (w/v), ground with a pestle, and the suspensions are plated onto appropriate media. The following isolation medium was used for isolation of *Agreia bicolorata*: 2 g peptone, 1 g glucose, 1 g yeast extract, 1 g casein peptone, 10 ml glycerol, 5 g chalk, 100 ml wort, 15 g agar, 900 ml distilled water, pH 7.2–7.4.

Maintenance procedures

Agreia strains can be maintained on CB agar or R2A agar for up to 2 months at 10°C. For long-term preservation, strains can be lyophilized by standard procedures. The three strains of *Agreia bicolorata* lyophilized in skim milk as a cryoprotectant have been safely maintained for more than 15 years since the isolation. Various agar media mentioned in the above section can be used for subculturing.

Differentiation of the genus *Agreia* from other genera

Phenotypic characteristics that delineate *Agreia* from other genera of the family *Microbacteriaceae* are listed in Table 140. The unique composition of peptidoglycan containing L-Dab and D-Orn as the diamino acids along with a high proportion of 3-hydroxylated glutamate, is the most striking chemotaxonomic marker of *Agreia*. The detection of DMA among the fatty acids is another feature delineating *Agreia* from other genera including phylogenetically neighboring *Subtercola*. In particular, both *Agreia bicolorata* and *Agreia pratensis* grown at 25°C were reported to have exclusively $C_{15:0}$ anteiso DMA (up to 4.2% of the total fatty acids), whereas the *Subtercola* species contain a higher content of this compound (10–11%) and, in addition, $C_{16:0}$ iso DMA (11.9–13.3%) and $C_{17:0}$ anteiso DMA (2.9–4.0%) (Männistö et al., 2000; Schumann et al., 2003).

Differentiation of the species of the genus *Agreia*

In contrast to the permanently yellow-pigmented *Agreia pratensis*, colonies of *Agreia bicolorata* are yellow-orange pigmented, often becoming red-orange to brown-orange with age (e.g. on MCB medium), and usually produce abundant polysaccharide slime. The cells of *Agreia bicolorata* are oxidase-positive, while *Agreia pratensis* shows negative oxidase reaction applying tetramethyl-*p*-phenylenediamine. The major menaquinone of *Agreia bicolorata* is MK-10 with MK-9 as a minor component and traces of MK-11 and MK-8, whereas the quinone system of *Agreia pratensis* was reported to consist of MK-10 (51%), MK-11 (21%), and MK-9 (13%). In addition, *Agreia bicolorata* displays higher tolerance to fosmidomycin (0.5 mg/ml), and pigment formation is not suppressed by 0.3 mg/ml of the antibiotic, whereas *Agreia pratensis* loses the pigmentation at a substantially lower (0.05 mg/ml) fosmidomycin concentration (Trutko et al., 2005). DNA–DNA hybridization tests or analyses of other adequate genomic characteristics, e.g. the comparison of housekeeping gene sequences (*gyrB*, *rpoB*, *recA*, and *ppk*) available for *Agreia bicolorata* (Stackebrandt et al., 2007) is expedient to support affiliation of an isolate with *Agreia bicolorata* or *Agreia pratensis*, or obtain evidence for its possible assignment to a new species.

Acknowledgements

This work was supported by the program MCB of the Russian Academy of Sciences. The author is grateful to Dr Hans-Jürgen Busse for sharing unpublished information on the polyamine composition of *Agreia*.

List of species of the genus *Agreia*

1. **Agreia bicolorata** Evtushenko, Dorofeeva, Dobrovolskaya, Streshinskaya, Subbotin and Tiedje 2001, 2077[VP]

bi.co.lo.ra′ta. L. adv. num. *bis* twice; L. part. adj. *coloratus -a -um* coloured; N.L. fem. part. adj. *bicolorata* two-coloured.

The characteristics are as described for the genus with the following additional information. Young cells are irregular rods (0.4–0.5 × 1.5–2.5 µm). Some cells display a weak but distinct motility, though flagella are not observed. Liquid cultures usually become viscous with age (4–7 d) in CB medium. Oxidase and catalase-positive. L-Arabinose, D-glucose, D-galactose, cellobiose, fructose, inositol (weak), inulin, lactose, maltose, mannose, mannitol, melibiose, raffnose, L-rhamnose, ribose, salicin, sorbitol, trehalose, turanose, or D-xylose are used as a carbon source for growth and energy on basal medium (Shirling and Gottlieb, 1966) supplemented with 0.1% (w/v) of yeast extract and 0.1% (w/v) of casitone. Adonitol, dextran, lyxose, *meso*-erythritol, or sorbose are not used for growth on the same basal medium. Alkaline reaction is observed with citrate, fumarate, gluconate (weak), 2-oxoglutarate, and malate, but negative with oxalate or tartrate applying bromocresol purple as a pH indicator (for the method, see Zgurskaya et al., 1993). Weak growth is observed only with a few amino acids (DL-leucine, DL-methionine, or DL-proline) used as a nitrogen source. H_2S is produced from peptone. Tween 40, Tween 80, and esculin are hydrolyzed, but starch, hypoxanthine, and xanthine are not. Sensitive to 6% NaCl. Rhamnose is the major cell-wall sugar; mannose, and fucose are present in minor amounts (molar ratio ~7:1:0.5 for the type strain).

Sequence accession no. (16S rRNA gene): AF159363, AM410672.

2. **Agreia pratensis** (Behrendt et al., 2002) Schumann, Behrendt, Ulrich and Suzuki 2003, 2043[VP] (*Subtercola pratensis* Behrendt, Ulrich, Schumann, Naumann and Suzuki 2002, 1452)

pra.ten′sis. L. fem. adj. *pratensis* found in meadows/grassland.

The characteristics are as described for the genus with the following additional information based on the data of Behrendt et al. (2002), Schumann et al. (2003), and own recent morphological observations.

Young cells are irregularly shaped rods (0.4–0.5 × 1.5–2.3 µm). Colonies are yellow, shiny, slightly convex, and circular, with entire margins. Strictly aerobic. Catalase-positive and oxidase-negative. The optimum growth temperature is about 25°C; growth occurs at 4°C (slow) and at −2°C (very slow). In the Biolog test systems, L-arabinose, D-fructose, D-galactose, D-glucose, inulin, D-maltose, D-mannitol, D-mannose, raffinose, sucrose, D-trehalose, ribose, and D-xylose are oxidized. Weak reactions are observed with melibiose and are strain-dependent with inositol (type strain negative) and L-rhamnose (type strain positive). Reaction is negative with adonitol, lactose, D-melezitose, D-sorbitol, and L-sorbose. Esculin, Tween 60, and Tween 80 are hydrolyzed. None of the tested strains hydrolyses starch, casein, gelatin, DNA, or cellulose. Voges–Proskauer test and formation of levan from sucrose are negative.

Source: the phyllosphere of grasses.

DNA G+C content (mol%): 65 (HPLC).

Type strain: P 229/10, DSM 14246, JCM 12145, LMG 21000, NBRC 103054, VKM Ac-2510.

Sequence accession no. (16S rRNA gene): AJ310412.

Genus III. **Agrococcus** Groth, Schumann, Weiss, Martin and Rainey 1996, 239[VP]

Peter Kämpfer and Hans-Jürgen Busse

Ag.ro.coc′cus. Gr. n. *agros* field or soil; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; N.L. masc. n. *Agrococcus* a coccus from soil.

Irregular, spherical, ovoid or short rods, 0.7–1.0 µm in diameter and 1.1–1.7 µm in length. Cells occur singly and in pairs, short flexible chains, or small irregular clusters. Nonsporeforming. **Gram-stain-positive** and **nonmotile. Aerobic** or **microaerobic**. Colonies are circular, convex, and smooth; the pigmentation varies between white, cream, yellow, and orange depending on culture conditions. Colony size ranges from 2–7 mm. Catalase-positive; oxidase-negative.

The diagnostic **cell-wall diamino acid** is **diaminobutyric** acid and the **acyl type** is **acetyl**. The major respiratory quinones are **menaquinone MK-10, or MK-10 and MK-11, or MK-11 and MK-12**. The predominant **fatty acids** are **iso-** and **anteiso-branched acids** (>96%), with the major compounds being $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso. **Spermidine** is the only abundant **polyamine** (Altenburger et al., 1997; Wieser et al., 1999; Zlamala et al., 2002a).

Phylogenetically, this genus is a member of the family *Microbacteriaceae*.

DNA G+C content (mol%): 65–75.

Type species: **Agrococcus jenensis** Groth, Schumann, Weiss, Martin and Rainey 1996, 239[VP].

Further descriptive information

The genus *Agrococcus* and its type species *Agrococcus jenensis* were described to include two strains containing diaminobutyric acid (DAB) in their cell wall; they were isolated during a study of actinomycetes that produce bioactive compounds (Groth et al., 1996). Six additional species were subsequently described (Table 142). *Agrococcus citreus* was isolated from a medieval wall painting in the chapel of castle Herberstein in Styria, Austria (Wieser et al., 1999). *Agrococcus baldri* was collected from the air within the "Virgilkapelle" underneath the "Stephansplatz" in Vienna, Austria (Zlamala et al., 2002a). *Agrococcus lahaulensis* was isolated from a soil sample from Lahaul-Spiti Valley, Himalayas, India (Mayilraj et al., 2006). *Agrococcus casei* was isolated from smear-ripened cheeses (Bora et al., 2007). *Agrococcus jenjuensis* (AM396260) was isolated from dried seaweed found at Samyang Beach, Jeju, Republic of Korea (Lee, 2008). *Agrococcus versicolor* was isolated from the phyllosphere of potato plants in Dahnsdorf, Germany (Behrendt et al., 2008a). Phylogenetically, the genus is a member of the family *Microbacteriaceae* (Groth et al., 1996). The seven species share more than 95% 16S rRNA gene sequence similarity and several characteristic which support their affiliation in a single genus. Their peptidoglycan contains the diamino butyric acid (DAP). The peptidoglycans of all species except *Agrococcus casei* also contain the amino acids alanine, glycine, aspartate, and glutamate. The peptidoglycans of *Agrococcus jenensis*, *Agrococcus versicolor*, *Agrococcus jejuensis*, and *Agrococcus lahaulensis* also contain threonine. *Agrococcus casei* exhibits the most unique peptidoglycan lacking both of the amino acids aspartate and threonine (Bora et al., 2007). Most species contain a quinone system consisting of the predominant quinones MK-11 and MK-12. *Agrococcus lahaulensis* also contains large amounts of MK-10 (Bora et al., 2007); the quinone system of *Agrococcus versicolor* comprises the major compounds MK-10 and MK-11 and that of *Agrococcus jejuensis* MK-10 and significant amounts of MK-9. The major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso. In addition to some species-specific compounds, the polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and an unknown glycolipid (Bora et al., 2007; Mayilraj et al., 2006; Wieser et al., 1999; Zlamala et al., 2002a). The predominant polyamine is spermine, although so far only *Agrococcus jenensis* (Altenburger

et al., 1997), *Agrococcus citreus* (Wieser et al., 1999), and *Agrococcus baldri* (Zlamala et al., 2002a) have been analyzed for this trait. This polyamine pattern is unique within the family *Microbacteriaceae* (Altenburger et al., 1997) and may be a specific marker of the genus *Agrococcus*. Analyses of *Agrococcus jenensis*, *Agrococcus citreus*, and *Agrococcus baldri* using Fourier-transform infra-red (FT-IR) revealed a homogeneous cluster for the five strains of *Agrococcus baldri*, whereas two strains of *Agrococcus jensensis* and the type strain of *Agrococcus citreus* were intermingled (Zlamala et al., 2002a). Thus, FT-IR is of limited suitability to identify *Agrococcus* at the species level. On the other hand, MALDI-TOF analyses have shown that strains of *Agrococcus versicolor* can be reliably identified and distinguished from related species such as *Agrococcus casei*, *Agrococcus baldri*, *Agrococcus citreus*, *Agrococcus lahaulensis*, and *Agrococcus jenensis* (Behrendt et al., 2008a).

Based upon 16S rRNA gene sequences deposited in databases, the following strains reveal higher than 96.0% sequence similarity to one of the type strains of *Agrococcus*. These strains are designated "*Corynebacterium* cf. *aquaticum*" V4.B0.26 (accession no. AJ244681; Fritz, 2000), *Agrococcus* sp. QSSC2–2 (AF170759), *Agrococcus* sp. Bt 15 (AJ971867), bacterium PH2 (AY345361), *Agrococcus* sp. Tibet-IT72 (DQ177486), *Microbacteriaceae* bacterium 4_C7/16_17 (EF540491), *Agrococcus* sp. 8_1Kb (EF540451), *Agrococcus* sp. G2DM-57 (DQ416789), *Agrococcus* sp. DNG5 (FJ423764), *Agrococcus* sp. m8–15 (DQ923165), *Agrococcus* sp. Everest-gws-11 (EU584505), *Agrococcus* sp. ZXM075 (FJ436727), *Agrococcus* sp. MSCB-4 (EF103201), *Corynebacteriaceae* bacterium NR121 (DQ520815), *Agrococcus jenenensis* B16 (EU169180), *Agrococcus jenensis* strain 1RN-3D2 (EU379252), *Agrococcus jenenensis* XJU-1 (EF672044), *Agrococcus jenensis* zf-IIRht16 (DQ223675) *Agrococcus* sp. RCML-30 (FJ005071), and *Agrococcus* sp. Ens24 (DQ339623). These strains were isolated from sea water of the Mediterranean Sea near to Nice, from an Antarctic quartz stone sublithic community, the gut of a bumble bee, Loihi submarine volcano, permafrost at Qinghai-Tibet Plateau, semi-coke, north eastern region of Estonia, a chromium polluted landfill site near a contaminated stream in Gorwa Industrial Estate, Baroda, Gujarat, India (Desai et al., 2009), forest soil, an aquatic system in the valley of Cuatro Cienegas, Coahuila, Mexico, glacial meltwater, Mount Everest, during massive green algae blooms in coastal water of Qingdao, China, snow in Western China, soil sample from north Delhi, India, the rhizosphere soil of *Bashania fangiana*, the Wolong Nature Reserve, Sichuan Province, China, commercial airline cabin air (Osman et al., 2008a), necrotic trunk, China, ice cores, East Rongbuk Glacier, Mt. Qomolangma (Zhang et al., 2006), Xinjiang Province, China, and from alpine subnival plants, respectively. *Microbacteriaceae* bacterium 4_C7/16_17 shares 100% 16S rRNA gene similarity with the type strain of *Agrococcus versicolor* suggesting a relatedness at the species level. *Agrococcus* sp. Tibet-IT72, *Agrococcus jenenensis* B16, and "*Corynebacterium* cf. *aquaticum*" share 99.9%, 99.7%, and 99.6%, respectively, 16S rRNA gene sequence similarity with the type strain of *Agrococcus jenensis* and, hence, they can be considered authentic members of this species. *Agrococcus* sp. MSCB-4, *Agrococcus jenensis* strain 1RN-3D2, and *Agrococcus* sp. Everest-gws-11 most likely are representatives of *Agrococcus citreus* with which they share 99.9–100% 16S rRNA gene similarity. In addition, Tiago et al. (2004) found an *Agrococcus*-like organism, designated *Agrococcus jenensis* AC72 (AJ717350), in nonsaline alkaline groundwater samples in Cabeco de Vide, Portugal. 16S rRNA gene sequence similarity (98.0%) with the type strain of *Agrococcus jenensis* suggests that this strain was misidentified. Also, *Agrococcus jenensis* zf-IIRht16 must be considered to be misidentified because its 16S rRNA gene sequence similarity with the type strain is even lower. Other potential members of the genus of unknown sources are the catechol-degrading *Microbacterium* sp. Atl-19 (EF028128), *Agrococcus* sp. CGMCC 1.3033 (EU660308), and *Agrococcus* sp. CGMCC 1.3033 (EU660307). Recently, an *Agrococcus* strain was also detected in the air above the Atacama Desert in Chile applying a culture-independent approach (Fred Rainey, pers. communication). These results emphasize the very wide distribution of this genus.

Strains of at least two species, *Agrococcus jenensis* and *Agrococcus baldri*, show photochromogenic pigmentation. Strains usually grow well on complex media at 28°C supplemented with 0–4% NaCl (w/v). Their source of isolation (sandstone, wall painting, air, quartz stone) may indicate that at least some members of the genus *Agrococcus* have developed mechanisms to withstand desiccation, but so far this assumption has not been investigated. No specific isolation medium has been described. Characteristics useful for differentiation of species are listed in Table 143.

Pathogenicity. The pathogenic potential of species of this genus has not been reported.

Maintenance procedures

Agrococcus cultures may be lyophilized by procedures commonly used for many aerobic heterotrophic bacteria of the class *Actinobacteria*.

Differentiation of the genus *Agrococcus* from other genera

The genus *Agrococcus* can be distinguished from other genera in the family *Microcbacteriaceae* and other cocci of the order *Micrococcales* by the presence of diamino butyric acid in the cell-wall peptidoglycan, the menaquinone type, and the predominance of the polyamine spermine. Differential features are specified in Table 142. Note added in proof: *Agrococcus* sp. DNG5 (FJ423764) has since been described as *Agrococcus terreus*.

List of species of the genus *Agrococcus*

1. **Agrococcus jenensis** Groth, Schumann, Weiss, Martin and Rainey 1996, 239[VP]

je.nen′sis. N.L. masc. adj. *jenensis* of or belonging to the Thuringian town Jena, where the organism was isolated.

Cells are irregular, spherical or ovoid to short rods, 0.7–1.0 × 0.7–1.7 µm. A few cells may be up to 2.6 µm long. Cells occur singly, in pairs, in short flexible chains of about 3–6 cells, or small irregular clusters. Colonies are circular, slightly convex, and smooth. Colony diameter ranges from 2–4 mm. The color of the colonies varies depending on culture conditions and illumination from whitish to yellow or intense orange. Nitrate is not reduced to nitrite; hydrogen sulfide is produced. Starch and esculin are hydrolyzed. Hydrolysis of casein is variable or negative, depending on the method applied (Zlamala et al., 2002a). Acids are produced from fructose, mannitol, L-rhamnose, and D-glucitol. Acid production from sucrose, glycerol, and inulin is variable, depending on the method applied (Zlamala et al., 2002a). Succinate is utilized as a carbon source. Malate utilization is positive or negative, depending on the method applied (Zlamala et al., 2002a). Acetate, aconitate, benzoate, citrate, formate, and tartrate are not utilized. Urea, xanthine, hypoxanthine, gelatin, adenine, tyrosine, and Tween 80 are not decomposed. Tyrosine and hippurate decomposition is negative or variable, depending on the method applied (Zlamala et al., 2002a). Cells are susceptible to ampicillin, chloramphenicol, ciprofloxacin, erythromycin, gentamicin, kanamycin, lincomycin, neomycin, nitrofuran, oxacillin, oxytetracyclin, penicillin G, polymyxin B, rifampin, and streptomycin. Cells are resistant to sulfonamide.

The predominant quinones are MK-11 and MK-12. The branched fatty acids $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ anteiso, and $C_{15:0}$ iso predominate. The polar lipids comprise diphosphatidylglycerol, phosphatidylglycerol, two unknown glycolipids, and one unknown phospholipid. Additionally, three unknown lipids and two yellow pigment spots are visible after two-dimensional thin-layer chromatography (Wieser et al., 1999). The polyamine pattern is characterized by the predominance of spermine (Altenburger et al., 1997). The cell wall contains the amino acids alanine, glycine, threonine, diaminobutyrate, aspartate, and glutamate. The acyl type is acetyl. Whole-cell sugars are glucose, rhamnose, and minor amounts of ribose, mannose, galactose, and an unknown compound. Mycolic acids are absent.

Source: soil and sandstone surface.

DNA G+C content (mol%): 74 (HPLC).

Type strain: 2002-39/1, ATCC 700087, CCUG 35514, CIP 106528, DSM 9580, NBRC 16126, JCM 9950, NBRC 100415.

Sequence accession no. (16S rRNA gene): AM410679, X92492.

2. **Agrococcus baldri** Zlamala, Schumann, Kämpfer, Rosselló-Mora, Lubitz and Busse 2002a, 1215[VP]

bal′dri. N.L. gen. n. *baldri* of Baldr, ancient German god of light, referring to the photochromogenic behavior.

Cells are irregular spherical, ovoid, or rod-shaped. They vary in size from 0.7–1.0 × 1.1–1.7 µm. Cells occur singly, in pairs, or in small irregular clusters. They stain Gram-positive and are nonmotile. Non-spore-forming. Colonies are slightly convex and smooth. Colony diameters on TSA (tryptic soy broth agar) are in a range of 2–7 mm. The color of the colonies on nutrient agar is light yellow when grown in the light and white when grown in the dark. Aerobic. Catalase is produced. Oxidase is negative. Nitrate is not reduced to nitrite. Other biochemical characteristics are given in Table 142.

The cell-wall diamino acid is diaminobutyrate; additionally alanine, glycine, glutamate, and aspartate are found. Threonine is absent. The polar lipids are comprised of diphosphatidylglycerol, phosphatidylglycerol, two unknown glycolipids, and one unknown polar lipid. The predominant fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso, whereas $C_{16:0}$ iso and $C_{15:0}$ iso are present in significant amounts. The major menaquinones are MK-11 and MK-12. Spermine is the predominant polyamine.

Source: isolated from the air in the "Virgilkapelle" a medieval chapel, approximately 12 m underneath Stephansplatz the most famous place in the center of Vienna, Austria.

DNA G+C content (mol%): 73.8–74.9 (HPLC).

Type strain: V-108, CCM 4953, DSM 14215, JCM 12132, NBRC 103055.

Sequence accession no. (16S rRNA gene): AJ309928.

3. **Agrococcus casei** Bora, Vancanneyt, Gelsomino, Swings, Brennan, Cogan, Larpin, Desmasures, Lechner, Kroppenstedt, Ward and Goodfellow 2007, 95[VP]

ca.se′i. L. gen. n. *casei* of cheese, named because the organism was isolated from smear-ripened cheeses.

Aerobic, stains Gram-positive, non-spore-forming, nonmotile, catalase-positive actinomycete that forms irregular, ovoid to short rods. Cells are 0.3–0.4 × 0.8–1.0 µm and occur singly, in pairs or short chains, and in small irregular clusters. Circular, cream-colored, smooth colonies with entire edges are formed on tryptic soy agar. Grows at 20–30°C, but not at 4 or 42°C. Good growth occurs at pH 6.0–10.0. Starch and Tween 80 are hydrolyzed but esculin and Tween 20 are not. Tributyrin is not degraded. Acid is produced from glucose and mannose but not from cellobiose, fructose, maltose, mannitol, sucrose, or trehalose. Growth on a range of carbon sources is variable. The cell-wall diamino acid is diaminobutyrate; alanine, glycine, and glutamate are also found. The peptidoglycan type is B2. Whole-organism sugars are galactose, glucose, and mannose. The polar lipids comprise diphosphatidylglycerol, phosphatidylglycerol, an unknown glycolipid, unknown polar lipids, and four uncharacterized phospholipids. The predominant fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{15:0}$ iso. The main menaquinones are MK-11 and MK-12.

Source: the surface of Gubbeen cheese. Representative strains were isolated from the surfaces of smear-ripened cheeses.

DNA G+C content (mol%): 65 (HPLC).

Type strain: R-17892t2, DSM 18061, JCM 14916, LMG 22410.

Sequence accession no. (16S rRNA gene): DQ168427.

4. **Agrococcus citreus** Wieser, Schumann, Martin, Altenburger, Burghardt, Lubitz and Busse 1999, 1168[VP]

ci′tre.us. L. masc. adj. *citreus* of or pertaining to the citron-tree; intended to mean lemon-yellow, describing the lemon-yellow pigmentation.

Cells are irregular spherical, ovoid, or rod shaped. The cell sizes vary from 0.7–1.0 × 1.1–1.7 µm. Cells occur singly, in pairs, or in small irregular clusters. They stain Gram-positive and are nonmotile. Non-spore-forming. Colonies are slightly convex and smooth. Colony diameters are in a range of 2–4 mm. The color of colonies on nutrient agar is yellow. Aerobic and microaerophilic. Catalase is produced. Oxidase-negative. Nitrate is not reduced to nitrite. Acids are produced from arabinose, fructose, mannitol, rhamnose, ribose, and sorbitol. Acid is produced weakly from mannose, glycerol, and xylose. Acid is not produced from cellobiose, dextrin, galactose, glucose, glycerol, inulin, lactose, maltose, raffinose, salicin, sucrose, starch, and trehalose. Acetate and aconitate are utilized as carbon sources. Benzoate, citrate, formate, malate, succinate, and tartrate are not utilized. Starch, esculin, and tyrosine are decomposed. Adenine, casein, gelatin, hippurate, xanthine, hypoxanthine, urea, and Tween 80 are not decomposed. Cells are sensitive to ampicillin, chloramphenicol, ciprofloxacin, erythromycin, gentamicin, kanamycin, lincomycin, neomycin, oxacillin, tetracycline, penicillin G, polymyxin B, rifampin, and streptomycin and are resistant to nitrofuran.

The cell-wall diamino acid is diaminobutyrate (DAB); additionally, alanine, glycine, glutamic, and aspartate are found. Threonine is absent. The whole cell sugars are glucose, rhamnose, mannose, ribose, galactose, and tyvelose. The polar lipids comprise diphosphatidylglycerol, phosphatidylglycerol, two unknown glycolipids, and four uncharacterized polar lipids. The predominant fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. $C_{15:0}$ iso, $C_{15:1}$ iso, $C_{17:0}$ iso and $C_{16:0}$ are present in minor amounts. The main menaquinones are MK-11 and MK-12. Spermine is the predominant polyamine.

Source: a medieval wall painting in the church of castle Herberstein in Styria, Austria.

DNA G+C content (mol%): 74 (HPLC).

Type strain: D-1/1a, ATCC 700859, CIP 106287, DSM 12453, JCM 12398.

Sequence accession no. (16S rRNA gene): AJ012826.

5. **Agrococcus jejuensis** Lee 2008, 2299[VP]

je.ju.en′sis. N.L. masc. adj. *jejuensis* of or belonging to Jeju, Republic of Korea, where the type strain was isolated.

Cells are aerobic, Gram-stain-positive, non-spore-forming, oxidase-negative, catalase-positive, nonmotile rods 1.3–1.5 µm × 0.3–0.4 µm. Colonies are circular, smooth, translucent, yellow-colored, and 1–2 mm in diameter. Growth occurs at 10–37°C, with an optimum at 30°C. No growth occurs at 4 or 42°C. pH for growth is in the range 6.1–12.1. Growth occurs in the presence of 0–3% NaCl, but not at 4%. Positive for gelatin hydrolysis, but negative for indole production and glucose fermentation. Nitrate is not reduced to nitrite. Positive for β-galactosidase, but negative for arginine dihydrolase and urease. Assimilates D-glucose, malate, maltose, D-mannitol, D-mannose, and *N*-acetyl-D-glucosamine, but not adipate, D-arabinose, caprate, citrate, gluconate, or phenyl acetate (API 20NE). Hydrolyzes casein and elastin, but not starch. Does not degrade hypoxanthine, DL-tyrosine, or xanthine. Acid is produced from melibiose and salicin. Acid is not produced from adonitol, D-arabinose, L-arabinose, 2,3-butanediol, dulcitol, *meso*-erythritol, D-galactose, glycerol, *myo*-inositol, inulin, D-lactose, melezitose, methyl-D-glucoside, methyl-D-mannoside, 1,2-propanediol, D-raffinose, L-rhamnose, D-sorbitol, L-sorbose, D-xylitol, or D-xylose. Acid production from L-ribose is weak. Positive for alkaline phosphatase, leucine arylamidase, glucosidase, esterase (C4) (weak), and esterase lipase (C8) (weak), but negative for lipase (C14), valine arylamidase, cysteine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, mannosidase, and fucosidase (API ZYM). The diagnostic cell-wall diamino acid is 2,4-diaminobutyric acid; alanine, glycine, glutamic acid, threonine, and aspartic acid are also detected. The acyl type of the muramic acid is acetyl. Mycolic acids are not present. Predominant menaquinones are MK-10 and MK-9. Major fatty acids are $C_{15:0}$ anteiso (56.7%) and $C_{16:0}$ iso (13.2%). Phospholipids are diphosphatidylglycerol and phosphatidylglycerol.

Source: a dried seaweed sample collected on Samyang Beach, Jeju, Republic of Korea.

DNA G+C content (mol%): 73.0 (HPLC).

Type strain: SSW1-48, JCM 14256, KCTC 19198.

Sequence accession no. (16S rRNA gene): AM396260.

6. **Agrococcus lahaulensis** Mayilraj, Suresh, Schumann, Kroppenstedt and Saini 2006, 1809[VP]

la.haul.en′sis. N.L. masc. adj. *lahaulensis* of or belonging to Lahaul Valley, located in the Indian Himalayas, where the type strain was isolated.

The cells vary in size from 0.6–1.0 µm × 1.0–1.5 µm. Stain Gram-positive, non-acid-fast, aerobic, non-spore-forming, and nonmotile. On TSA, colonies are lemon yellow colored, circular, glistening, and opaque with an entire margin. Colony sizes are in the range of 0.7–3.0 mm. Cells are irregular spherical, occurring in pairs and in clusters. Mycelial growth is not observed.

Catalase-positive and oxidase-negative. Tolerates up to 7.0% NaCl and grows at temperatures 25–37°C, with an optimum temperature of 30°C. Growth occurs at pH 6–10 with an optimum at pH 8.0. Growth is not observed at pH 5.2. Decomposes casein, Tween 20, starch, and gelatin. It is negative for indole production from tryptophan, urease, hydrogen sulfide production, methyl red test, Voges–Proskauer reaction, citrate utilization, decomposition of esculin and tyrosine, and nitrate reduction. Acid is produced from D-rhamnose, D-fructose, and D-trehalose but not from D-glucose, L-arabinose, D-cellobiose, *meso*- inositol, D-mannitol, D-maltose, D-galactose, D-raffinose, glycerol, salicin, sucrose, and D-xylose. Utilization of compounds as

sole source of carbon is given in Table 142. In the Biolog GN test, reactions are positive for dextrin, maltotriose, L-rhamnose, γ-hydroxybutyric acid, glycerol, adenosine, 2′-deoxyadenosine, inosine, thymidine, L-arabinose, D-fructose, D-mannitol, D-ribose, and D-xylose and negative for D-gluconic acid, α-D-glucose, D-mannose, D-psicose, D-sorbitol, D-agatose, turanose, D-fructose 6-phosphate, L-alaninamide, α-cyclodextrin, β-cyclodextrin, glucogen, inulin, mannan, Tween 40, Tween 80, *N*-acetyl-D-glucosamine, *N*-acetyl-β-D-mannosamine, amygdalin, D-arabitol, arbutin, D-cellobiose, L-fucose, D-galactose, D-galacturonic acid, gentiobiose, *m*-inositol, α- D-lactose, lactulose, maltose, D-melezitose, D-melibiose, α-methyl-D-galactoside, β-methyl-D-galactoside, 3-methyl-glucose, α-methyl-D-glucoside, β-methyl-D-glucoside, α-methyl-D-mannoside, palatinose, D-raffinose, salicin, sedoheptulosan, stachyose, sucrose, D-trehalose, xylitol, acetic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, *p*-hydroxy-phenylacetic acid, α-ketoglutaric acid, α-ketovaleric acid, lactamide, D-lactic acid methyl ester, L-lactic acid, D-malic acid, L-malic acid, pyruvatic acid methyl ester, succinic acid monomethyl ester, propionic acid, pyruvic acid, succinamic acid, succinic acid, *N*-acetyl-L-glutamic acid, D-alanine, L-alanine, L-alanyl-glycine, L-asparagine, L-glutamic acid, glycyl-L-glutamic acid, L-serine, L-pyroglutamic acid, putrescine, 2,3-butanediol, uridine, adenosine-5′-monophosphate, thymidine-5′-monophosphate, uridine-5′-monophosphate, α-D-glucose 1-phosphate, D-glucose 6-phosphate, and DL-α-glycerol phosphate.

The diagnostic cell-wall diamino acid is diaminobutyrate (DAB). The peptidoglycan also contains alanine, glycine, aspartate, glutamate, and threonine. The cell-wall sugars are glucose, rhamnose, ribose, mannose, and galactose. The polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and two unknown glycolipids. Mycolic acids are absent. The abundant fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{15:0}$ iso, and $C_{16:0}$ iso. The major menaquinones are MK-10, MK-11, and MK-12. The acyl type is acetyl.

Source: soil, 0.45 m below an ice glacier at 4200 m above sea level in Lahaul Valley, Himachal Pradesh, India.

DNA G+C content (mol%): 74.1 (T_m).

Type strain: K22-21, DSM 17612, JCM 14301, MTCC 7154.

Sequence accession no. (16S rRNA gene): DQ156908.

7. **Agrococcus versicolor** Behrendt, Schumann and Ulrich 2008a, 2837[VP]

ver.si′co.lor. L. masc. adj. *versicolor* color changing.

Cells are nonsporeforming, nonmotile, short to ovoid rods (0.5–0.6 × 0.8–1.2 µm) and occur singly or in pairs, sometimes forming small irregular clusters. Gram-stain-positive and strictly aerobic. Colonies on nutrient agar are dark pink to red in color and are smooth with regular margins. Young, solitary, growing colonies are yellow, turning dark pink with age. The optimal growth temperature is 21°C; no growth occurs at 4 or 37°C. Nitrate and nitrite are not reduced. Growth occurs at 1% and 2% NaCl but not at higher concentrations. Catalase activity is present, but oxidase, urease, L-phenylalanine deaminase, lysine and ornithine decarboxylase, arginine dihydrolase, and tryptophan deaminase activities are absent. β-Galactosidase activity is weak. Gelatin, casein, and esculin are hydrolyzed, but starch and tyrosine are not. Hydrogen sulfide is not produced. Indole production from L-tryptophan and the reaction in the Voges–Proskauer test are negative. Using Biolog microplates GP2, positive for oxidation of dextrin, *N*-acetyl-D-glucosamine, L-arabinose, cellobiose, D-fructose, D-gluconic acid, α-D-glucose, maltose, D-mannitol, D-mannose, palatinose, D-psicose, D-ribose, sucrose, D-tagatose, turanose, D-xylose, propionic acid, and glycerol. Oxidation of maltotriose, trehalose, α-hydroxybutyric acid, α-ketovaleric acid, L-alaninamide, and adenosine is observed after prolonged incubation. The following substrates are not oxidized: α- and β-cyclodextrin, glycogen, inulin, mannan, Tweens 40 and 80, *N*-acetyl-D-mannosamine, amygdalin, D-arabitol, arbutin, D-galactose, L-fucose, D-galacturonic acid, gentiobiose, *myo*-inositol, D-lactose, lactulose, melezitose, melibiose, methyl-D-galactoside, methyl β-D-galactoside, methyl-D-glucoside, methyl β-D-glucoside, methyl -D-mannoside, raffinose, L-rhamnose, salicin, sedoheptulosan, D-sorbitol, stachyose, xylitol, acetic acid, β-hydroxybutyric acid, α-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, ketoglutaric acid, lactamide, D-lactic acid methyl ester, L-lactic acid, D- and L-malic acid, monomethyl succinate, succinamic acid, succinic acid, *N*-acetyl L-glutamic acid, D- and L-alanine, L-alanyl glycine, L-asparagine, L-glutamic acid, glycyl L-glutamic acid, L-pyroglutamic acid, L-serine, putrescine, 2,3-butanediol, 2′-deoxyadenosine, inosine, thymidine, uridine, adenosine 5′-monophosphate, thymidine 5′-monophosphate, uridine 5′-monophosphate, D-glucose 1-phosphate, D-glucose 6-phosphate, and DL-glycerol phosphate. Oxidative acid production with API 50 CH is positive for ribose and L-arabinose but only weakly positive for D-glucose, D-fructose, D-mannose, sucrose, and turanose. Acid production is negative for glycerol, erythritol, D-arabinose, L-xylose, D-adonitol, methyl β-D-xylopyranoside, D-galactose, L-sorbose, L-rhamnose, dulcitol, inositol, D-sorbitol, methyl-D-mannopyranoside, methyl-D-glucopyranoside, amygdalin, arbutin, salicin, D-lactose (bovine origin), melibiose, trehalose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, D-lyxose, D-tagatose, D- and L-fucose, D- and L-arabitol, potassium gluconate, potassium 2-ketogluconate, and potassium 5-ketogluconate. Strain-specific reactions are shown for D-mannitol, *N*-acetylglucosamine, D-cellobiose, and maltose. The diagnostic cell-wall diamino acid is diaminobutyric acid; alanine, glycine, threonine, aspartic acid, and glutamic acid are also present. The major fatty acids are $C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{16:0}$, and $C_{17:1}$ anteiso, and minor fatty acids are $C_{17:0}$ anteiso, $C_{16:0}$ iso, $C_{14:0}$, $C_{17:0}$ iso, and $C_{14:0}$ iso. The major menaquinones are MK-10 and MK-11.

Source: the phyllosphere of potato plants in Dahnsdorf, Germany.

Type strain: K 114/01, DSM 19812, LMG 24386.

Sequence accession no. (16S rRNA gene): AM940157.

Genus IV. **Agromyces** Gledhill and Casida 1969a, 346[AL] emend. Zgurskaya, Evtushenko, Akimov, Voyevoda, Dobrovolskaya, Lysak and Kalakoutskii 1992, 638[VP]

Vladimir N. Akimov and Lyudmila I. Evtushenko

Ag.ro.my′ces. Gr. n. *agros* field or soil; N.L. masc. n. *myces* (from Gr. masc. n. *mukes -etis*) fungus; N.L. masc. n. *Agromyces* soil fungus.

Young cultures produce **thin (mostly 0.2–0.6 µm in diameter) branched vegetative hyphae, short branching filaments or irregular rods that subsequently break up into diphtheroid, rod-like to coccoid fragments.** Scant aerial hyphae may occur on rare occasions. Nonmotile. Nonsporeforming. **Gram-stain-positive type** of cell wall. Non-acid-fast. Lysozyme sensitive. Colonies on nutrient agar medium are generally **yellow or white**, circular, 1–2 mm in diameter, opaque, **often penetrating into the agar**. **Chemo-organotrophs**, having a respiratory type of metabolism. **Aerobic to microaerophilic**. Catalase and oxidase test reactions intensities vary among species. Most strains grow well on standard laboratory media at near neutral pH. Some species are nutritionally exacting. Use a wide range of organic compounds as sole sources of carbon for growth and energy. Mesophilic; optimal growth at ~24–30°C; growth range ~7–40°C.

The cell-wall peptidoglycan is a group B type, based upon 2,4-diaminobutyric acid (L-isomer predominating). **The muramic acid residue of the peptidoglycan is *N*-acetylated.** Menaquinones are the sole respiratory quinones; **the predominant component is typically an unsaturated menaquinone with 12 isoprene units (MK-12);** the second most common components are MK-13 and MK-11. **Major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.** Straight-chain saturated acids are present in small quantities. Mycolic acids are absent. Principal polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and characteristic glycolipids. Polyamine patterns include putrescine as the predominant compound.

Usually occurring in soils; some species can be associated with plants or animals. *Agromyces* species or strains have never been isolated from unequivocally pathological material from humans, warm-blooded animals, or plants.

DNA G+C content (mol%): 65–73.

Type species: **Agromyces ramosus** Gledhill and Casida 1969a, 346[VP].

Further descriptive information

The genus *Agromyces* belongs to the family *Microbacteriaceae*, order *Micrococcales*, and, at the time of writing, includes 19 species and 2 subspecies (Table 144). The 16S rRNA gene sequence analysis shows that *Agromyces* species examined form a coherent phylogenetic cluster, with sequence similarity levels above 93.8%. At least five phylogenetic subclusters may be further distinguished within the genus (Figure 177).

Agromyces species vary in cell morphology, ranging from thin (mostly 0.2–0.6 µm in diameter), extensively branching vegetative hyphae to small (0.2–0.4 × 0.5–1.5 µm), straight or slightly curved rods as reported for *Agromyces allii* (Jung et al., 2007). On agar media, they typically display a distinct growth cycle. Branching hyphae or short filaments, produced in an early growth phase, undergo septation and fragmentation, often very rapidly, to yield diphtheroid and irregular rod-like nonmotile elements; a proportion of the cells may be coccoid. Aerial mycelia are usually absent, except for *Agromyces aurantiacus*. The latter produces scant, sparsely branching aerial hyphae on glycerol-asparagine agar (Li et al., 2003). The consistency and composition of the growth medium can affect the hyphal formation, fragmentation intensity, and the fragment size and shape. The cell diameter may also vary depending on growth medium. The formation of hyphae by *Agromyces ramosus* is enhanced in the presence of fructose, sucrose, or carbohydrates containing a terminal sucrose moiety (Gledhill and Casida, 1969a). The mean cell diameter of *Agromyces ramosus* in 5-d-old shaken culture in nutrient broth (0.3% beef extract and 0.5% glucose) is 0.66 µm, while the diameter of cells grown on some other media can be half or less of this value, down to 0.18 µm on Ashby's agar with 0.2% glucose (Gledhill and Casida, 1969a).

Visible colonies of most species usually appear on agar plates after 2–3 d of incubation. Colonies are circular, somewhat convex, smooth and may be rough, often penetrating into agar media. The colony color of most *Agromyces* strains is yellow or white; color intensity and shade vary depending on the species, culture age, and growth conditions. The color of colonies (substrate mycelium) of the type strain of *Agromyces aurantiacus* can be yellow, light orange-yellow to pink-white or pink-gray (Li et al., 2003). Pigmentation of *Agromyces ramosus* is usually not evident, but a pale yellow, alcohol-soluble pigment (a carotenoid) may be observed under some growth conditions (Gledhill and Casida, 1969a; Jones et al., 1970). The yellow pigments of *Agromyces bracchium*, *Agromyces cerinus*, *Agromyces fucosus*, *Agromyces hippuratus*, *Agromyces luteolus*, *Agromyces mediolanus*, and *Agromyces rhizospherae*) are C_{40}–C_{50}-carotenoids (Takano et al., 2006; Trutko et al., 2005; Weeks and Garner, 1967). The pigment biosynthesis in some species (*Agromyces cerinus*, *Agromyces fucosus*, *Agromyces hippuratus*, and *Agromyces mediolanus*) is light-induced (Liaaen-Jensen and Andrewes, 1972; Trutko et al., 2005). Pigmentation (but not growth) of all carotenoid-producing *Agromyces* strains tested up to date is inhibited by fosmidomycin at a low concentration of 0.05 mg/ml (Trutko et al., 2005), which is indicative of the nonmevalonate pathway of the pigment biosynthesis (Kuzuyama, 2002; Lichtenthaler et al., 2000). The data on complete sequence of decaprenoxanthin biosynthetic operon of *Agromyces mediolanus* ATCC 13930 (= JCM 1376 = K. Suzuki CNF 134) and enzymes involved in the biosynthesis are available from public databases.

Agromycetes are Gram-stain-positive in terms of cell-wall composition, but the Gram-staining test may be indistinct or negative, particularly at fragmentation stage (Gledhill and Casida, 1969a). The peptidoglycans of *Agromyces* species are based upon 2,4-diaminobutyric acid (Dab) and, if reported, contain Dab, glycine, glutamate, and alanine in a molar ratio close to 2:1:1:1 (Fiedler and Kandler, 1973; Zgurskaya et al., 1992; Sasaki et al., 1998; and recent descriptions of *Agromyces* species). The molar ratio of amino acids corresponds to the peptidoglycan B2γ type, [L-Dab]D-Glu–D-Dab, as reported for *Agromyces ramosus* and *Agromyces mediolanus* (Fiedler and Kandler, 1973; Schleifer and Kandler, 1972). Sasaki et al. (1998) also found that five *Agromyces* species (*Agromyces ramosus*, *Agromyces cerinus*, *Agromyces fucosus*, *Agromyces hippuratus*, *Agromyces mediolanus*) possess

[a]Data are complied from Gledhill and Casida (1969a); Zgurskaya et al. (1992); Suzuki et al. (1996); Groth et al. (1996); Takeuchi and Hatano (2001); Dorofeeva et al. (2003); Li et al. (2003); Rivas et al. (2004a); Ortiz-Martinez et al. (2004); Jurado et al. (2005a, 2005b, 2005c); Jung et al. (2007); and Yoon et al. (2008).

[b]Symbols: –, negative; +, positive; w, weakly positive or delayed reaction; d, different among strains within a species (reaction for type strain is given behind oblique stroke); v, variable between experiments; nd, not determined.

[c]Data for the type strains unless indicated.

[d]O, orange; Y, yellow; P, pink-white or pink-gray. Yellow color of *Agromyces* species may vary in intensity and shade depending on culture age and growth conditions.

[e]BH, branching hyphae; SF, short filaments (up to 6 μm and more) with rudimentary branching; IR, cells mostly display irregular rods in young cultures. Note: the length of hyphae and "shorter filaments" and fragmentation intensity may vary depending on the growth medium.

[f]Aerial mycelium was observed after 2–3 weeks on ISP 5 medium.

[g]The predominant menaquinone, followed by the most abundant second (third) component constituting >25% of the main peak (where available); see the species descriptions for details and references. Numerals indicate the numbers of isoprene units in the side chain.

[h]Ara, arabinose; Fru, fructose; Fuc, fucose; Gal, galactose; Glu, glucose; Man, mannose; Rha, ramnose; Rib, ribose; Tyv, tyvelose; Xyl, xylose. Sugars in parentheses were found only in some strains of a taxon, either in trace (mannose) or in significant amounts (xylose for *Agromyces allii*, fucose and glucose for *Agromyces fucosus*). Square brackets indicate sugars determined in whole cells. Order of sugars is ranged in accordance with decrease of their amounts (where available) or given in the same way as in original papers (see species descriptions for details).

[i]Different cell-wall sugar pattern (rhamnose and glucose) was reported for some other strains assigned to *Agromyces ramosus* (Gledhill and Casida, 1969a). Whole cells of the type strain were reported to contain glucose and ribose also (Zgurskaya et al., 1992).

[j]Glucose, ribose, mannose, fucose, and xylose in different combinations were also detected in whole cells of the indicated taxa (see species descriptions for details).

[k]Data from Suzuki et al. (1996).

[l]Data on acid production as determined using the API test systems, bioMérieux (Jurado et al., 2005a, 2005b, 2005c; Li et al., 2003; Takeuchi and Hatano, 2001; Yoon et al., 2008), with the exception of reactions for *Agromyces allii*, *Agromyces hippuratus*, and some data on *Agromyces ramosus* and *Agromyces cerinus* subsp. *cerinus* obtained by conventional methods (Gledhill and Casida, 1969a; Groth et al., 1996; Jung et al., 2007; Zgurskaya et al., 1992). The results of conventional and API tests may sometimes differ.

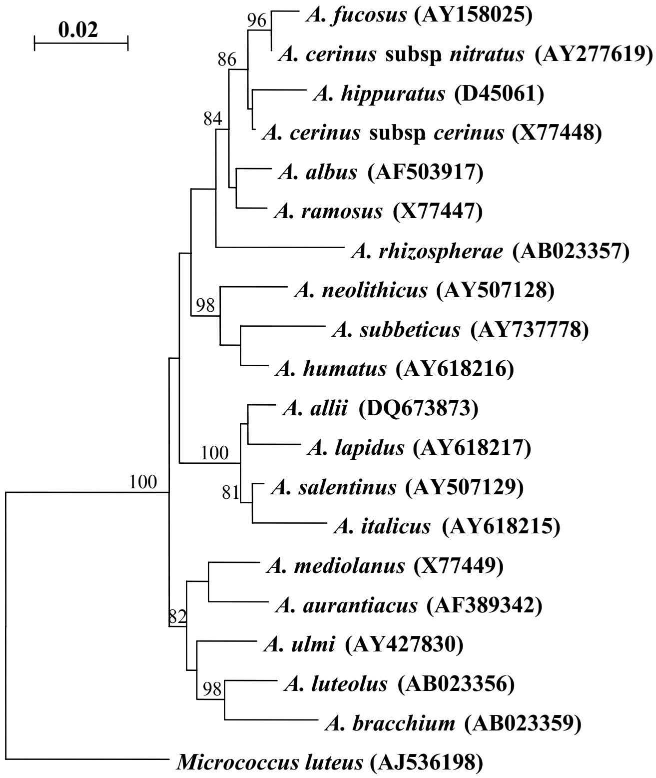

FIGURE 177. Phylogenetic dendogram based on 16S rRNA gene comparison of the type strains of the genus *Agromyces*. Bar = 0.02 inferred nucleotide substitution per nucleotide. Values at nodes indicate bootstrap values for 500 replicates.

almost exclusively the L-isomer of Dab, which suggests that their peptidoglycan differs from the B2γ type in that D-Dab is almost fully substituted by L-Dab. Although the peptidoglycan structure was not completely determined, these results suggest that it contains L-Dab in the interpeptide bridge (the peptidoglycan type [L-Dab]D-Glu–L-Dab). Muramic acid occurs in the *N*-acetyl form, as shown for several species (Jurado et al., 2005a, 2005b, 2005c).

Sugars determined in the cell wall or whole cells of most strains are rhamnose, galactose, and mannose (typically small quantities). In addition, glucose, arabinose, fucose, fructose, ribose, tyvelose, and xylose in various combinations have been reported for some species (Table 144). In several *Agromyces* strains tested so far (*Agromyces cerinus* subsp. *cerinus*, *Agromyces cerinus* subsp. *nitratus*, *Agromyces fucosus*, and *Agromyces hippuratus*) different cell-wall teichoic acids or related phosphorous-containing anionic polymers have been revealed (Gnilozub et al., 1994b; Naumova et al., 2001; Shashkov et al., 1993, 1995). No phosphorous-containing anionic polymers have been found in the cell walls of *Agromyces mediolanus* and a few other unnamed organisms of this genus. The tested type strains of *Agromyces cerinus* subsp. *cerinus*, *Agromyces cerinus* subsp. *nitratus*, *Agromyces fucosus*, and *Agromyces hippuratus* also contain lipoteichoic acids composed of poly(glycerolphosphate) and hydrophobic chains, fatty acids of which largely include $C_{17:0}$ iso (22–38%), $C_{15:0}$ anteiso (11–36%), $C_{16:0}$ iso (15–20%), and $C_{18:0}$ (6.0–17%) (Gnilozub et al., 1994a).

Most *Agromyces* species are aerobes; some also grow microaerophilically (Jurado et al., 2005a, 2005b, 2005c). *Agromyces ramosus* displays pronounced microaerophily; poor anaerobic growth has been reported for some strains (Gledhill and Casida, 1969a). In addition, this species has a low CO oxidizing activity (Bartholomew and Alexander, 1979); CO_2 is not required for growth (Gledhill and Casida, 1969a). The *Agromyces* species are mostly catalase-positive except for *Agromyces ramosus*, *Agromyces aurantiacus*, and *Agromyces ulmi* (Gledhill and Casida, 1969a; Li et al., 2003; Rivas et al., 2004a). *Agromyces ramosus* also shows negative reaction in the benzidine and oxidase tests (Gledhill and Casida, 1969a). Nevertheless, it produces cytochromes *b*, *c*, and aa_3 (where the latter is the cytochrome oxidase), suggesting the presence of a cytochrome electron transport system (Jones et al., 1970). Negative or variable reactions in oxidase tests have also been found in some other *Agromyces* species (Jurado et al., 2005c; Rivas et al., 2004a; Table 144), which suggests *Agromyces* species differ in the composition of terminal parts of respiratory chains. The major respiratory menaquinone of most *Agromyces* species is MK-12; the second most abundant component is MK-13 or MK-11. Minor or trace amounts of MK-7, MK-8, MK-9, MK-10, and MK-14 are also present (e.g. Collins and Jones, 1980; Suzuki et al., 1996; Takeuchi and Hatano, 2001; Rivas et al., 2004a).

Saturated anteiso- and iso-methyl branched fatty acids predominate in the cellular fatty acid profiles, and the components $C_{17:0}$ anteiso, $C_{15:0}$ anteiso, and $C_{16:0}$ iso may contribute up to 93–96% of the total FAMEs (Suzuki et al., 1996; Takeuchi and Hatano, 2001). $C_{17:0}$ anteiso or $C_{15:0}$ anteiso (and their sum) typically predominate. Polar lipids are represented mostly by diphosphatidylglycerol, phosphatidylglycerol, and one or two distinctive glycolipids (Collins, 1982; Collins and Jones, 1980; Jung et al., 2007; Jurado et al., 2005a, b; Jurado et al., 2005c). In addition, one to four minor unidentified phospholipids have been reported for some species (Jurado et al., 2005a, b; Jurado et al., 2005c; Zgurskaya, 1992). *Agromyces ramosus* contains two glycolipids with staining characteristics indicative of the possible presence of galactose and/or mannose within these lipids (Collins, 1982). The only glycolipid, designated G_2, which is most likely identical to one of the *Agromyces ramosus* glycolipids, has been detected in *Agromyces mediolanus* (Collins and Jones, 1980). It is noteworthy that this glycolipid is also present, along with 1–2 other characteristic glycolipids, in strains of *Clavibacter*, *Leifsonia*, and *Rathayibacter* (Collins and Bradbury, 1986; Collins and Jones, 1980). The glycolipid with the same chromatographic behavior and staining characteristics has also been found in strains of *Frigoribacterium* (Kämpfer et al., 2000), *Agreia*, and some other *Microbacteriaceae* (N.G. Vinokurova and L.I. Evtushenko, unpublished data).

Polyamines were determined for the type strains of *Agromyces cerinus* subsp. *cerinus*, *Agromyces cerinus* subsp. *nitratus*, *Agromyces fucosus*, *Agromyces hippuratus*, and *Agromyces mediolanus* (Altenburger et al., 1997). The total polyamine content is lower (0.21–0.28 μmol/g) than in most other representatives of the family *Microbacteriaceae*, with putrescine as the predominant component (0.11–0.21 μmol/g). The second most abundant polyamine is spermidine, spermine, or 1,3-diaminopropane, depending on the species; cadaverine, *sym*-homospermidine, and *sym*-norspermidine may occur in minor or trace amounts (Altenburger et al., 1997).

The majority of *Agromyces* strains grow well on standard nutrient media such as trypticase soy broth agar (TSBA)*, *Corynebacterium* (CB) medium†, rich (R) medium‡, peptone-yeast extract (PY) medium§, and some other media based on peptone, yeast extract, and glucose. Knowledge of minimal nutritional requirements of *Agromyces* species is incomplete. Some strains grow well on a basal mineral medium (e.g. ISP 9 medium**) with glucose as a carbon source and ammonium salt as a source of nitrogen (Li et al., 2003; Zgurskaya et al., 1992), whereas others exhibit growth on the same medium in the presence of 0.01% yeast extract (Zgurskaya et al., 1992).

Organic nitrogen is required for growth of some strains (Gledhill and Casida, 1969a; Zgurskaya et al., 1992). *Agromyces aurantiacus* grows on Czapek agar (nitrate as a nitrogen source), and some other simple, chemically defined media (Li et al., 2003). *Agromyces ramosus* is the most nutritionally exacting among the *Agromyces* species so far described. The study of nutritional requirements of this species (Gledhill and Casida, 1969a) showed that best growth is observed in the basal medium [0.04% K_2HPO_4, 0.05% $(NH_4)_2HP0_4$, 0.05% NaCl, 0.005% $MgSO_4{\cdot}7H_2O$, 0.001% $FeCl_3$, and 0.2% fructose, pH 7.0] supplemented with 0.5% vitamin-free Casamino Acids (Difco), 0.5% tryptone, and a 13 vitamin solution. The growth in the same basal medium supplemented with vitamin-free Casamino acids and vitamins is slower, and even weaker with vitamin-free Casamino acids only.

Members of the genus *Agromyces* use a wide range of organic compounds as sole sources of carbon for growth and possess various enzymic activities (Table 144). The published data (Dorofeeva et al., 2003; Gledhill and Casida, 1969a; Groth et al., 1996; Jung et al., 2007; Jurado et al., 2005a, b; Jurado et al., 2005c; Li et al., 2003; Ortiz-Martinez et al., 2004; Rivas et al., 2004a; Suzuki et al., 1996; Takeuchi and Hatano, 2001; Zgurskaya et al., 1992) show that all or the majority of the strains tested so far decompose esculin, casein, and starch, but not adenine and Tween 80. Most tested strains produce acids from starch, D-fructose, and glycogen, but not from adonitol, D- and L-arabitol, dulcitol, erythritol, inositol, D-lyxose, L-sorbose, D-tagatose, L-xylose, methyl-β-xyloside. Most strains do not assimilate aconitate, gluconate, 2- and 5-ketogluconate. Strains of the genus usually show activities (API ZYM) for esterase lipase(C8), leucine arylamidase, valine arylamidase, cystine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, but not for lipase (C14), trypsin, and α-fucosidase (except for *Agromyces cerinus* subsp. *nitratus*). Cultured strains typically do not produce indole and show negative reactions in the methyl red and Voges–Proskauer tests.

Agromyces strains also possess enzymic activities useful for biotechnological applications. Members of *Agromyces mediolanus*, *Agromyces cerinus* subsp. *cerinus*, *Agromyces fucosus*, and some other strains transform steroids (Donova, 2006; Ke et al., 2007; Mamoli, 1939; Spassov et al., 1983). Strains of *Agromyces mediolanus* assimilate aniline (Aoki et al., 1982; Suzuki et al., 1996) and degrade detergent compounds such as tallow-alkyl-sulfate, alkyl-ethoxylate-sulfate, and linear-alkyl-benzene-sulfonate (Goodnow and Harrison, 1972). *Agromyces ulmi* decomposes xylan (Rivas et al., 2004a). *Agromyces ramosus* possesses enzymic system able to destroy the cells of *Saccharomyces cerevisiae*, *Staphylococcus aureus*, and several Gram-stain-negative bacteria including *Escherichia coli*, *Agrobacterium tumefaciens*, and *Pseudomonas fluorescens* (Casida, 1983). Certain unnamed members of the genus *Agromyces* degrade nylon (6-aminohexanoate) oligomers (Yasuhira et al., 2007) and metabolize a range of organophosphonate compounds as sole phosphorus sources for growth and use phosphonoacetate as a sole carbon, energy, and phosphorus source for growth (O'Loughlin et al., 2006; Panas et al., 2007). Some strains of this genus are also capable of producing alcohol dehydrogenase (Llyod and Keene, 2008) and indole-3-acetic acid (Vasanthakumar and McManus, 2004).

Most *Agromyces* species grow optimally at near neutral pH; some species are able to initiate growth at pH values 5.0 and/or 9.5–10.0 (Jurado et al., 2005b; Jurado et al., 2005c; Yoon et al., 2008). Alkaliphilic representatives have also been reported (e.g. Yasuhira et al., 2007). Agromycetes are generally considered non-halophilic but some species, e.g. *Agromyces terreus*, grow optimally in the presence of 0.5–1.0% (w/v) NaCl (Yoon et al., 2008). Up to 8% NaCl is tolerated by other species, i.e. very weak growth is observed for *Agromyces brachium*, *Agromyces luteolus*, and *Agromyces rhizospherae* (Takeuchi and Hatano, 2001). Representatives of the genus can be resistant to high concentrations of heavy metals (up to 6 mM in the case of Zn) and mobilize metals (Zn and Cd) supposedly by the release of specific ligands (Kuffner et al., 2008). The exact mechanisms enabling the accumulation process are unclear so far.

The DNA base ratios of the majority of *Agromyces* species range from 68.9 mol% (the type strain of *Agromyces ramosus*) to 73.3 mol% (*Agromyces mediolanus* and *Agromyces rhizospherae*) as determined by Suzuki et al. (1996) and Takeuchi and Hatano (2001) using HPLC. Somewhat higher values for the type strain of *Agromyces ramosus* were reported in earlier works (Döpfer et al., 1982; Gledhill and Casida, 1969a). Among 14 tested strains assigned to *Agromyces cerinus* subsp. *cerinus*, *Agromyces cerinus* subsp. *nitratus*, *Agromyces fucosus*, and *Agromyces hippuratus* (Zgurskaya, 1992), a plasmid was found only in *Agromyces fucosus* VKM Ac-1346. The plasmid size, as determined by agarose gel electrophoresis, was approximately 67 kb.

The bacteriophages for *Agromyces ramosus* can be isolated from soil suspended in heart infusion broth (Difco) by shaking the suspension for 12 h followed by a diluting phage isolation procedure; the addition of *Agromyces ramosus* to the enrichment suspension is usually not necessary (Moore, 1974). It is

* Trypticase soy broth agar, TSA: trypticase soy broth (Difco), 30 g; agar, 15 g; distilled water, 1 liter.

† Corynebacterium medium, CB (DSMZ medium 53 (DSMZ, 2001): casein peptone, tryptic digest, 10 g; yeast extract, 5.0 g; glucose, 5 g; NaCl, 5 g; agar, 15 g; distilled water, 1 liter (pH 7.2–7.4).

‡ R medium (Suzuki et al., 1996; Yamada and Komagata, 1972b): Bacto peptone, 10 g; yeast extract, 5 g; malt extract, 5 g; Casamino acids, 5 g; beef extract, 2 g; glycerol, 2 g; Tween 80, 50 mg; $MgSO_4{\cdot}7H_20$, 1 g; agar, 15 g; water, 1 liter (pH 7.2).

§ Peptone-yeast extract (PY) medium (Takeuchi and Hatano, 2001): Polypeptone (Wako Pure Chemicals), 10 g; yeast extract, 2 g; $MgSO_4{\cdot}7H_2O$, 1 g; distilled water, 1 liter (pH 7.2).

** See Shirling and Gottlieb (1966) for the composition of ISP media cited here and in other sections of this chapter.

worth mentioning that significant differences in abundance of bacteriophages for *Agromyces* strains in some environments can be observed among sampling time period, as reported by Nakayama et al. (2007) for the floodwater of a Japanese paddy.

No serological cross-reactivity with sera raised against representatives of the genera *Actinomyces*, *Rothia*, *Bacterionema*, and *Ramibacterium* was shown for 24 strains assigned to *Agromyces ramosus* (Gledhill and Casida, 1969a).

The following antibiotics (µg per disk) inhibited *Agromyces* strains: tetracycline (30), chloramphenicol (100), imipenem (10), ofloxacin (10), oxytetracycline hydrochloride (30), rifampin (30), vancomycin hydrochloride (30) (Groth et al., 1996; Jurado et al., 2005a, b; Jurado et al., 2005c; Yoon et al., 2008). Sensitivity to several other antibiotics varied between strains or species (Table 144). Representatives of *Agromyces cerinus* subsp. *cerinus*, *Agromyces cerinus* subsp. *nitratus*, *Agromyces fucosus*, and *Agromyces hippuratus* are inhibited by antibacterial substances (termed bacteriocins in the original works) produced by the type strain of *Rathayibacter tritici*, some strains of *Clavibacter michiganensis* subsp. *tesselarius*, and *Clavibacter michiganensis* subsp. *sepedonicus* (Zgurskaya, 1992; Zgurskaya et al., 1992). The type strain of *Agromyces hippuratus* displays inhibitory activity against Gram-stain-positive bacteria including *Bacillus subtilis* and representatives of *Clavibacter michiganensis* subspecies (Zgurskaya, 1992; Zgurskaya et al., 1992). *Agromyces* species closely related to *Agromyces allii* and *Agromyces terreus* has been found to possess antifungal activity against *Mariannaea elegans* and *Rhizomucor variabilis* (Lauer et al., 2008).

The usual natural habitat of *Agromyces* species is soil of different origins, including polluted sites and plant rhizosphere. Like many other soil bacteria, agromycetes are probably involved in the turnover of organic matter in soil and may directly or indirectly contribute to the promotion of plant growth. Members of this genus are also found in other diverse environments including marine sediments (Gontang et al., 2007), mangrove rhizosphere (Takeuchi and Hatano, 2001), and the water phase of tropospheric clouds, 500,000 year-old glacial ice, and some other low temperature environments (Amato et al., 2007a, 2007b; Christner, 2002; Clocksin et al., 2007). Representatives of the genus have also been isolated from cyanobacterial biofilms on cave walls (Jurado et al., 2005b), plants and plant-derived materials (Dorofeeva et al., 2003; Rivas et al., 2004a), and occasionally among endophytic bacterial populations in plant roots (Conn and Franco, 2004; Zakhia et al., 2006). It is noteworthy in this context that *Agromyces* sp. ORS 1437H isolated from the root nodules of a legume species, *Argyrolobium uniflorum*, contains the dinitrogenase reductase-like gene (Zakhia et al., 2006). The determined *nifH* sequence (AJ968686) of this strain is almost identical to those found in *Microbacterium* species isolated from root nodules of *Ononis natrix* subsp. *falcate*, and shows close similarity to the *nifH* gene of *Sinorhizobium meliloti*. However, strain ORS 1437H, like the *Microbacterium* strains, did not induce nodule formation when tested on the wide-host-spectrum legume species *Macroptilium atropurpureum* and no *nodA* gene could be amplified by PCR (Zakhia et al., 2006). Agromycetes are also occasionally found in the soybean cyst nematode (Nour et al., 2003), among cutaneous bacteria of four-toed salamanders (*Hemidactylium scutatum*) (Lauer et al., 2008), and among the human skin microbiota (Grice et al., 2008). No species or strains pathogenic for humans, warm-blooded animals, and plants have been reported within this genus.

Enrichment and isolation procedures

Many isolation media, e.g. nutrient agar (Difco), R2A agar (Difco), peptone/yeast extract/brain heart infusion agar (PY-BHI) described by Yokota et al. (1993a), ten-fold diluted CB agar (DSMZ medium 53), and many other media based on peptone and yeast extract are suitable for isolation of aerobic species of the genus *Agromyces* by using dilution plating methods. Humic acid-vitamin (HV) agar medium, developed by Hayakawa and Nonomura (1987, 1989), was successfully used for isolation of *Agromyces* species from the rhizosphere of mangroves (Takeuchi and Hatano, 2001) and also from a soil sample (Li et al., 2003). The XED agar medium containing xylan and yeast extract was used for isolation of *Agromyces ulmi* from the decayed stump of an elm tree (Rivas et al., 2004a). The dilution frequency procedure for isolation of *Agromyces ramosus* was described in detail by Casida (1965, 1986) and Gledhill and Casida (1969b); the original plating procedure was reported by Labeda et al. (1974). *Agromyces ramosus* grows very slowly during the first passages and can be lost easily; adapted strains usually grow well on nutritionally rich media (e.g. heart infusion agar, Oxoid Ltd.).

Maintenance procedures

The agromycetes can be freeze-dried and preserved in liquid nitrogen by standard procedures.

Differentiation of the genus *Agromyces* from other genera

Agromyces strains form a phylogenetically coherent group based on 16S rRNA gene analysis that is clearly distinct from other genera of *Microbacteriaceae* (Figure 173). In young cultures, the production of well-developed branching hyphae, which may penetrate into agar media, is the most striking visible phenotypic feature that differentiates many *Agromyces* species from all other genera of the family *Microbacteriaceae*. Chemotaxonomic characteristics essential for delineation of agromycetes are listed in Table 140. The L-Dab-based peptidoglycan and fatty acid profile are the salient characteristics that differentiate *Agromyces* species from the related genus *Humibacter*, which has Dab in combination with ornithine in the cell wall and a significant amount of cyclohexyl fatty acid ($C_{17:0}$ Ch) (Vaz-Moreira et al., 2008b).

Taxonomic comments

The genus *Agromyces* was established by Gledhill and Casida (1969a) with the type species *Agromyces ramosus* to accommodate filamentous, branching, fragmenting, nutritionally fastidious, catalase and oxidase-negative soil isolates, considered to be intermediary forms to the facultative-to-anaerobic (*Actinomyces*) and aerobic (*Nocardia*) genera of the order *Actinomycetales*. *Agromyces ramosus* was the only recognized species in the genus till 1992, when Zgurskaya and co-authors described two new species, each with two subspecies, *Agromyces cerinus* subsp. *cerinus* and *Agromyces cerinus* subsp. *nitratus*, and *Agromyces fucosus* subsp. *fucosus* and *Agromyces* subsp. *hippuratus*, and emended the genus description (Zgurskaya et al., 1992). The 14 aerobic

soil isolates assigned by these authors to *Agromyces* possess the morphological and chemotaxonomic characteristics typical of the genus *Agromyces* but are able to grow on relatively simple media under aerobic conditions and show positive catalase and oxidase reactions. Suzuki and co-authors (1996) reclassified the familiar organisms *"Corynebacterium mediolanum"* JCM 3346 (= DSM 20152 = NCIMB 7206), *"Flavobacterium dehydrogenans"* JCM 1376 (= ATCC 13930), and some aniline-assimilating strains (Aoki et al., 1982) as *Agromyces mediolanus*. All other *Agromyces* species considered in this chapter were proposed within the period 2001–2008. Their descriptions are largely based on the type strains, except for *Agromyces allii* (Jung et al., 2007), *Agromyces rhizospherae* (Takeuchi and Hatano, 2001), and *Agromyces ulmi* (Rivas et al., 2004a).

The proposal of novel species within the genus *Agromyces* is justified by the results of 16S rRNA gene analysis and/or DNA–DNA hybridization studies, along with the phenotypic traits. Exceptions are the descriptions of *Agromyces cerinus* and *Agromyces fucosus*, which were done without analyzing 16S rRNA gene sequences (Zgurskaya et al., 1992). Moreover, the affiliation of strains to *Agromyces fucosus* (except for the type strain) and further division of this species into two subspecies is not supported by the DNA–DNA relatedness data and was based on phenotypic characters only (Zgurskaya et al., 1992). Suzuki et al. (1996) later found that the DNA–DNA similarity between the type strains of *Agromyces fucosus* subsp. *fucosus* and *Agromyces fucosus* subsp. *hippuratus* is 45–47%, and subsequent taxonomic revision of the latter resulted in its elevation to the species level (Ortiz-Martinez et al., 2004).

The taxonomic situation with *Agromyces cerinus* subsp. *nitratus* also invites comments. The type strains of *Agromyces cerinus* subsp. *cerinus* and *Agromyces cerinus* subsp. *nitratus* show a relatively high DNA–DNA similarity (68% and 60–62%), as reported by Zgurskaya et al. (1992) and Suzuki et al. (1996). According to Ortiz-Martinez et al. (2004), the strains exhibit the difference in the melting temperature (ΔT_m) equal to 4.1°C which is close to the borderline for species differentiation (Rosselló-Mora and Amann, 2001; Wayne et al., 1987). On the other hand, the 16S rRNA gene sequence identity between *Agromyces cerinus* subsp. *cerinus* and *Agromyces cerinus* subsp. *nitratus* is 99.4%, a value characteristic of many closely related species within the *Microbacteriaceae* and some other families of the order *Micrococcales*. The partial *gyrB* sequence similarity (Stackebrandt et al., 2007) between the type strains of these subspecies (91.5%) is also of the same level as between some closely related species of the family, e.g. *Microbacterium foliorum* and *Microbacterium phyllosphaerae*. The above data along with differences of the *Agromyces cerinus* subspecies in the composition of cell-wall polysaccharides (Shashkov et al., 1993, 1995), the polyamine patterns (Altenburger et al., 1997), and other phenotypic features suggest that *Agromyces cerinus* subsp. *nitratus* could be treated as a separate species in the future.

On compiling additional phenotypic data, strain *Agromyces mediolanus* JCM 9631 may also be classified in the future as a separate species. The strain shows only 46–47% DNA–DNA similarity to the type strain of *Agromyces mediolanus* and differs significantly from other *Agromyces mediolanus* strains in the 16S rRNA gene sequences (Suzuki et al., 1996).

Some of the strains assigned to *Agromyces ramosus* (Gledhill and Casida, 1969a) may also represent at least one novel species, taking into consideration their differences in cell-wall sugar composition and the heterogeneity of physiological and biochemical characteristics.

Differentiation of the species of the genus *Agromyces*

The characteristics useful for differentiation of *Agromyces* species at the phenotypic level are listed in Table 144 and outlined in the descriptions of species. These include, in particular, the colony color, menaquinone system, cell-wall sugar and polyamine patterns, as well as physiological and biochemical characters. It should be emphasized that the whole cells but not the purified cell wall were analyzed in some species for sugar content. Accordingly, some reported sugars may not be located in the cell wall, which should be taken into account while comparing the "cell-wall sugars." When determined under similar conditions, some species have quantitative differences in the predominant cellular fatty acids (Jurado et al., 2005a, 2005b, 2005c; Takeuchi and Hatano, 2001). Comparative analyses of polar lipids and polyamines performed under standardized growth conditions and analytical procedures may provide further chemotaxonomic information useful for differentiation (Altenburger et al., 1997; Jurado et al., 2005a, 2005b, 2005c). Partial sequence of 16S rRNA gene (about 900 bp from the 5′-end) of an isolate would greatly facilitate its species identification within the genus and species groups composing the phylogenetic subclusters (Figure 177). The DNA–DNA hybridization studies or analysis of other genomic characteristics for determination of inter- and intraspecies relatedness (Schumann et al., 2009) might be necessary to differentiate closely related species.

In general, *Agromyces ramosus* strains are easily recognizable among all other species of this genus due to their relatively weak growth, pronounced microaerophily, and requirement of nutritionally rich media. *Agromyces albus* and *Agromyces ulmi* are distinguishable among all other rapidly growing *Agromyces* species owing to their white colonies. Orange to pinkish colonies on some diagnostic media and the ability to form scant aerial hyphae are indicative of *Agromyces aurantiacus*. The species *Agromyces ramosus*, *Agromyces aurantiacus*, and *Agromyces ulmi* also exhibit a negative catalase reaction, in contrast to the remaining *Agromyces* species. Cream-colored to beige colonies are characteristic of the species *Agromyces italicus*, *Agromyces neolithicus*, and *Agromyces terreus*. The species *Agromyces allii* and *Agromyces mediolanus* are also readily recognized due to their cell morphology (usually irregular rods with no hyphal formation).

List of species of the genus *Agromyces*

1. **Agromyces ramosus** Gledhill and Casida 1969a, 346[AL]

ra.mos′us. L. masc. adj. *ramosus* much-branched.

The characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description of Gledhill and Casida (1969a) unless indicated otherwise.

After initial growth on agar or in liquid media, microcolonies are composed of branched vegetative hyphae which subsequently undergo septation and fragment into irregular rod-like to coccoid elements. Microaerophilic to aerobic; in heart infusion agar (Difco) shake tubes, growth occurs primarily as a distinct microaerophilic band approximately 2.5 mm below the agar surface, with comparatively less growth above and below this region. Some strains have been reported to show poor growth under anaerobic conditions. Pigmentation is usually not evident under normal growth conditions, but the concentrated masses of cells may be pale yellow due to production of a carotenoid pigment (Jones et al., 1970).

All strains are catalase-negative and exhibit negative reactions with benzidine and tetramethyl-*p*-phenylenediamine. Sugars are oxidized without gas production. Organic nitrogen required for growth. Many biochemical characteristics of 60 soil isolates assigned to *Agromyces ramosus* by Gledhill and Casida (1969a) varied (see the original paper for details). Grow well at 20 and 37°C (optimum at 30°C); some strains show growth at 40°C. Optimal pH is 6.6–7.1. Growth on most agar media is relatively slow, requiring up to 7 d to produce visible colonies. The growth rate (and the pigment concentration) can be increased by culturing on fresh horse blood agar or on soil extract agar supplemented with bovine catalase or MnO_2 (Jones et al., 1970). The presence of other organisms can also stimulate growth and pigment formation (Casida, 1986). Growth in liquid media is poor, cells usually adhere to the glass surface and then settle to the bottom; growth could be increased by adding glass beads to provide additional surface area.

The major menaquinone determined for the type strain is MK-12 (56–62%), followed by MK-13 (14–15%); other menaquinones, MK-7 to MK-11 and MK-14, occur in minor (1–8%) amounts (Sasaki et al., 1998; Suzuki et al., 1996). The predominant cellular fatty acids determined for the type strain are $C_{15:0}$ anteiso (38%), $C_{17:0}$ anteiso (38%), and $C_{16:0}$ iso (16%) (Suzuki et al., 1996). Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and two characteristic glycolipids (Collins, 1982). Cell-wall sugars are rhamnose, galactose, xylose, and mannose.

Strains assigned to *Agromyces ramosus* were isolated from soils of different origin, ranging from fertile meadow to barren desert soils. *Agromyces ramosus* was reported to be 10- to 100 fold more numerous in many soil samples than the total microflora normally cultured on plates.

Source: soil.

DNA G+C content (mol%): 68.9 (HPLC).

Type strain: ATCC 25173, CIP 103037, DSM 43045, JCM 3108, LMG 16680, NBRC 13899, VKM Ac-1198.

Sequence accession no. (16S rRNA gene): X77447.

2. **Agromyces albus** Dorofeeva, Krausova, Evtushenko and Tiedje 2003, 1437[VP]

al′bus. L. masc. adj. *albus* white, referring to the white color of colonies.

The general characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Dorofeeva et al., 2003).

Colonies are white and may penetrate into agar media. After initial growth on agar, microcolonies are composed of branched vegetative hyphae which subsequently break up into diphtheroid and short, irregular rod-like fragments. Aerobic. Growth occurs between 7°C (weak) and 37°C; optimum is ~26–28°C. Adonitol, cellobiose, D-fucose, inositol, lyxose, maltose, D-mannitol, D-mannose, melibiose, L-rhamnose, raffinose, salicin, L-sorbose, sucrose, trehalose, turanose, and D-xylose are used as carbon sources for growth on basal medium (Shirling and Gottlieb, 1966) supplemented with 0.1% (w/v) yeast extract and 0.1% (w/v) casitone. Sensitive to the following antibiotics (μg/ml): ampicillin (10), cefazolin (10), doxycycline (5), erycycline (10), gentamicin (30), karbonicillin (30), levomycetin (10), metacycline (10), oletetrin (10), oxacillin (30), and rifampin (10). Tolerates amikacin (30), clindamycin (30), lincomycin (30), rubomycin (30), and streptomycin (30).

Predominant menaquinone is MK-12, with a smaller amount of MK-11. The major cellular fatty acids are $C_{15:0}$ anteiso (37%), $C_{17:0}$ anteiso (24%), and $C_{16:0}$ iso (20%). Cell-wall sugars include rhamnose as the predominant component; glucose, galactose, and mannose occur in smaller amounts. For further descriptive information see Dorofeeva et al. (2003) and Jurado et al. (2005c).

Source: a sample of leaves and inflorescence of *Androsace* sp. (the family Primulaceae), collected in the Central-Chernozem Biosphere Park, Belgorod region, Russia. The plant material was not subjected to surface sterilization.

DNA G+C content (mol%): 69.0 (T_m).

Type strain: UCM Ac-623, CIP 108259, DSM 15934, JCM 13565, NBRC 103057, VKM Ac-1800.

Sequence accession no. (16S rRNA gene): AF503917.

3. **Agromyces allii** Jung, Lee, Oh and Yoon 2007, 591[VP]

al′li.i. N.L. gen. n. *allii* of *Allium*, referring to the source of isolation of the microorganisms, the rhizosphere of *Allium victorialis* var. *platyphyllum*.

The general characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Jung et al., 2007).

Colonies are yellow-pigmented. Cells usually display irregular, slightly curved rods (0.2–0.4 × 0.5–1.5 μm). No growth occurs under anaerobic conditions on nutrient agar (Difco), with or without nitrate. Growth is observed between 4 and 33°C, with an optimum at 30°C. Optimal pH for growth is 6.5–7.5; no growth occurs at pH 5.0 and at 3% (w/v) NaCl. No activities for arginine decarboxylase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase. D-Glucose, D-galactose, D-cellobiose,

D-mannose, D-trehalose, D-xylose, L-arabinose, sucrose, maltose, and salicin are used for growth as determined by conventional methods.

Predominant menaquinones are MK-11 and MK-12 (peak area ratios of approximately 45–47% and 35–38%, respectively). The major cellular fatty acids reported for the type strain and the second strain (UMS-101) are $C_{15:0}$ anteiso (39 and 34%), $C_{16:0}$ iso (29 and 12%), $C_{17:0}$ anteiso (18 and 17%), and $C_{16:0}$ (6 and 24%). Major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and an unidentified glycolipid. Whole-cell sugars include rhamnose, ribose, and galactose; xylose has been detected in the type strain only.

The two described strains of this species have almost identical 16S rRNA gene sequences and show a mean DNA–DNA hybridization of 91%. For further descriptive information see Jung et al. (2007).

Source: the rhizhosphere of *Allium victorialis* var. *platyphyllum*, a type of wild edible greens grown on Ulleung Island, Korea.

DNA G+C content (mol%): 71.1–71.3 (HPLC).

Type strain: strain UMS-62, CIP 109546, JCM 13584, KCTC 19181.

Sequence accession no. (16S rRNA gene): DQ673873.

4. **Agromyces aurantiacus** Li, Zhang, Xu, Cui, Xu, Zhang, Schumann, Stackebrandt and Jiang 2003, 306[VP]

au.ran.ti.a′cus. N.L. masc. adj. *aurantiacus* orange-colored.

The general characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Li et al., 2003).

Colonies are orange-yellow of different intensity on inorganic salts-starch agar (ISP 4) and yeast extract-malt extract agar (ISP 2), pink-gray on oatmeal agar (ISP 3), and pink-white on Czapek agar and glycerol-asparagine agar (ISP 5). Young cultures on agar media produce branched vegetative hyphae which break up into diphtheroid and rod-like, irregular fragments at a later growth stage. Light yellow-brown aerial mycelium is observed in 2–3-weeks cultures on ISP5 agar medium. Aerobic. Both young (16 h) and older (4 d) cultures on tryptone soy broth agar (Oxoid) show negative catalase reaction. Optimal growth temperature is 28°C. The following carbon sources are used for growth as determined by conventional methods (Shirling and Gottlieb, 1966; Williams et al., 1989): glucose, galactose, fructose, sucrose, xylose, raffinose, D-arabinose, inulose, sorbitol, mannitol, and inositol; lactose and rhamnose are not utilized.

Predominant menaquinone is MK-12; minor components are MK-13 and MK-11. Major cellular fatty acids include $C_{15:0}$ anteiso (37%), $C_{17:0}$ anteiso (24%), and $C_{16:0}$ iso (20%). Principal phospholipids are phosphatidylglycerol and diphosphatidylglycerol. Whole cell sugars include rhamnose and small quantities of galactose, glucose, and mannose. For further descriptive information see Li et al. (2003).

Source: a soil sample collected from Xishuangbanna in Yunnan Province, China.

DNA G+C content (mol%): 72.8 (T_m).

Type strain: YIM 21741, AS 4.1717, CCTCC 001012, DSM 14598, JCM 12113.

Sequence accession no. (16S rRNA gene): AF389342.

5. **Agromyces bracchium** Takeuchi and Hatano 2001, 1536[VP]

brac′chi.um. L. n. *brachium* a twig, referring to the twig-like morphology.

The general characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Takeuchi and Hatano, 2001), unless indicated.

Colonies are yellow and sometimes penetrate into agar media. After initial growth on CB agar, microcolonies are composed of rudimentary branching filaments which relatively rapidly (18–24 h) fragment into short irregular rods to coccoid cells (recent observations). In liquid PY medium, filamentous and occasionally branching cells (approximately 5.0–6.0 µm or more in length) are observed in the early growth phase. These fragment into irregular rods (1.5–3.0 µm) during exponential growth stage.

Aerobic. Grows optimally at 20–30°C. Good growth occurs in the presence of 5% (w/v) NaCl; very weak growth may be observed at 8%.

The major menaquinone is MK-12 (78%) with minor amounts of MK-13 (14%) and MK-11 (8%). Predominant cellular fatty acids are $C_{15:0}$ anteiso (42%), $C_{17:0}$ anteiso (26%), and $C_{16:0}$ iso (28%). Cell-wall sugars include rhamnose (80%), glucose (7%), mannose (7%), and galactose (6%). For further descriptive information see Takeuchi and Hatano (2001).

Source: soil of mangrove rhizosphere (*Bruguera gymnorrhiza*) on Iriomote Island, Japan.

DNA G+C content (mol%): 70.0 (HPLC).

Type strain: 65, DSM 14596, NBRC 16238, JCM 11433, VKM Ac-2088.

Sequence accession no. (16S rRNA gene): AB023359.

6. **Agromyces cerinus** Zgurskaya, Evtushenko, Akimov, Voyevoda, Dobrovolskaya, Lysak and Kalakoutskii 1992, 639[VP]

ce′ri.nus. L. masc. adj. *cerinus* wax-colored, yellow like wax.

Colonies are typically whitish yellow to yellow and penetrate into agar media. The pigment production is light-induced (Trutko et al., 2005). After initial growth on agar, microcolonies are composed of branching vegetative hyphae which are occasionally septated. As growth proceeds, the hyphae undergo further septation and fragment into irregular rod-like to coccoid cells in 3–4 d culture. Optimal growth temperature is 26–28°C.

Two subspecies were described within this species (Zgurskaya et al., 1992). *Agromyces cerinus* subsp. *cerinus* includes strains that show DNA similarity levels ranging from 71–92%, containing tyvelose and rhamnose in their cell walls, and clustering together based on numerical analysis. Strain VKM Ac-1351 attributed to *Agromyces cerinus* subsp. *nitratus* exhibits a level of 60–68% DNA similarity with the type strain of *Agromyces cerinus* subsp. *cerinus* (Suzuki et al., 1996; Zgurskaya et al., 1992) but differs from the other strains of *Agromyces cerinus* in its cell-wall sugars and in a number of biochemical characteristics. Considering other genotypic and chemotaxonomic features revealed subsequently and discussed in the Taxonomic comments section, it is quite likely that *Agromyces cerinus* subsp. *nitratus* will be elevated to the species level in future.

DNA G+C content (mol%): 71.5–71.9 (HPLC).

Type strain: ATCC 51762, CIP 103632, DSM 8595, NBRC 15780, JCM 9083, LMG 16155, VKM Ac-1340.

Sequence accession no. (16S rRNA gene): AM410680, D45060, X77448.

6a. **Agromyces cerinus subsp. cerinus** Zgurskaya, Evtushenko, Akimov, Voyevoda, Dobrovolskaya, Lysak and Kalakoutskii 1992, 640[VP]

The general characteristics are as described for the genus and species and listed in Table 144. Additional information is taken from the original description unless indicated otherwise.

Most strains grow on medium containing *meso*-inositol as a carbon source. Organic nitrogen is not required for good growth. Elastin, guanine, pectin, and Tween 80 are not decomposed. The purified cell wall of the type strain contains (μg/mg dry wt) rhamnose (29), tyvelose (29), galactose (9.9), and mannose (7.3) (Zgurskaya, 1992). The same predominant cell-wall sugars (rhamnose, tyvelose, and galactose) in varying amounts are found in the other strains of this subspecies, while mannose is absent or occurs in minor or trace quantities. Whole cells were reported to include (μg/mg, dry wt): rhamnose (10.8–29.5), glucose (7.1–18.1), galactose (5.3–11.9), ribose (5.1–9.1), tyvelose (1.0–9.8), mannose (2.8–8.2), and xylose (0.4–7.3). Five strains of *Agromyces cerinus* subsp. *cerinus*, including the type strain, contain an unusual poly(arabitol phosphate) teichoic acid in the cell wall (Shashkov et al., 1995). The overall polyamine content of the type strain is 0.26 μmol/g (dry wt) and includes putrescine (42%), 1,3-diaminopropane (39%), cadaverine (7.7%), spermidine (7.7%), and spermine (3.8%) (Altenburger et al., 1997). The major menaquinone of the type strain is MK-12 (60%) followed by MK-13 (21%); other components MK-11, MK-10, MK-9, and MK-14 occur in small quantities (1–8%) or in a trace amount (MK-7) (Suzuki et al., 1996). Predominant cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. Principal phospholipids are diphosphatidylglycerol and phosphatidylglycerol; an unidentified minor phospholipid has been detected in the type strain. For further descriptive information, see Zgurskaya et al. (1992), Groth et al. (1996), Suzuki et al. (1996), and Jurado et al. (2005a, 2005b, 2005c).

Source: soil in a grove of birches, Moscow, Russia.

DNA G+C content (mol%): 72.0 (T_m); 70.5 (HPLC).

Type strain: ATCC 51762, CIP 103632, DSM 8595, NBRC 15780, JCM 9083, LMG 16155, VKM Ac-1340.

Sequence accession no. (16S rRNA gene): AM410680, D45060, X77448.

6b. **Agromyces cerinus subsp. nitratus** Zgurskaya, Evtushenko, Akimov, Voyevoda, Dobrovolskaya, Lysak and Kalakoutskii 1992, 640[VP]

ni.tra′tus. N.L. n. *nitras -atis* nitrate; N.L. masc. adj. *nitratus* pertaining to the ability to reduce nitrate.

The general characteristics are as described for the genus and species and listed in Table 144. Additional information is taken from the original description unless indicated otherwise.

L-Arabinose, melibiose, and starch are used as carbon sources on ISP 9 (Shirling and Gottlieb, 1966) as basal medium supplemented with 0.01% (w/v) yeast extract. Organic nitrogen is required for good growth. Nitrate is reduced to nitrite. Cell-wall sugars detected in the purified cell wall are galactose and smaller quantities of glucose and ribose (molar ratio, 1.0:0.3:0.2) and traces of mannose. Whole cell sugars detected include galactose, glucose, ribose, xylose, and mannose. An unusual anionic poly(ribofuranosylribitol phosphate) polymer is present in the cell wall (Shashkov et al., 1993). The overall polyamine content is 0.22 μmol/g (dry wt) and includes putrescine (64%), spermine (18%), spermidine (14%) and cadaverine (4.5%) (Altenburger et al., 1997). The major menaquinone is MK-12 (61%), and the next most abundant component is MK-13 (24%); other menaquinones, i.e. MK-11, MK-10, MK-14, and MK-7 occur in small quantities (1–7%) or in a trace amount (MK-9) (Suzuki et al., 1996). Predominant cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. Principal phospholipids are diphosphatidylglycerol and phosphatidylglycerol.

Agromyces cerinus subsp. *nitratus* is readily distinguished from *Agromyces cerinus* subsp. *cerinus* by the ability to reduce nitrate, the absence of rhamnose and tyvelose both in the whole cells and in the purified cell walls, and the polyamine profile with putrescine, spermine, and spermidine as the major components.

For further descriptive information, see Zgurskaya et al. (1992), Suzuki et al. (1996), and Jurado et al. (2005a, 2005b).

Source: soil in a grove of birches, Moscow, Russia.

DNA G+C content (mol%): 72.0 (T_m); 70.9 (HPLC).

Type strain: ATCC 51763, CIP 103634, DSM 8596, NBRC 15783, JCM 9084, LMG 16157, VKM Ac-1351.

Sequence accession no. (16S rRNA gene): AM410681, AY277619.

Additional comments: the phenotypic and genotypic features of *Agromyces cerinus* subsp. *nitratus* suggest that this subspecies could be treated as a separate species in the future (see the *Taxonomic comments* section for details).

7. **Agromyces fucosus** Zgurskaya, Evtushenko, Akimov, Voyevoda, Dobrovolskaya, Lysak and Kalakoutskii 1992, 640[VP] emend. Ortiz-Martinez, Gonzalez, Evtushenko, Jurado, Laiz, Groth and Saiz-Jimenez 2004, 1555

fu.co′sus. N.L. n. *fucosum* fucose; N.L. masc. adj. *fucosus* (*sic*), containing fucose in the cell wall.

The general characteristics are as described for the genus and species and listed in Table 144. Additional information is taken from Zgurskaya et al. (1992) and Ortiz-Martinez et al. (2004) unless indicated otherwise.

Colonies are whitish yellow to intense yellow and occasionally penetrate into the agar media. The pigment biosynthesis is light-induced (Trutko et al., 2005). After initial growth on CB agar, microcolonies are composed of branching vegetative hyphae and short filaments. As growth

proceeds, they undergo septation and fragment into irregular rod-like to coccoid cells in 2–3 d cultures.

Optimum growth is at 26–30°C. Strains are able to grow at 7°C; growth at 37°C is variable between experiments. D-Arabinose, cellobiose, D-fructose, D-galactose, D-glucose, maltose, D-mannose, melezitose, methyl D-glucoside, L-rhamnose, salicin, sucrose, trehalose, and D-xylose are used for growth as sole carbon sources on basal medium ISP 9 supplemented with 0.01% (w/v) yeast extract.

Arbutin and esculin are hydrolyzed; adenine, elastin, guanine, pectin, and testosterone are not decomposed or hydrolyzed. Hippurate, hypoxanthine, Tween 40, and tyrosine are decomposed by some strains, including the type strain. Casein is not hydrolyzed (except for by the type strain). Production of H_2S from peptone is variable among strains; the type strain shows a positive reaction. Nitrate reduction is negative or weak. No growth occurs on agar media supplemented with 5% NaCl.

Purified cell walls of four strains contain varying quantities of rhamnose, galactose, and fucose, and trace amounts of mannose in some strains, including the type strain. Whole cells of the examined strains include rhamnose, galactose, glucose, mannose, ribose, and fucose. Cell wall contains 1,3-poly(glycerol phosphate) teichoic acid with *N*-acetylglucosamine substituents (Malysheva, 1994; Naumova et al., 2001). Overall polyamine content determined for the type strain is 0.21 μmol/g (dry wt), and includes putrescine (57%), 1,3-diaminopropane (24%), spermidine (9.5%), and spermine (4.8%) (Altenburger et al., 1997). The major menaquinone determined in the type strain is MK-12 (67%); the next most abundant menaquinone is MK-13 (15%); other components, i.e. MK-11, MK-10, MK-9, and MK-14 occur in small quantities (1–9%) (Suzuki et al., 1996). Predominant cellular fatty acids are $C_{15:0}$ anteiso (47%), $C_{17:0}$ anteiso (28%), and $C_{16:0}$ iso (15%). Principal phospholipids are diphosphatidylglycerol and phosphatidylglycerol. For further descriptive information see Zgurskaya et al. (1992), Groth et al. (1996), Suzuki et al. (1996), and Jurado et al. (2005a, 2005b, 2005c).

Source: soil in a grove of birches, Moscow, Russia.

DNA G+C content (mol%): 70–72 (T_m); 70.6 (HPLC).

Type strain: ATCC 51764, CCUG 35506, CIP 103633, DSM 8597, NBRC 15781, IMET 11529, JCM 9085, LMG 16156, VKM Ac-1345.

Sequence accession no. (16S rRNA gene): AJ784791.

8. **Agromyces hippuratus** (Zgurskaya, Evtushenko, Akimov, Voyevoda, Dobrovolskaya, Lysak and Kalakoutskii 1992) Ortiz-Martinez, Gonzalez, Evtushenko, Jurado, Laiz, Groth and Saiz-Jimenez 2004, 1555[VP] (*Agromyces fucosus* subsp. *hippuratus* Zgurskaya, Evtushenko, Akimov, Voyevoda, Dobrovolskaya, Lysak and Kalakoutskii 1992, 640)

hip.pu.ra′tus. N.L. n. *hippuras -atis* hippurate; N.L. masc. adj. *hippuratus* pertaining to the ability to decompose hippurate.

The general characteristics are as described for the genus and species and listed in Table 144. Additional information is taken from Zgurskaya et al. (1992) and Ortiz-Martinez et al. (2004) unless indicated otherwise.

Colonies are whitish yellow to intense yellow and occasionally penetrate into the agar. Produces a yellow carotenoid pigment, biosynthesis of which is light-induced (Trutko et al., 2005). After initial growth on agar, microcolonies are typically composed of branched and occasionally septated vegetative hyphae. As growth proceeds, these undergo further septation and fragment into irregular rod-like to coccoid cells in 3–4 d cultures.

Optimum growth is at 26–30°C. Strains are able to grow at 7°C; weak or no growth occurs at 37°C. D-Arabinose, cellobiose, D-fructose, D-galactose, D-glucose, maltose, D-mannose, melezitose, melibiose, L-rhamnose, salicin, sucrose, trehalose, and D-xylose are used for growth as sole carbon sources on ISP 9 (Shirling and Gottlieb, 1966) as basal medium supplemented with 0.01% (w/v) yeast extract. No growth occurs on media supplemented with 5% NaCl.

The major menaquinone revealed in the type strain is MK-12 (67%) followed by MK-13 (15%); other components, i.e. MK-11, MK-10, MK-9, and MK-14 occur in small quantities (1–9%) (Suzuki et al., 1996). Predominant cellular fatty acids are $C_{15:0}$ anteiso (52%), $C_{17:0}$ anteiso (18%), and $C_{16:0}$ iso (14%). Principal phospholipids detected are diphosphatidylglycerol and phosphatidylglycerol; strain VKM Ac-1353 contains an unidentified phospholipid. The total polyamine content determined in the type strains is 0.24 μmol/g (dry wt) and composed of putrescine (58%), spermidine (29%), spermine (13%), and trace amounts of 1,3-diaminopropane, *sym*-homospermidine, and *sym*-norspermidine (Altenburger et al., 1997). Cell walls of both described strains of this species (VKM Ac-1352 and VKM Ac-1353) contain 1,5-poly(ribitol phosphate) teichoic acid with tetrasaccharide substituents consisted of residues of rhamnose and *N*-acetylglucosamine. The predominant sugar in purified cell walls is rhamnose. Minor amounts of galactose and traces of mannose may occasionally occur. Whole cells of the above strains contain rhamnose, galactose, glucose, ribose, mannose, and trace amounts of xylose and fucose. For further descriptive information see Zgurskaya et al. (1992) and Ortiz-Martinez et al. (2004).

DNA G+C content (mol%): 71–72 (T_m); 70.8 (HPLC).

Type strain: ATCC 51765, CIP 103635, DSM 8598, NBRC 15782, JCM 9086, LMG 16158, VKM Ac-1352.

Sequence accession no. (16S rRNA gene): not available.

9. **Agromyces humatus** Jurado, Groth, Gonzalez, Laiz, Schuetze and Saiz-Jimenez 2005c, 874[VP]

hu.ma′tus. L. masc. part. adj. *humatus* buried.

The general characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (2005c).

Colonies are yellow-pigmented. Young cultures on agar media produce branching vegetative hyphae which subsequently break up into irregular rod-like and diphtheroid fragments. Aerobic. Growth occurs at 15–37°C (optimal growth at 28°C) and at pH 5–9.5. NaCl is tolerated up to 2% (w/v).

Major menaquinones are MK-13 and MK-12. Predominant fatty acids include $C_{15:0}$ anteiso (42%), $C_{17:0}$ anteiso (34%), and $C_{16:0}$ iso (16%). Polar lipids are phosphatidylglycerol, phosphatidylglycerol, one unidentified phospholipid,

and two unidentified glycolipids. Whole cell sugars include glucose, galactose, rhamnose, and mannose. For further descriptive information see Jurado et al. (2005c).

Source: the wall of a tomb located in the Little Apostle cubicle, Domitilla Catacombs, Rome, Italy.

DNA G+C content (mol%): 70.6 (T_m).

Type strain: strain CD5, CIP 108741, DSM 16389, HKI 0327, JCM 14319, NCIMB 14012.

Sequence accession no. (16S rRNA gene): AY618216.

10. **Agromyces italicus** Jurado, Groth, Gonzalez, Laiz, Schuetze and Saiz-Jimenez 2005c, 874[VP]

i.ta′li.cus. L. masc. adj. *italicus* of or belonging to Italy, the origin of the type strain.

The characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Jurado et al., 2005c).

Colonies are cream-colored. Young cultures on agar media produce branching vegetative hyphae which subsequently break up into irregular rod-like and diphtheroid fragments. Aerobic to microaerophilic. Growth occurs at 10–37°C (optimal growth at 28°C) and at pH 5–9.5. NaCl is tolerated up to 4% (w/v), no growth is observed at 6% NaCl.

Major menaquinones are reported to be MK-12 and MK-13. Predominant fatty acids are $C_{15:0}$ anteiso (51%), $C_{17:0}$ anteiso (15%), $C_{16:0}$ iso (15%), and $C_{15:0}$ iso (14%). Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, two unidentified phospholipids, and an unidentified glycolipid. Whole cell sugars include galactose, ribose, glucose, and mannose. For further descriptive information see Jurado et al. (2005c).

11. **Agromyces lapidis** Jurado, Groth, Gonzalez, Laiz, Schuetze and Saiz-Jimenez 2005c, 874[VP]

la.pi′dis. L. gen. n. *lapidis* of a stone.

The characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Jurado et al., 2005c).

Colonies are yellow-colored. Young cultures on agar media are composed of branching vegetative hyphae which subsequently break up into irregular rod-shaped and diphtheroid fragments. Aerobic to microaerophilic. Growth occurs at 15–37°C (with an optimum temperature of 28°C) and at pH 5–9.5. NaCl is tolerated up to 4% (w/v); no growth is observed at 6% NaCl.

Major menaquinones are MK-12 and MK-13. Predominant fatty acids are $C_{15:0}$ anteiso (48%), $C_{16:0}$ iso (17%), $C_{17:0}$ anteiso (13%), and $C_{15:0}$ iso (11%). Polar lipid profile includes diphosphatidylglycerol, phosphatidylglycerol, one unidentified phospholipid, and two unidentified glycolipids. Major menaquinones are MK-12 and MK-13. Whole cell sugars detected are glucose, galactose, mannose, and ribose. For further descriptive information, see Jurado et al. (2005c).

DNA G+C content (mol%): 70.4 (T_m).

Type strain: CD55, DSM 16390, HKI 0324, IAM 15275, JCM 14321, NCIMB 14013.

Sequence accession no. (16S rRNA gene): AY618217.

12. **Agromyces luteolus** Takeuchi and Hatano 2001, 1535[VP]

lu.te.o′lus. L. dim. masc. adj. *luteolus* yellowish, somewhat yellow.

The characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Takeuchi and Hatano, 2001), unless indicated.

Colonies are yellow to whitish yellow and occasionally penetrate into agar media. After initial growth on CB agar, microcolonies are composed of rudimentary branching vegetative hyphae and short filaments which fragment as growth proceeds and display diphtheroid, irregular shaped rods and coccoid cells in 3–4 d culture (recent observations). In liquid PY medium, filamentous or elementary branching cells (up to 5.0 µm or more in length) are produced in the early growth phase, which fragment into irregular rods (0.2–0.4 × 1.5–3.0 µm) during exponential growth phase.

Grows optimally at 20–30°C. Good growth is observed in the presence of 5% (w/v) NaCl; very weak growth occurs at 8% NaCl.

Major menaquinones are MK-12 (65%) and MK-11 (35%). Predominant cellular fatty acids include $C_{16:0}$ iso (48%), $C_{15:0}$ anteiso (33%), and $C_{17:0}$ anteiso (9.4%). Cell-wall sugars are rhamnose (67%), fructose (25%), mannose (6%), and glucose (2%). For further descriptive information, see Takeuchi and Hatano (2001).

Source: the surface of root of mangrove (*Sonneratia alba*) on Iriomote Island, Japan.

DNA G+C content (mol%): 71.1 (HPLC).

Type strain: strain 8, DSM 14595, JCM 11431, NBRC 16235, NCIMB 13882, VKM Ac-2085.

Sequence accession no. (16S rRNA gene): AB023356.

13. **Agromyces mediolanus** (*ex* Mamoli 1939) Suzuki, Sasaki, Uramoto, Nakase and Komagata 1996, 92[VP] ("*Corynebacterium mediolanum*" Mamoli 1939, 1863)

me.di.o′la.nus. N.L. masc. adj. *mediolanus* (*sic*) of or belonging *Mediolanum*, the old name of Milan, Italy.

The characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Suzuki et al., 1996) unless indicated otherwise.

Colonies are whitish yellow to yellow due to carotenoid pigment, biosynthesis of which is light-induced (Trutko et al., 2005; Weeks and Garner, 1967). After initial growth on agar, cells are typically composed of irregular rods (0.3–0.6 × 1.4–3.0 µm) or short filaments; a rudimentary mycelium may occasionally be formed on some media (recent observations). Week-old cultures are composed mainly of short irregular rods, but a proportion of the cells may be coccoid. Aerobic to microaerophilic (Jurado et al., 2005c). Optimal growth temperature is 28–30°C.

Strains of this species hydrolyze starch (except for the type strain) and assimilate fumarate, hippurate (except for the type strain), propionate, and urate as determined by conventional methods. DNase-negative. The following characters are variable among strains: nitrate reduction, assimilation of glyoxalate, acid production from mannose, ribose, salicin, and sucrose (the type strain is positive in the listed activities). Acid is not produced by the type and some other strains from L-rhamnose, fructose, maltose, and amygdalin.

The major menaquinone is MK-12 (54–61%); the next most abundant menaquinones are MK-11 (14–20%) and MK-10 (12–15%); other components, i.e. MK-7, MK-8, MK-9, and MK-13 occur in minor (1–5%) or trace amounts (Sasaki et al., 1998; Suzuki et al., 1996). Predominant cellular fatty acids are $C_{15:0}$ anteiso (26–33%), $C_{17:0}$ anteiso (37–46%), and $C_{16:0}$ iso (17–28%) (Collins and Jones, 1980; Suzuki et al., 1996). The polar lipid profiles of two strains (the type strain and "*Flavobacterium dehydrogenans*" NCIMB 872) were almost identical and included diphosphatidylglycerol, phosphatidylglycerol (in very small quantities), and one characteristic glycolipid (Collins and Jones, 1980). The overall polyamine content is 0.28 μmol/g (dry wt); putrescine (75%) and 1,3-diaminopropane (25%) are the major compounds; cadaverine, spermine, spermidine, *sym*-homospermidine, and *sym*-norspermidine occur in trace amounts (Altenburger et al., 1997).

The levels of DNA–DNA hybridization of the type strain JCM 3346 and three other strains assigned to *Agromyces mediolanus* (JCM 1376, JCM 9632 and JCM 9633) are very high (80–99%), while the DNA–DNA hybridization between strain JCM 9631 and the above four strains ranged from 46–65%. This relationship coincides with a lower 16S rRNA gene sequence similarity determined among these strains. Suzuki et al. (1996) suggested that strain JCM 9631 is distinct from the other four strains at least at the subspecies level, but no clear differentiating phenotypic characters, except for acid production from mannitol, were observed. Therefore, strain JCM 9631 was not reclassified to a novel species.

DNA G+C content (mol%): 72.3 (HPLC).

Type strain: ATCC 14004, CIP 104860, DSM 20152, JCM 3346, NBRC 15704, NCIMB 7206, VKM Ac-1388.

Sequence accession no. (16S rRNA gene): HM641754, X77449.

14. **Agromyces neolithicus** Jurado, Groth, Gonzalez, Laiz and Saiz-Jimenez 2005a, 157[VP]

ne.o.li′thi.cus. N.L. masc. adj. *neolithicus* neolithic, referring to the origin of the neolithic paintings in Grotta dei Cervi, the source of the soil from which the organism was isolated.

The characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Jurado et al., 2005a).

Colonies are beige-colored. Young cultures are composed of branching vegetative hyphae which subsequently break up into irregular rod-shaped and diphtheroid fragments. Aerobic to microaerophilic. Growth occurs at 15–37°C, with an optimum at 28°C.

Major menaquinones are MK-13 and MK-12. Predominant cellular fatty acids include $C_{15:0}$ anteiso (38%), $C_{17:0}$ anteiso (32%), $C_{16:0}$ iso (13%), and $C_{15:0}$ iso (13%). Major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, two unidentified phospholipids, and an unidentified glycolipid. Whole cell sugars include glucose, galactose, and mannose. For further descriptive information see Jurado et al. (2005a).

Source: a soil sample of the Grotta dei Cervi, Italy.

DNA G+C content (mol%): 65.3 (T_m).

Type strain: strain 23-23, CIP 108987, DSM 16197, HKI 0321, JCM 4322, NCIMB 13990.

Sequence accession no. (16S rRNA gene): AY507128.

15. **Agromyces rhizospherae** Takeuchi and Hatano 2001, 1536[VP]

rhi.zo.sphe′ra.e. N.L. *rhiza* root; Gr. n. *sphaira* sphere; N.L. gen. n. *rhizospherae* of the sphere of the root.

The characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Takeuchi and Hatano, 2001), unless indicated.

Colonies are yellow-colored and occasionally penetrate into agar media. After initial growth on CB agar, microcolonies are composed of rudimentary branched vegetative hyphae or short filaments which relatively rapidly (1–2 d) fragment into short irregular rods to coccoid cells; older cultures (1–2 weeks) usually display coccobacillaric forms (recent observation). In a liquid culture in PY medium, cells display irregular rods (0.2–0.4 × 1.5–3.0 μm) or short, occasionally branching filaments in the early growth phase, which fragment into short rods (mean 0.2–0.4 × 0.8–1.5 μm) to coccoid cells during exponential growth phase.

Aerobic. Grows optimally at 20–30°C. Good growth occurs in the presence of 5% (w/v) NaCl; very weak growth is also observed at 8%.

The major menaquinones determined for the type strain are MK-12 (52%) and MK-11 (48%), while the second strain (IFO 16237) contains MK-12 as the predominant component (81%), with small amounts of MK-11 (19%). Predominant cellular fatty acids reported for the two strains are $C_{16:0}$ iso (54 and 44%), $C_{15:0}$ anteiso (26 and 27%), and $C_{17:0}$ anteiso (13 and 19%). Cell-wall sugars are rhamnose (89%), glucose (4–5%), and mannose (6–7%).

The two described strains of this species share 99.2% 16S rRNA gene sequence similarity and show 69–73% DNA–DNA hybridization. For further descriptive information see Takeuchi and Hatano (2001).

DNA G+C content (mol%): 71.2–73.3 (HPLC).

Type strain: strain 14, DSM 14597, NBRC 16236, JCM 11432, VKM Ac-2086.

Sequence accession no. (16S rRNA gene): AB023357.

16. **Agromyces salentinus** Jurado, Groth, Gonzalez, Laiz and Saiz-Jimenez 2005a, 156[VP]

sa.len.ti′nus. N.L. masc. adj. *salentinus* of or belonging to Salentine Peninsula, the location of Grotta dei Cervi, the area from which the organism was isolated.

The characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Jurado et al., 2005a).

Colonies are yellow-pigmented. Young cultures are composed of branching vegetative hyphae which subsequently break up into diphtheroid and irregular rod-like fragments. Aerobic to microaerophilic. Optimal growth temperature is 20–28°C.

Predominant menaquinone is MK-12 (78%), with minor amounts of MK-13 (14%) and MK-11 (8%). Major cellular fatty acids are $C_{15:0}$ anteiso (52%), $C_{17:0}$ anteiso (25%), and $C_{16:0}$ iso (13%). Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, an unidentified glycolipid, and four unidentified phospholipids. Whole cell sugars include rhamnose, glucose, galactose, arabinose, and ribose. For further descriptive information see Jurado et al. (2005a).

Type strain: strain 20–5, DSM 16198, HKI 0320, JCM 14323, NCIMB 13989.

Sequence accession no. (16S rRNA gene): AY507129.

17. **Agromyces subbeticus** Jurado, Groth, Gonzalez, Laiz and Saiz-Jimenez 2005b, 1900[VP]

sub.be′ti.cus. N.L. masc. adj. *subbeticus* of or belonging to the Subbetic Mountain Range, Southern Spain, where the Cave of Bats is located.

The characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Jurado et al., 2005b).

Colonies are intense yellow. After initial growth on agar, cells are composed of irregular rods or short branching filaments (2.5–4.0 µm in length), that subsequently fragment into short, rod-shaped and diphtheroid elements. Aerobic to microaerophilic. Growth occurs at 6–37°C (optimally at 28°C) and at pH values of 5–9.5. NaCl is tolerated up to 4% (w/v).

Major menaquinones are MK-12 (58%) and MK-13 (35%). Predominant cellular fatty acids are $C_{15:0}$ anteiso (46%), $C_{17:0}$ anteiso (20%), $C_{15:0}$ iso (16%), and $C_{16:0}$ iso (12%). Polar lipids include diphosphatidylglycerol, phosphatidylglycerol, an unidentified phospholipid, and two unidentified glycolipids. Whole cell sugars detected are rhamnose, glucose, galactose, and mannose. For further descriptive information see Jurado et al. (2005b).

DNA G+C content (mol%): 71.2 (T_m).

Type strain: strain Z33, DSM 16689, HKI 0340, JCM 14324, NCIMB 14025.

Sequence accession no. (16S rRNA gene): AY737778.

18. **Agromyces terreus** Yoon, Schumann, Kang, Park and Oh 2008, 1311[VP]

ter′re.us. L. masc. adj *terreus* of the earth.

Colonies on TSA are cream-colored. Cells are usually curved or straight irregular rods or short filaments (0.2–0.5 × 0.7–5.0 µm). No growth is observed under anaerobic conditions on nutrient agar (NA, Difco) or on na supplemented with nitrate. Growth occurs at 10–35°C with an optimum temperature of 25°C. Growth is observed at pH 5.0 and 10.0 but not at pH 4.5 or 10.5; optimal pH for growth is 7.0–8.0. Growth occurs at 0–6.0% (w/v) NaCl; best growth is in the presence of 0.5–1.0% (w/v) NaCl (tested in tripticase soy broth prepared according to the formula of the Difco medium). Tweens 20, 40, and 60 are hydrolyzed. Negative for arginine decarboxylase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase. Susceptible to the following antibiotics (amount per disk): polymyxin B (100 U), streptomycin (50 µg), penicillin G (20 U), cephalothin (30 µg), gentamicin (30 µg), carbenicillin (100 µg), neomycin (30 µg), and oleandomycin (15 µg), but not to lincomycin (15 µg).

The menaquinones detected include MK-11 (49%), MK-12 (31%), and MK-10 (16%). The predominant cellular fatty acids are $C_{15:0}$ anteiso (41%), $C_{17:0}$ anteiso (21%), $C_{16:0}$ iso (19%), and $C_{15:0}$ iso (12%). Major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and an unidentified glycolipid. Sugars detected in whole cells are galactose and ribose. For further descriptive information see Yoon et al. (2008).

Source: soil the Dokdo island, Korea.

Sequence accession no. (16S rRNA gene): EF363711.

19. **Agromyces ulmi** Rivas, Trujillo, Mateos, Martinez-Molina and Velazquez 2004a, 1989[VP]

ul′mi. L. fem. gen. n. *ulmi* of the elm tree, referring to the isolation source of this microorganism.

The characteristics are as described for the genus and listed in Table 144. Additional information is taken from the original description (Rivas et al., 2004a).

Colonies are usually white. After initial growth on agar, cells are composed of branching vegetative hyphae which, after 15 h, break up into diphtheroid and irregular-shaped fragments (0.8–1.0 × 1.3–2.4 µm). Aerobic, albeit showing negative catalase and oxidase reactions. Optimal growth temperature is 28°C. Cellulose, gentiobiose, and xylan are used as carbon sources. Acids are produced from D-lyxose, L-sorbose, and xylitol.

The menaquinone system of the type strain includes MK-12, MK-11, MK-10, MK-13, and MK-9 (50:35:11:2:2), whereas the second described strain (XIL05) of this species contains these components in a slightly different proportion (61:23:3:7:4). The major fatty acids found for the two strains were similar: $C_{15:0}$ anteiso (46%), $C_{16:0}$ iso (24–25%), and $C_{17:0}$ anteiso (20–22%). Polar lipids reported for the type strain are diphosphatidylglycerol, phosphatidylglycerol, and an unidentified glycolipid. Cell-wall sugars include rhamnose, fucose, and glucose. The two described strains of this species have almost identical 16S rRNA gene sequences and show 100% DNA–DNA hybridization. For further descriptive information see Rivas et al. (2004a).

Genus V. **Clavibacter** Davis, Gillaspie, Vidaver and Harris 1984, 113[VP]

Gerard S. Saddler and Ellen M. Kerr

Cla.vi.bac′ter. L. n. *clava* cudgel; N.L. masc. n. *bacter* rod; N.L. masc. n. *Clavibacter* club-shaped rod.

Pleomorphic rods (0.4–0.75 × 0.8–2.5 μm), often in angular, **V-formations** with no marked rod–coccus development cycle. Gram-stain-positive, non-acid-fast, nonmotile, and nonsporeforming. Obligate aerobes; growth factors are required for growth. **Acid production from carbohydrates is slow and weak**; acid is produced aerobically from glucose and glycerol. No acid is produced from adonitol, esculin, *meso*-inositol, melezitose, β-methyl-D-glucoside, raffinose, rhamnose, or ribose. Nitrate and nitrite are not reduced or utilized; casein is not hydrolyzed. Catalase-positive; oxidase, lipase, tyrosinase, and urease-negative. Optimum growth temperature 20–29°C; maximum temperature for growth is 35°C. **The cell-wall peptidoglycan, based on the presence of 2,4-diaminobutyric acid (DAB), is type B2γ**. Mycolic acids are not found. Nonhydroxylated fatty acids, specifically iso-methyl and anteiso-methyl branched chains fatty acids, predominate. Phosphatidylglycerol, diphosphatidylglycerol, and some unknown glycosyldiacylglycerols are the major polar lipids. Spermidine and spermine are the major polyamines with minor amounts of putrescine. **Isoprenoid quinones, comprising menaquinones with 9 isoprene units (MK-9) predominate.**

DNA G+C content (mol%): 65–75.

Type species: **Clavibacter michiganensis** corrig. (Smith 1910) Davis, Gillaspie, Vidaver and Harris 1984, 113[VP] (*Bacterium michiganense* Smith, 1910, 794; C*orynebacterium michiganense* Jensen 1934, 47).

Further descriptive information

The genus *Clavibacter* is a member of the family *Microbacteriaceae*, alongside other phytopathogenic coryneforms currently included in the genera *Curtobacterium*, *Leifsonia*, and *Rathayibacter*. Historically, all phytopathogenic coryneforms were contained within *Corynebacterium* principally on the basis of morphological and staining characteristics (Keddie and Jones, 1981). Subsequently, a subgroup, all of which contained 2,4-diaminobutyric acid (DAB) in their cell-wall peptidoglycan (type B2γ of Schleifer and Kandler, 1972), were assigned to the genus *Clavibacter* by Davis and co-workers (1984). When originally described, *Clavibacter* encompassed five species: *Clavibacter michiganense* [*sic*], *Clavibacter iranicum*, *Clavibacter rathayi*, *Clavibacter tritici*, and *Clavibacter xyli*. Additional taxonomic revision resulted in the present classification of these taxa, whereby they were redistributed across three genera: *Clavibacter*, *Leifsonia* (Evtushenko et al., 2000), and *Rathayibacter* (Zgurskaya et al., 1993). Differences in menaquinone profiles were highly significant; membership of *Clavibacter* was restricted to the species *Clavibacter michiganensis* which contains major amounts of MK-9 and, to a lesser extent, MK-7, MK-8, and MK-10. In contrast, MK-10 predominates in *Rathayibacter iranicus*, *Rathayibacter rathayi*, and *Rathayibacter tritici* (Carlson and Vidaver, 1982; Collins, 1983; Collins and Jones, 1980), and MK-11 in *Leifsonia xyli* (Sasaki et al., 1998). Analysis of D- to L-DAB isomers found in the peptide subunit and the interpeptide bridge of the peptidoglycan added further weight to the current classification. All members of the genus *Clavibacter* have D- and L-DAB in almost equal proportions, in contrast to *Rathayibacter* which possesses the L-isomer almost exclusively (Sasaki et al., 1998). Cell-wall sugars comprise rhamnose, galactose, and mannose; arabinose is not found and some strains contain fucose (Davis et al., 1984). Principal phospholipids are phosphatidylglycerol, diphosphatidylglycerol, and some unknown glycosyldiacylglycerols (Collins et al., 1980; Collins and Jones, 1980). Spermidine and spermine are the major polyamines, with minor amounts of putrescine, in contrast to *Curtobacterium*, where putrescine is absent (Altenburger et al., 1997). Nonhydroxylated, branched-chain fatty acids predominate, specifically 14-methylhexadecanoic ($C_{17:0}$ anteiso) and 12-methyltetradecanoic acids ($C_{15:0}$ anteiso; Collins and Jones, 1980; Kämpfer and Kroppenstedt,1996). Significant quantities of 14-methylpentadecanoic ($C_{16:0}$ iso) and octadecenoic acids ($C_{18:1}$) are also found. Kämpfer and Kroppenstedt (1996) concluded that it was not possible to differentiate *Clavibacter michiganensis* subspecies by fatty acids profiles, contrasting with the view of Henningson and Gudmestad (1991) who suggested that the ratios between key, minor fatty acid components could be used to differentiate subspecies and even suggested that the differences were such that the subspecific taxa merit elevation to the rank of species. The fatty acid profiles from a range of isolates of *Clavibacter michiganensis* subsp. *michiganensis* were typical for the genus with little variation found between isolates. Saturated, straight-chain fatty acids, namely dodecanoic ($C_{12:0}$) and hexadecanoic acids ($C_{16:0}$), were found in significant amounts (Gitaitis and Beaver, 1990) and the presence of the unsaturated, branched-chain acid, 12-methyltetradecenoic acid ($C_{15:1}$ anteiso), was considered diagnostic for this subspecies.

In general, members of the genus *Clavibacter* produce irregular rods which vary in size and shape (0.4–0.75 × 0.8–2.5 μm) and are arranged in V-formations. There is no marked rod–coccus cycle and branching does not occur (Davis, 1986). The mode of cell division has been considered to be of taxonomic significance, with all the *Clavibacter* subspecies examined dividing by bending division (Komagata et al., 1969), resulting in the V-form cell arrangements. Carlson and Vidaver (1982) found that colony color was a useful diagnostic characteristic; subspecies *nebraskensis* and *tessellarius* produce orange-pigmented colonies, while subsp. *sepedonicus* is usually nonpigmented and subspp. *insidiosus* and *michiganensis* are yellow when grown on NBY* Agar (Vidaver, 1967). Colonial variants are evident in some *Clavibacter michiganensis* subspecies. Smidt and Vidaver (1987) noted that *Clavibacter michiganensis* subsp. *nebraskensis* produced four morphological types: orange fluidal colonies typical of the subspecific description; a non-fluidal, dark-orange variant; a fluidal, yellow variant; and a fluidal, slightly orange-pigmented variant that, in younger colonies, appeared almost white. Variation has also been found among strains of *Clavibacter michiganensis* subsp. *sepedonicus* where both the fluidal, wild-type and afluidal variants are commonly found (Kokošková et al., 2005; Mills et al., 2007).

*NBY Medium (g/liter): Nutrient broth (Difco), 8.0; yeast extract (Difco), 2.0; K_2HPO_4, 2.0; KH_2PO_4, 0.5; agar, 15.0. Added separately: 50 ml of sterile glucose (50%, w/v aq.) and 1 ml of sterile 1 M $MgSO_4 \cdot 7H_2O$.

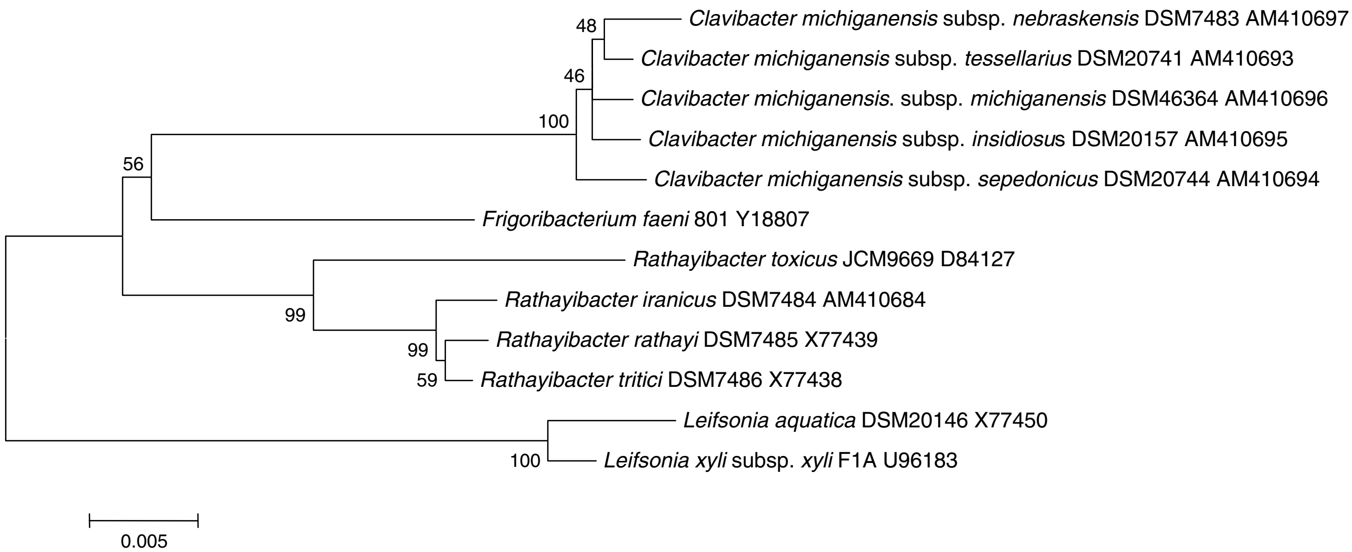

FIGURE 178. Phylogeny of the genus *Clavibacter* and close relatives drawn from the family *Microbacteriaceae* including representatives of the genera *Frigoribacterium*, *Rathayibacter*, and *Leifsonia*. Maximum composite likelihood with clustering achieved by the neighbor joining method to produce a bootstrap consensus tree was performed using MEGA4. Bar = 0.5% difference in the 16S rRNA gene sequences. Five hundred bootstrap trees were generated, and bootstrap confidence levels (shown as percentages above nodes) were determined.

Clavibacter strains are all chemo-organotrophs with a respiratory metabolism, producing acid weakly from a range of carbohydrates. Growth is relatively slow and B-vitamins are required (Collins and Bradbury, 1986). All strains produce catalase but not oxidase, tyrosinase, urease, and lipase (Davis et al., 1984). The complete genome sequence of *Clavibacter michiganensis* subsp. *michiganensis* has confirmed that the pathways for glycolysis, the pentose phosphate pathways and gluconeogenesis are all present and complete (Gartemann et al., 2008).

Li and De Boer (1995) found a high degree of 16S rRNA gene similarity between *Clavibacter michiganensis* subspecies; the subspecies displayed less than 1% dissimilarity. In this study, *Clavibacter michiganensis* was found to be closely related to *Leifsonia xyli* (basonym *Clavibacter xyli*), but more distantly related to members of the family *Corynebacteriaceae*, *Mycobacteriaceae*, and *Nocaridaceae*. A more comprehensive subsequent analysis shows that the genera *Clavibacter* and *Rathayibacter* form a discrete clade in which four major phylogenetic groups can be recognized (Lee et al., 1997); I, *Clavibacter michiganensis*; II, *Clavibacter xyli*; III, *Rathayibacter iranicus* and *Rathayibacter tritici*; and IV, *Rathayibacter rathayi*. On the basis of these results, a new classification was proposed, specifically that *Rathayibacter tritici/Rathayibacter iranicus* should be assigned to a different genus from that of *Rathayibacter rathayi* and that *Clavibacter xyli* should be encompassed within a separate genus. While the former suggestion has yet to be acted upon, the latter has seen *Clavibacter xyli* assigned to the genus *Lieifsonia* (Evtushenko et al., 2000). Circumscription of the genus *Frigoribacterium* on the basis of 16S rRNA gene sequence comparison (Kämpfer et al., 2000) reveals a high degree of relatedness to both *Rathayibacter* and *Clavibacter*, the former was found to be 96.1–97.1% similar, while the latter 96.9–97.1%. A comprehensive analysis of the family *Microbacteriaceace* encompassing representatives of 15 genera reaffirmed the close relationship between *Clavibacter*, *Frigoribacterium*, *Rathayibacter*, and *Curtobacterium* (Evtushenko and Takeuchi, 2006), with *Leifsonia* more distantly related. These relationships are demonstrated clearly in Figure 178 where the close relationship between *Clavibacter*, *Frigoribacterium*, and *Rathayibacter* is evident as is the more distant relationship to *Leifsonia*.

DNA–DNA hybridization studies show that *Clavibacter michiganensis* subspp. *michiganensis* and *insidiosus* are more closely related to each other (73–74% DNA–DNA relatedness) than they are to subspp. *sepedonicus* (51–56%) and *nebraskensis* (45–46%; Döpfer et al., 1982). Subsequently, *Clavibacter michiganensis* subsp. *tessellarius* was found to be 56% related to *Clavibacter michiganensis* subsp. *michiganensis* (Zgurskaya et al., 1993), Hence, the subspecies *sepedonicus*, *nebraskensis*, and *tessellarius* could be given species status if the threshold value of 70% for species differentiation is to be applied.

The phylogeny of the family *Microbacteriaceae* based on sequencing DNA of gyrase subunit B (*gyrB*), RNA-polymerase subunit B (*rpoB*), recombinase A (*recA*), and polyphosphate kinase (*ppk*) genes shows that although suprageneric relationships vary between each gene phylogeny, the genus *Clavibacter* remains a coherent entity (Stackebrandt et al., 2007). One of the significant findings of this study is that in none of the 16 trees generated did the topologies coincide with the key taxonomic marker for this group, namely the diagnostic diamino acid of the peptidoglycan, suggesting that this characteristic may have evolved independently several times or that it has regularly been subject to horizontal gene transfer. The complete genome sequence of *Clavibacter michiganensis* subspp. *michiganensis* (Gartemann et al., 2008) and *sepedonicus* (Bentley et al., 2008) has revealed a number of similarities but also many striking differences between these subspecies. *Clavibacter michiganensis* subsp. *michiganensis* has a circular chromosome of 3.298 Mb

comprising 2,984 predicted coding sequences, along with two circular plasmids, pCM1 (27.4 kb) and pCM2 (70 kb), which are essential for pathogenicity (Gartemann et al., 2008). Earlier studies have shown that curing plasmids from *Clavibacter michiganensis* subsp. *michiganensis* causes a loss of pathogenicity (Bermpohl et al., 1996). Similarly, *Clavibacter michiganensis* subsp. *sepedonicus* has a circular chromosome of 3.259 Mb comprising 3,058 predicted coding sequences along with two plasmids essential for pathogenicity, pCS1 (50.4 kb; Mogen et al., 1988) and pCSL1 (94.8 kb; Bentley et al., 2008). However, *Clavibacter michiganensis* subsp. *michiganensis* lacks complete insertion elements and transposons with no evidence of genome reduction, as has been found in other xylem-limited pathogens. Indeed, *Clavibacter michiganensis* subsp. *michiganensis* was found to possess a similar number of transporters and regulators as can be found in many soil-inhabiting bacteria. In contrast, *Clavibacter michiganensis* subsp. *sepedonicus* contains 106 insertion sequence elements which are implicated in the extensive chromosomal rearrangement observed. Functional disruption of many genes involved in carbohydrate metabolism, transcriptional regulation, and pathogenicity all suggest a recent adaptation to life in a more restricted niche and the general relaxation of the selective pressures that would normally be found applied to a more generalized, soil-inhabiting lifestyle.

A number of monoclonal antibodies have been raised against *Clavibacter michiganensis* subsp. *sepedonicus* (De Boer and Wieczorek, 1984); two of them show no cross-reactivity with other *Clavibacter michiganensis* subspecies or saprophytes isolated from potato. One of these monoclonals, 9A1 (McAb 5; De Boer and Wieczorek, 1984), reacted poorly in ELISA, resulting in the discovery of new more effective ELISA-monoclonal, 1H3 (De Boer et al., 1988). Monoclonal 9A1 has been used effectively for immunofluorescence testing (De Boer et al., 1994) and in conjunction with *in situ* hybridization (Li et al., 1997). Specificity of the monoclonal antibody (MAb) Cmm1 to *Clavibacter michiganensis* subsp. *michiganensis* was assessed (Kaneshiro et al., 2006) by screening 236 strains of the subspecies and representative saprophytes likely to be found on the tomato host. Of the *Clavibacter michiganensis* subsp. *michiganensis* strains tested, 99% reacted with this antibody with no cross-reactivity to common saprophytes. Polyclonals have been used successfully in conjunction with immunomagnetic separation to enhance the sensitivity of detection of *Clavibacter michiganensis* subsp. *michiganensis* from naturally infected tomato seeds (de Leon et al., 2006, 2008).

Phage have been described from a number of subspecies of *Clavibacter*, specifically for subspp. *insidiosus* (Cook and Katznelson, 1960), *michiganensis* (Echandi and M. Sun, 1973), and *nebraskensis* (Shirako et al., 1986; Smidt and Vidaver, 1987). Members of the genus *Clavibacter* are known to produce bacteriocins (Echandi, 1976; Gross and Vidaver, 1979a; Smidt and Vidaver, 1987). One such peptide bacteriocin, michiganin A, from *Clavibacter michiganensis* subsp. *michiganensis*, and active against *Clavibacter michiganensis* subsp. *sepedonicus*, has been recently characterized as a type B lantibiotic (Holtsmark et al., 2006), a compact, globular molecule which shows similarities to actagardine, produced by *Actinoplanes liguriae*. In addition, a 14 kDa antimicrobial protein and a low molecular mass antimicrobial putatively identified as a tunicamycin have been detected (Holtsmark et al., 2007).

The extracellular polysaccharide (EPS) composition of *Clavibacter michiganensis* subsp. *michiganensis* has been determined as fucose, glucose, galactose (2:1:1; molar ratio; Bermpohl et al., 1996). It is thought that EPS plays only a minor role in symptom expression as EPS$^-$ mutants maintain virulence, while plasmid-cured strains that produce EPS do not. Current thinking, based on the model of van Alfen and co-workers (1987), suggests that EPS interferes with water transport by physically plugging xylem vessels, but that it is not directly involved in virulence (Eichenlaub et al., 2006). Analysis of the genome of *Clavibacter michiganensis* subsp. *michiganensis* reveals at least four gene clusters implicated in EPS production, and that mutants specifically generated in one of these clusters will lead to the production of rough colonies from the mucoid, wild-type (Eichenlaub et al., 2006). *Clavibacter michiganensis* subsp. *michiganensis* is known to induce a hypersensitive-like reaction (HR) in the non-host plant, four-o'clock flower (*Mirabilis jalapa* L.; Bermpohl et al., 1996). Analysis of the HR-inducing activity revealed that it was heat-stable and sensitive to protease digestion and, in this respect, similar to harpin and popA described previously in Gram-stain-negative phytopathogens (Alarcón et al., 1998). Similar findings have been reported for *Clavibacter michiganensis* subsp. *sepedonicus*, in which HR-induction occurs in tobacco (Nissinen et al., 2001). It has been demonstrated that HR-induction and cellulase production are required to cause disease. A plasmid-free isolate of *Clavibacter michiganensis* subsp. *sepedonicus* that could induce HR on tobacco, but was unable to produce cellulose, was able to colonize the host plant efficiently but could only produce weak symptoms. In contrast, a strain that was unable to induce HR but could produce cellulase was impaired in its ability to colonize the host and caused no symptoms. Co-inoculation of both strains into the host restored disease development to its typical state (Nissinen et al., 2001). The significance of plant cell-wall degrading enzymes in the pathogenicity of *Clavibacter michiganensis* subsp. *michiganensis* has also been demonstrated (Eichenlaub et al., 2006; Evtushenko and Takeuchi, 2006). A 78 kDa CelA protein with similarity to endo-β-1,4-glucanases has been found to play a major role in pathogenicity (Jahr et al., 2000), although it is clear that this endoglucanase alone is insufficient to express the virulent wild-type phenotype (Gartemann et al., 2003; Jahr et al., 1999). It is likely that a second pathogenic determinant, the product of the *pat-1* gene, a serine protease-like enzyme (Dreier et al., 1997), is also required for pathogenicity. Recent work on *Clavibacter michiganensis* subsp. *sepedonicus* has demonstrated that virulence/pathogenicity in this subspecies is not just dependent on CelA and an, as yet uncharacterized, HR-inducing protein (Holtsmark et al., 2008). In this study, the expression of CelA and eight putative virulence factors were examined including CelB, another cellulase-encoding gene; a pectate lyase; a xylanase; and five homologs of the *Clavibacter michiganensis* subsp. *michiganensis pat-1* gene. Although further work is required, it is evident that additional proteins are likely to be involved in symptom expression in *Clavibacter michiganensis* subsp. *sepedonicus*.

Members of the genus *Clavibacter* are exclusively plant pathogens that primarily cause vascular disease in a variety of significant crops, specifically: alfalfa (*Clavibacter michiganensis* subsp. *insidiosus*), maize (*Clavibacter michiganensis* subsp. *nebraskensis*), potato (*Clavibacter michiganensis* subsp. *sepedonicus*), tomato (*Clavibacter*

michiganensis subsp. *michiganensis*), and wheat (*Clavibacter michiganensis* subsp. *tessellarius*). Three of the subspecies: subspp. *insidiosus*, *michiganensis*, and *sepedonicus* are subject to quarantine restrictions due to the losses they can induce (Eichenlaub et al., 2006). *Clavibacter michiganensis* subsp. *michiganensis* is primarily spread by movement of asymptomatic seedlings or carried on seed. Infection can spread rapidly under controlled conditions, e.g. in greenhouses, and spreads in irrigation waters and through cultural practices (trimming, harvesting etc.; EPPO, 2005). *Clavibacter michiganensis* subsp. *sepedonicus* is carried as a latent infection on potato tubers and can persist for long periods of time as dried slime in stores, packing material, and on farm machinery. In Northern Europe, *Clavibacter michiganensis* subsp. *sepedonicus* may persist for a limited period in the field in common weeds and field crops, in contrast to North America where the weed *Solanum rostratum* has the potential to serve as a disease-reservoir (van der Wolf et al., 2005). *Clavibacter michiganensis* subsp. *sepedonicus* is unable to survive in surface waters for extended periods (van der Wolf and Beckhoven, 2004), nor can it survive or spread in soil (Kaemmerer et al., 2007); plant-to-plant transmission in the field is thought to be insignificant (Mansfeld-Giese, 1997). Typically for all subspecies, survival away from the principal host is limited and is only likely to occur in soil and water when the bacteria are associated with debris from previously infected host plants.

Enrichment and isolation procedures

The recovery of *Clavibacter* isolates from the environment is hampered by their general slow growth, frequently resulting in swamping/overgrowth by associated saprophytes. In many cases the bacteria are frequently present as asymptomatic infections in host plants in very low numbers, making isolation especially difficult. In cases where disease symptoms are expressed, the bacteria are likely to be present in significant amounts and direct isolation from the affected tissues onto media designed to support good growth can be effective. Media such as NBY*, YGM*, GYCA† (Dye, 1962), and Doppel's Medium‡ (Lelliott and Stead, 1987) are all suitable for the cultivation of *Clavibacter*. In situations where asymptomatic infections are suspected or where problems with overgrowth have been encountered, semi-selective media are required. CNS medium§ (Gross and Vidaver, 1979a) can be used to selectively isolate *Clavibacter michiganensis* subspp. *michiganensis*, *nebraskensis* and *tessellarius*. A modified semi-selective medium, mSCM** (Waters and Bolkan, 1992), modified from the earlier SCM medium of Fatmi and Schaad (1988), can also be used to isolate *Clavibacter michiganensis* subsp. *michiganensis*. On this medium it produces mucoid colonies with yellow flecks and is easily distinguishable from saprophytes which tend to be much smaller in size. A semi-selective medium, MTNA††, which contains mannitol, trimethoprim, nalidixic acid, and amphotericin B, has proven effective at recovering *Clavibacter michiganensis* subsp. *sepedonicus* from artificially inoculated and naturally infected symptomless tubers (Jansing and K. Rudolph, 1998), as has NCP-88‡‡ (de la Cruz et al., 1992).

Maintenance procedures

Standard methods of preservation can all be applied to *Clavibacter*, though there is evidence that freeze-drying may result in a loss of virulence (Evtushenko and Takeuchi, 2006). Most cultures can be stored on solid media at 6°C for several months, and survival can be achieved in the medium-term (several years) by storage at −70 to −80°C in 15–25% glycerol (v/v) (Collins and Bradbury, 1986; Jacobs and Sundin, 2001; Kaneshiro et al., 2006).

Differentiation of the genus *Clavibacter* from other genera

Identification to the genus can be readily achieved using chemotaxonomic methods to identify DAB in the peptidoglycan, the presence of MK-9 in the cell wall, and spermidine and spermine as the major the polyamines. Sequencing 16S rRNA gene is also reliable for differentiating *Clavibacter* from other members of the family *Microbacteriaceae* (Evtushenko and Takeuchi, 2006; Stackebrandt et al., 2007) as are other genes, namely DNA gyrase subunit B (*gyrB*), RNA-polymerase subunit B (*rpoB*), recombinase A (*recA*), and polyphosphate kinase (*ppk*) (Stackebrandt et al., 2007). Further characteristics are listed in Table 145.

Taxonomic comments

Clavibacter is a well-defined, homogeneous genus that contains only one species, *Clavibacter michiganensis* encompassing five subspecies (subspp. *michiganensis*, *insidosus*, *nebraskensis*, *sepedonicus*, and *tessellarius*). Biochemical characteristics useful in distinguishing these subspecies are listed in Table 146. Commercial identification systems such as Biolog have been used to identify *Clavibacter* strains. Using an early version of the identification library (Biolog, release 3.5), Harris-Baldwin and Gudmestad (1996) found that results were highly variable with as few as 27% of *Clavibacter michiganensis* subsp. *nebraskensis* strains being correctly identified to the genus. Further, many strains were misidentified to *Curtobacterium*. More recent studies have shown that all virulent *Clavibacter michiganensis* subsp. *michiganensis* could be correctly identified to the species using Biolog, though hypovirulent and avirulent strains proved more problematic (Kaneshiro et al., 2006). Essentially similar results were obtained in a comprehensive study of *Clavibacter michiganensis* subsp. *sepedonicus*,

*YGM medium (g/liter): Bacto yeast extract (Difco), 2.0; D(+)-glucose (monohydrate), 2.5; K_2HPO_4, 40.25; KH_2PO_4, 0.25; $MgSO_4{\cdot}7H_2O$, 0.1; $MnSO_4{\cdot}H_2O$ 0.015; NaCl, 0.05; $FeSO_4{\cdot}7H_2O$ 0.005; Bacto agar (Difco), 18.

†GYCA medium (g/liter): glucose, 5.0; yeast extract, 5.0; $CaCO_2$ (finely ground), 41.0: agar, 15.0. pH 7.2.

‡Doppel's medium (g/liter): glucose, 10.0, yeast extract, 8.0; casein hydrolysate (not vitamin-free), 8.0; K_2HPO_4, 2.0; $MgSO_4{\cdot}7H_2O$, 0.3; agar, 12. pH 7.2.

§CNS medium: NBY* supplemented with lithium chloride, 10.0; nalidixic acid, 25 mg (freshly dissolved in 0.1 M NaOH, 10 $mg.ml^{-1}$); polymyxin $B.SO_4$, 32 mg (added as a 10 $mg.ml^{-1}$ freshly prepared aq. solution); actidione/cycloheximide, 40 mg (added as a 10 $mg.ml^{-1}$ aq. stock solution); chlorothalonil/Bravo 6F, 0.0625 ml (diluted 1:50 from a stock solution of tetrachloro-isophthalonitrile).

**mSCM (g/liter): pourite 0.013; $K_2HPO_4{\cdot}3H_2O$, 2.62; KH_2PO_4, 0.5; $MgSO_4{\cdot}7H_2O$, 0.25; boric acid, 1.5; mannose, 10.0; yeast extract, 0.1; nalidixic acid (Na salt), 0.03; nicotinic acid, 0.1; cycloheximide, 0.2; agar, 12.

††MTNA medium (g/liter): yeast extract (Difco), 2.0; mannitol, 2.5; K_2HPO_4, 0.25; KH_2PO_4, 0.25; NaCl, 0.05; $MgSO_4{\cdot}7H_2O$, 0.1; $MnSO_4{\cdot}H_2O$, 0.015; $FeSO_4{\cdot}7H_2O$, 0.005; agar (Oxoid No. 1), 16.0. pH 7.2. After autoclaving, add trimethoprim, 0.06 (5 $mg.ml^{-1}$ in 96% methanol); nalidixic acid, 0.002 (5 $mg.ml^{-1}$ in 96% methanol); amphotericin B, 0.01 (1 $mg.ml^{-1}$ in dimethyl sulfoxide).

‡‡NCP-88 medium (g/liter): Nutrient Agar (Difco), 23.0; yeast extract (Difco), 2.0; D-mannitol, 5.0; K_2HPO_4, 2; KH_2PO_4, 0.5; $MgSO_4{\cdot}7H_2O$, 0.25. pH to 7.2. After autoclaving add polymyxin B sulphate, 0.003 (aq.); nalidixic acid, 0.008 (stock solution prepared in 0.01 M NaOH); cycloheximide, 0.2 (stock solution prepared in 50% ethanol).

where fluidal, wild-type strains could be more reliably identified than afluidal and intermediate strains (Kokošková et al., 2005). API ZYM has been used successfully to distinguish *Clavibacter michiganensis* subsp. *sepedonicus* from the other subspecies in the genus (De Bruyne et al., 1992). In contrast, *Clavibacter michiganensis* subspp. *insidiosus*, *michiganensis*, and *nebraskensis* show greater heterogeneity and are difficult to differentiate from each other. Similar findings have been made using API 50CH and API ZYM, and *Clavibacter michiganensis* subsp. *sepedonicus* has been found to be highly homogeneous and easily distinguishable from the other *Clavibacter michiganensis* subspecies (Palomo et al., 2006).

It should be noted that, in much of the recent literature, the specific/subspecific epithets have been altered to the masculine form, subsequent to Davis and co-workers original description of the genus (1984), because generic names which end in *-bacter* are regarded as having the masculine gender (Bradbury, 1986; Collins and Bradbury, 1986; Zgurskaya et al., 1993). Regarding possible future changes to the current classification, Collins and Bradbury (1986) reviewed data from a wide variety of studies and concluded that the taxa now contained within the genus *Clavibacter* may warrant recognition at the species level, a view expressed more recently by Henningson and Gudmestad (1991), Evtushenko and Takeuchi (2006), and Eichenlaub and co-workers (2006). Such a move would derive the additional benefit of enabling the formal description of nonpathogenic or saprophytic strains, as the current classification places a major emphasis on phytopathogenicity.

List of species of the genus *Clavibacter*

1. **Clavibacter michiganensis** corrig. (Smith 1910) Davis, Gillaspie, Vidaver and Harris 1984, 113^{VP} (*Bacterium michiganense* Smith 1910, 794; C*orynebacterium michiganense* Jensen 1934, 47)

mi.chi.gan.en′sis. N.L. masc. adj. *michiganensis* of or pertaining to Michigan (USA).

The description is as for the genus. Acid is produced aerobically from glucose, glycerol, and mannitol, but not from adonitol, esculin, *meso*-inositol, melezitose, β-methyl-D-glucoside, raffinose, rhamnose, or ribose. Nitrate is not reduced and casein is not hydrolyzed. Catalase-positive; oxidase, lipase, tyrosinase, and urease-negative. Optimum growth temperature is 20–29°C.

DNA G+C content (mol%): 72–74 (Bd).

Type strain: CFBP 2352, CIP 104846, DSM 46364, ICMP 2550, JCM 9665, LMG 7333, NCPPB 2979, VKM Ac-1403.

Sequence accession no. (16S rRNA gene): AM410696, U09762, X77435.

1a. **Clavibacter michiganensis subsp. michiganensis** corrig. (Smith 1910) Davis, Gillaspie, Vidaver and Harris 1984, 113^{VP} (*Bacterium michiganense* Smith, 1910, 794; C*orynebacterium michiganense* Jensen 1934, 47)

mi.chi.gan.en′sis. N.L. masc. adj. *michiganensis* pertaining to Michigan, USA.

A pathogen of tomato (*Lycopersicon esculentum*) causing vascular wilt, canker, leaf, and fruit spot. The description is as for the genus and diagnostic tests are listed in 1. In addition, colonies are yellow on NBY agar; growth occurs on CNS agar. Rhamnose and fucose are present in the cell wall. Maximum growth temperature 34–35°C.

DNA G+C content (mol%): 73 (Bd).

Type strain: CFBP 2352, CIP 104846, DSM 46364, ICMP 2550, JCM 9665, LMG 7333, NCPPB 2979, VKM Ac-1403.

Sequence accession no. (16S rRNA gene): AM410696, U09762, X77435.

1b. **Clavibacter michiganensis subsp. insidiosus** corrig. (McCulloch 1925) Davis, Gillaspie, Vidaver and Harris 1984, 113^{VP} ("*Aplanobacter insidiosum*" McCulloch 1925, 497; *Corynebacterium insidiosum* Jensen 1934, 41)

in.si.di.o′sus. L. masc.adj. *insidiosus* deceitful, insidious.

A pathogen of alfalfa (*Medicago sativa*) causing wilt; plants are stunted and yellow with vascular discoloration of the roots. The description is as for the genus and diagnostic tests are listed in Table 145. In addition, colonies are yellow on NBY agar, many strains produce a dark blue-gray diffusible pigment (indigoidine). Growth does not occur on CNS agar. Rhamnose and fucose are present in the cell wall. Maximum growth temperature 31–32°C.

DNA G+C content (mol%): 73 (Bd).

Type strain: CCUG 38895, CFBP 2404, CIP 105048, CIP 105363, DSM 20157, ICMP 2621, LMG 3663, JCM 9664, NCPPB 1109, VKM Ac-1402.

Sequence accession no. (16S rRNA gene): AM410695, U09761.

1c. **Clavibacter michiganensis subsp. nebraskensis** corrig. (Vidaver and Mandel 1974) Davis, Gillaspie, Vidaver and Harris 1984, 113^{VP} (*Corynebacterium nebraskense* Vidaver and Mandel 1974, 482)

ne.bras.ken′sis. N.L. masc. adj. *nebraskensis* of or pertaining to Nebraska (USA).

A pathogen of maize (*Zea mays*) which gives rise to leaf spots and wilt, frequently referred to as "Goss's bacterial wilt." The description is as for the genus and diagnostic tests are listed in Table 145. In addition, colonies are orange on NBY agar; growth occurs on CNS agar. Rhamnose and fucose are present in the cell wall. Maximum growth temperature is 34°C.

DNA G+C content (mol%): 73.5 (Bd).

Type strain: ATCC 27794, CCUG 38894, CIP 105362, DSM 7483, ICMP 3298, JCM 9666, LMG 3700, LMG 5627, LMG 7223, NCPPB 2581, VKM Ac-1404.

Sequence accession no. (16S rRNA gene): AM410697, U09763, X77434.

1d. **Clavibacter michiganensis subsp. sepedonicus** corrig. (Spieckermann and Kotthoff 1914) Davis, Gillaspie, Vidaver and Harris 1984, 113^{VP} (*Bacterium sepedonicum* Spieckermann and Kotthoff 1914, 692; *Corynebacterium sepedonicum* Skaptason and Burkholder 1942, 441)

se.pe.don′i.cus. Gr. n. *sepedon* rottenness, decay; L. masc. suff. *-icus*, suffix used with the sense of pertaining to; N.L.

masc. adj. *sepedonicus*, pertaining to decay, intended to mean leading to decay.

A pathogen of potato (*Solanum tuberosum*) causing a vascular wilt and frequently leading to tuber rot, commonly referred to as "ring rot." The description is as for the genus and diagnostic tests are listed in Table 145. In addition, colonies are white on NBY agar; growth does not occur on CNS agar. Rhamnose, but not fucose, is present in the cell wall. Maximum growth temperature is 34°C.

DNA G+C content (mol%): 72 (Bd).

Type strain: ATCC 33113, CCUG 23908, CIP 104844, CFBP 2049, DSM 20744, ICMP 2535, JCM 9667, LMG 2889, NCPPB 2137, VKM Ac-1405.

Sequence accession no. (16S rRNA gene): AM410694, U09764.

1e. **Clavibacter michiganensis subsp. tessellarius** corrig. (Carlson and Vidaver 1982) Davis, Gillaspie, Vidaver and Harris 1984, 113[VP] (*Corynebacterium michiganense* subsp. *tessellarius* Carlson and Vidaver 1982, 322)

tes.sel.la′ri.us. L. masc. n. *tessellarius* a mosaic stone maker.

A pathogen of wheat (*Triticum aestivum*) which causes a mottling or mosaic of leaves. The description is as for the genus and diagnostic tests are listed in Table 145. In addition, colonies are orange on NBY agar; growth occurs on CNS agar. Rhamnose and fucose are present in the cell wall. Optimum temperature for growth 24–28°C. Grows at 10°C but not at 37°C.

DNA G+C content (mol%): 74 (Bd).

Type strain: 78181, ATCC 33566, CCUG 38896, CIP 105364, DSM 20741, ICMP 7221, JCM 9668, LMG 7294, NCPPB 3664, PDDCC 7221, VKM Ac-1406.

Sequence accession no. (16S rRNA gene): AM410693, U96181, U30254.

Genus VI. **Cryobacterium** Suzuki, Sasaki, Uramoto, Nakase and Komagata 1997, 477[VP] emend. Dastager, Lee, Ju, Park and Kim 2008a, 1243[VP]

Ken-ichiro Suzuki

Cry.o.bac.te′ri.um. Gr. n. *kruos* icy cold; L. neut. n. *bacterium* a small rod; N.L. neut. n. *Cryobacterium* a cold (preferring) rod.

Pleomorphic, **motile or nonmotile rod.** Nonsporeforming. Branching occurs in the early growth phase. **Gram-stain-positive, sometimes variable.** Rod forms occur in old culture. Optimal growth temperature ranges from 9–28°C. **Strictly aerobic.** Catalase-positive. Starch is hydrolyzed, sometimes weak reaction. Gelatin not hydrolyzed. Hydrolysis of casein and DNA are variable among species. Acid is produced from several sugars. The amino acids of cell-wall peptidoglycan are **L-2,4-diaminobutyric acid**, alanine, glycine, and glutamic acid. Rhamnose and fucose are characteristic cell-wall sugars; cell-wall acyl type is acetyl (*Cryobacterium psychrophilum*). Glucose and ribose are the characteristic whole cell sugars (*Cryobacterium mesophilum* and *Cryobacterium psychrophilum*). The main cellular fatty acids are iso- and anteiso-branched acids, predominantly 12-methyl tetradecanoic acid ($C_{15:0}$ anteiso). The major menaquinone(s) are **MK-10 or MK-11 and MK-12**. Mycolic acids are absent. The polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and one or more unidentified glycolipids.

DNA G+C content (mol%): 65–70.

Type species: **Cryobacterium psychrophilum** (*ex* Inoue and Komagata 1976) Suzuki, Sasaki, Uramoto, Nakase and Komagata 1997, 477 (*"Curtobacterium psychrophilum"* Inoue and Komagata 1976, 166).

Further descriptive information

Chemotaxonomy. The presence of 2,4-diaminobutyric acid is one of the essential phenotypic characteristics of the genus *Cryobacterium* and the analysis requires purification of cell-wall peptidoglycan from biomass (Komagata and Suzuki, 1987). The B type peptidoglycan structure characteristic for the family *Microbacteriaceae* and B2γ are estimated from the amino acid composition, namely glutamic acid:alanine:glycine:2,4-diaminobutyric acid is 1:1:1:2 as shown in Figure 179. However, the actual proportion of amino acids is variable in the B-type structure. The molar ratios of glutamic acid -glycine - alanine - 2,4-diaminobutyric acid are 1.0:1.0:0.6:1.3 for *Cryobacterium psychrophilum* (Suzuki et al., 1997), 1.0:0.8:1.0:1.6 for *Cryobacterium mesophilum* (Dastager et al., 2008a), and 1.0:0.9:0.5:1.1 for *Cryobacterium psychrotolerans.* In addition, two varieties of isomer composition of 2,4-diaminobutyric acid are known as a useful

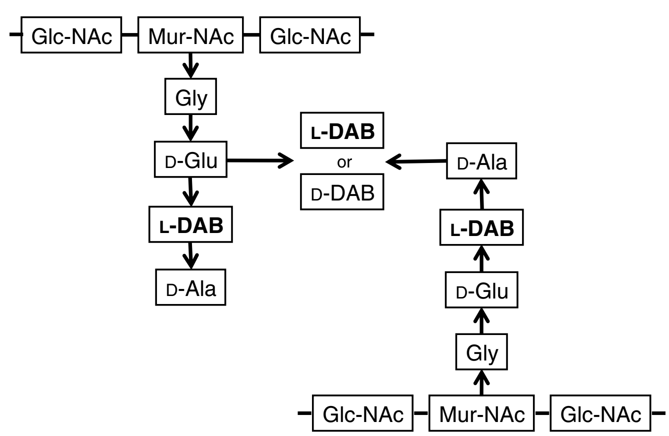

FIGURE 179. Variety of peptidoglycan containing 2,4-diaminobutyric acid. 2,4-Diaminobutyric acid of the peptidoglycan of the genus *Cryobacterium* contains exclusively L-isomers. GlcNAc, *N*-acetyl glucosamine; Mur, muramic acid; DAB, 2,4-diaminobutyric acid. *Arrows* indicate the direction from N-terminal to C-terminal.

taxonomic marker among the genera containing 2,4-diaminobutyric acid in the family *Microbacteriaceae*. Only L-form 2,4-diaminobutyric acid is found in the cells of *Cryobacterium psychrophilum* as in those of *Agrococcus*, *Agromyces*, *Leucobacter*, and *Rathayibacter* (Sasaki et al., 1998). In contrast, an almost equimolar mixture of the L-form and D-form of 2,4-diaminobutyric acid is found in the cells of representatives of the genera *Clavibacter*, *Leifsonia*, *Plantibacter*, *Pseudoclavibacter*, *Subtercola*, and *Yonghaparkia* (Schumann et al., 2009). The variation is possibly derived from the D-form 2,4-diaminobutyric acid present in the interpeptide bridge, while 2,4-diaminobutyric acid of the 3rd position of the peptide subunit is commonly L-2,4-diaminobutyric acid (Figure 179).

The members of the family *Microbacteriaceae* contain exclusively menaquinones with unsaturated isoprenoid chains from MK-8 to MK-14. The menaquinone profile of the genus *Cryobacterium* is around middle length from MK-10 to MK-12 and variable for the different species (Table 147). Small amounts of MK-8 and MK-9 were also found in the cells of *Cryobacterium psychrophilum*.

Major components of the cellular fatty acids of the genus *Cryobacterium* are iso- and anteiso-branched acids with 12-methyl tetradecanoic acid ($C_{15:0}$ anteiso) occurring predominantly. *Cryobacterium psychrophilum* is adapted to growth at low temperature and contains an increased amount of anteiso-branched unsaturated fatty acids in the membrane, especially 12-methyl tetradecenoic acid ($C_{15:1}$ anteiso). Unsaturated fatty acids such as 12-methyl tetradecenoic acid contribute to maintaining the fluidity of the cell membrane due to the low-melting-point. It is interesting that these psychrophilic bacteria such as *Cryobacterium psychrophilum* and *Cryobacterium psychrotolerans* contain unsaturated anteiso acids in the cells. *Cryobacterium psychrophilum*

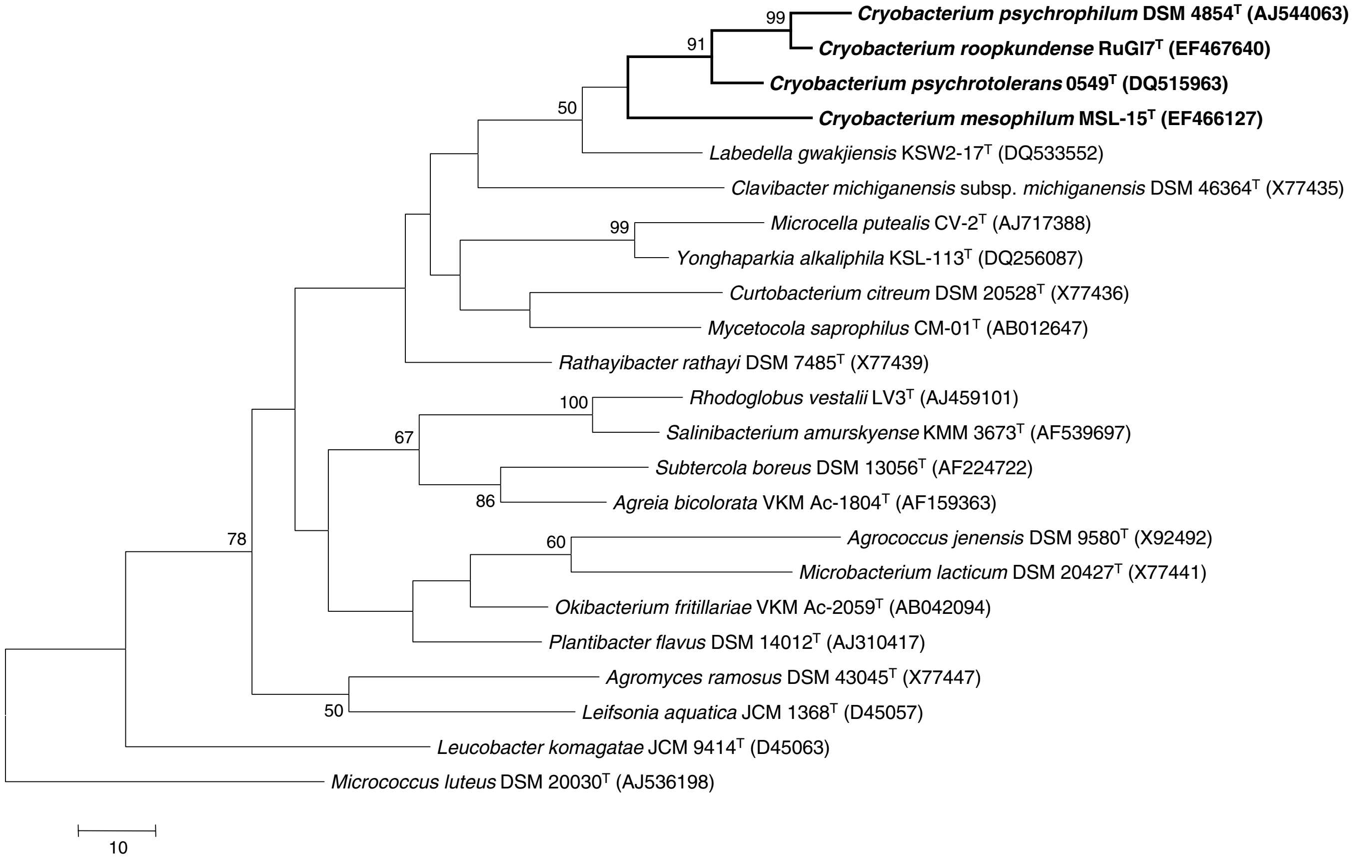

FIGURE 180. Phylogenetic tree derived from 16S rRNA gene sequences of the genus *Cryobacterium* and its taxonomic neighbors, constructed with the maximum parsimony method. The numbers at the branching points are the bootstrap values (>50%). Bar = 10 substitutions. (Tree courtesy of M. Hamada.)

increases the amount of the unsaturated acids in the cells grown under low temperatures (Suzuki et al., 1997).

Phylogeny. A phylogenetic tree based on the 16S rRNA gene sequences indicates a clear differentiation of the genus *Cryobacterium* from the other genera of the family *Microbacteriaceae* (Figure 180). However, there is no clear correlation between the phylogenetic position and the chemotaxonomic characteristics found for the most closely related genera.

Biochemical and physiological characteristics. Biochemical and physiological tests of members of the genus *Cryobacterium* show a wide variety among the species. The tests were carried out according to the methods described by Cowan and Steel (1965), Yamada and Komagata (1972b), and Kämpfer et al. (1991). The differences between the species are indicated in Table 147.

Enrichment and isolation procedures

The strains of the four species of the genus *Cryobacterium* were all isolated from soil. *Cryobacterium psychrophilum* was isolated aerobically at 0°C on PYG agar containing 1% peptone, 0.5% yeast extract, 0.3% glucose, and 1.5% agar (pH 7.2), paying attention to keep the process below 5°C for isolation of obligate psychrophiles (Inoue, 1976). *Cryobacterium psychrotolerans* and *Cryobacterium roopkundense* were isolated by cultivating a sample at 4°C on PYG medium (different composition from the above PYG) containing 0.5% polypeptone, 1% yeast extract, 1% glucose, and 40 ml salt solution which was composed of 0.02% $CaCl_2$, 0.04% $MgSO_4 \cdot 7H_2O$, 0.1% K_2HPO_4, 0.1% KH_2PO_4, 1% $NaHCO_3$, and 0.2% NaCl (pH 7.2) (Zhu et al., 2003) and ABM composed of 0.5% peptone, 0.2% yeast extract, and 1.5% agar (Reddy et al., 2010), respectively.

In contrast to these three species which were isolated under low temperature conditions, *Cryobacterium mesophilum* was isolated at 28°C by using ten-fold-diluted R2A agar (Difco).

Maintenance procedures

Strains are preserved by freezing at −80°C or lower or by lyophilization. The type strain of *Cryobacterium psychrophilum* can be lyophilized for long-term preservation. Although the strain does not grow at 18°C or higher, the lyophilized cells can be revived even after exposure to 37°C for 2 weeks. For lyophilization, it is recommended to harvest the cells at the late-exponential growth phase and to suspend them in 10% skim milk with 1% monosodium glutamate prior to freezing. Cells are suspended in 10–30% glycerol for freezing preservation.

Differentiation of the genus *Cryobacterium* from related genera

A phylogenetic analysis based on 16S rRNA gene sequences is the first step for allocation of isolates to this genus. The genus *Cryobacterium* is a member of the family *Microbacteriaceae* that

is characterized by B type peptidoglycan structure and unsaturated menaquinones with relatively long isoprenoid side chains. *Cryobacterium* species have 2,4-diaminobutyric acid as the characteristic diamino acid in the peptidoglycan which is found only in representatives of the family *Microbacteriaceae*. Twelve genera are known to contain 2,4-diaminobutyric acid in the peptidoglycan (Schumann et al., 2009). Differences in the occurrence of the isomers of 2,4-diaminobutyric acid enables a separation of these 12 genera into two groups (See subchapter chemotaxonomy above). The menaquinone systems of the genus *Cryobacterium* are variable ranging from MK-10 to MK-12 (Table 147) and do not allow unambiguous differentiation of the genus *Cryobacterium* from other 2,4-diaminobutyric acid containing genera. Species of the genus *Cryobacterium* can grow at temperatures from 4–28°C which distinguishes them from several 2,4-diaminobutyric acid contain taxa such as *Agrococcus*, *Agromyces*, and *Leucobacter*.

Taxonomic comments

Initially Inoue and Komagata (1976) proposed a new species of the genus *Curtobacterium* for the isolate strain 27-0-b on the basis of the presence of ornithine in the cell wall, although the name was not validated. Later, Suzuki et al. (1997) established the genus *Cryobacterium* for this strain based on the phylogenetic analysis of 16S rRNA gene sequence. Re-examination of the chemotaxonomy revealed that the strain contained 2,4-diaminobutyric acid in the cell wall and not ornithine. The other two species published later also contain 2,4-diaminobutyric acid in the cell wall demonstrating that the presence of this diamino acid is a common feature of the genus. The type strain of the type species, *Cryobacterium psychrophilum*, is known to contain exclusively the L-form of 2,4-diaminobutyric acid (Sasaki et al., 1998), but no information is available concerning the isomer of 2,4-diaminobutyric acid in the other three species. The cell-wall acyl type of *Cryobacterium psychrophilum* is acetyl, and sugars detected in the cell-wall hydrolysate are fucose and rhamnose, whereas no information is available for the other three species. However, glucose and ribose were detected in whole cell hydrolysate of *Cryobacterium psychrotolerans* and *Cryobacterium mesophilum*.

Differentiation of species of the genus *Cryobacterium*

The cell-wall peptidoglycan shows a common feature in the genus, while the menaquinone composition and the G+C content of genomic DNA are slightly variable. The range of growth temperatures is characteristic for the different species (Table 147). The biochemical and physiological features of the species are shown in Table 147. All species of the genus *Cryobacterium* have been described on the basis of one strain, each representing the type strain of the corresponding species. Sequence similarities of 16S rRNA genes of *Cryobacterium mesophilum* to *Cryobacterium psychrophilum* and *Cryobacterium psychrotolerans* are 94.8 and 96.6%, respectively. The DNA–DNA relatedness between the type strains of *Cryobacterium psychrotolerans* and *Cryobacterium psychrophilum* is 34% (Zhang et al., 2007a).

List of species of the genus *Cryobacterium*

1. **Cryobacterium psychrophilum** (*ex* Inoue and Komagata 1976) Suzuki, Sasaki, Uramoto, Nakase and Komagata 1997, 477[VP] (*"Curtobacterium psychrophilum"* Inoue and Komagata 1976, 166)

psy.chro′phi.lum. Gr. adj. *psuchros* cold; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*) loving; N.L. neut. adj. *psychrophilum* cold loving.

Nonmotile pleomorphic rods, 0.5–0.7 × 1.0–1.8 μm. Obligately psychrophilic. Growth occurs at 4–16°C, but optimal growth is observed at 9–12°C. No growth at 18°C and higher. Circular, opaque pink colonies are formed on R agar after 5 d at 10°C. Occasionally Gram-stain-variable. Nitrate is not reduced. DNA is hydrolyzed but casein is not. Starch is hydrolyzed weakly. Acid is produced from fructose, galactose, glucose, mannose, and sucrose but not from arabinose, glycerol, inulin, D-lactose, maltose, ribose, salicin, and D-xylose. Fumarate, glyoxylate, lactate, malate, propionate, pyruvate, and succinate are utilized, but *n*-butyrate, citrate, formate, glutalate, hippurate, maleate, tartrate, and uric acid are not utilized. 2,4-Diaminobutyric acid, alanine, glycine, and glutamic acid are the amino acids of cell-wall peptidoglycan (peptidoglycan type B2γ). Predominant menaquinones are MK-10 (50%) and MK-11 (17%). MK-8 (14%) and MK-9 (11%) are also found. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. Cells grown at lower than 10°C contain 20% or higher proportion of $C_{15:1}$ anteiso.

Type strain: 27-O-b, ATCC 43563, CCM 3311, CGMCC 1.1912, CIP 105227, DSM 4854, IAM 12024, JCM 1463, KCTC 3487, LMG 23845, NBRC 15735, NCIMB 2068, VKM Ac-2100.

Sequence accession no. (16S RNA gene): AJ544063, D45058.

2. **Cryobacterium mesophilum** Dastager, Lee, Ju, Park and Kim 2008a, 1243[VP]

me.so′phi.lum. Gr. adj. *mesos* middle; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*) loving; N. L. neut. adj. *mesophilum* middle (temperature) loving, mesophilic.

Cells are motile, irregular rods, 0.3–0.6 × 1.0–1.4 μm. Colonies are light yellow, smooth, circular, and convex with entire margins. Mesophilic; grows at 20–28°C; optimal growth at 28°C. Growth occurs at 0–3% NaCl and pH 6.0–11.0 (optimally 7.0–8.0). Nitrate is reduced. Starch and casein are hydrolyzed, but esculin and DNA are not. Acid is produced from arabinose and galactose but not from fructose, maltose, mannose, and sucrose. Galactose, glucose, inositol, D-lactose, mannitol, mannose, melibiose, D-raffinose, and L-rhamnose are used as sole carbon and energy sources, but arabinose, fructose, maltose, and ribose are not. The amino acids of the cell-wall peptidoglycan are 2,4-diaminobutyric acid, alanine, glycine, and glutamic acid. Predominant menaquinones are MK-11 (48%) and MK-12 (37%). Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. Major whole cell sugars are glucose and ribose.

Sequence accession no. (16S rRNA gene): EF466127.

3. **Cryobacterium psychrotolerans** Zhang, Wang, Cui, Yang, Liu, Dong and Zhou 2007a, 868[VP]

psy.chro.to′le.rans. Gr. adj. *psuchros* cold; L. pres. part. *tolerans* tolerating; N.L. part. adj. *psychrotolerans* cold tolerating.

Cells are motile irregular rods, 0.5–0.8 × 1.8–3.6 µm. Yellow, smooth, circular, and convex colonies with entire margins are formed. Growth occurs at 4–27°C and pH 5.0–10.0, optimally at 20–22°C and pH 7.0–8.0. Growth occurs at 0–4% (w/v) NaCl. Nitrate is reduced. Casein and starch are hydrolyzed, but DNA is not. The Simmons' citrate and Voges–Proskauer tests are negative. L-Arabinose, D-cellobiose, fructose, glycerol, galactose, glucose, inulin, maltose, D-mannose, melezitose, ribose, salicin, xylose, glutamate, lactose, succinate, and acetate are utilized, but erythritol, galactitol, mannitol, raffinose, L-rhamnose, sorbinose, sorbitol, sucrose, citrate, gluconate, fumalate, hippurate, malate, pyruvate, and tartrate are not utilized. Acid is produced from arabinose, glucose, maltose, and xylose. The amino acids of the cell-wall peptidoglycan are 2,4-diaminobutyric acid, alanine, glycine, and glutamic acid. The predominant menaquinones are MK-11 (39%), MK-12 (38%), and MK-10 (16%). Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{15:1}$ anteiso, $C_{16:0}$ iso, $C_{15:0}$ iso, and $C_{17:0}$ anteiso. Whole cell sugars are glucose and ribose predominantly.

Type strain: 0549, CGMCC 1.5382, DSM 21575, JCM 13925.
Sequence accession no. (16S rRNA gene): DQ515963.

4. **Cryobacterium roopkundense** Reddy, Pradhan, Manorama and Shivaji 2010, 869[VP]

ro.op.kun.den′se. N.L. neut. adj. *roopkundense* of or pertaining to Lake Roopkund, the area from where the type strain was isolated.

Cells are Gram-stain-positive, aerobic motile rods, 0.8 × 2.5 µm. Colonies are convex, shiny pink colored, and 2–3 mm in diameter on LB agar. Optimum growth occurs at 15–18°C and pH 7.0. Catalase-positive and oxidase-negative. Nitrate is reduced. Gelatin is hydrolyzed, but casein, starch, and DNA are not. The Simmons' citrate and Voges–Proskauer tests are negative. Lysine, arginine, and ornithine decarboxylases, urease, phosphatase, and β-galactosidase are negative. Acid is not produced from erythritol, *myo*-inositol, inulin, D-melibiose, ribose, D-sorbitol, sorbose, trehalose, or D-xylose. Citrate and malonate are utilized, but acetate, adonitol, D-arabinose, L-arabinose, cellobiose, dulcitol, D-fructose, galactose, gluconate, D-glucose, glucosamine, glycereol, *myo*-inositol, inulin, lactose, maltose, D-mannitol, D-mannose, melibiose, melezitose, methyl α-D-glucoside, methyl α-D- mannoside, raffinose, D-rhamnose, D-ribose, salicin, sorbitol, L-sorbose, sucrose, trehalose, xylitol, and D-xylose are not.

The cell-wall peptidoglycan contains 2,4-diaminobutyric acid as the diagnostic diamino acid. The predominant menaquinones are MK-11 (53%), MK-10 (26%), and MK-12 (21%). Major cellular fatty acids are $C_{15:0}$ anteiso and $C_{15:1}$ anteiso in the cells grown on LB agar at 15°C for 7 d.

Sequence accession no. (16S rRNA gene): EF467640.

Genus VII. **Curtobacterium** Yamada and Komagata 1972a, 425[AL]

Gerard S. Saddler and Patricia Messenberg Guimarães

Cur.to.bac.te′ri.um L. adj. *curtus* shortened; L. neut. n. *bacterium* a small rod; N.L. neut. n. *Curtobacterium* a short rodlet

Short irregular rods (0.3–0.6 × 0.5–3.0 µm); pleomorphism is not distinctive. Cells become shorter to coccoid in older cultures. Branching is not found, **bending type cell division**. Nonsporeforming. Not all species are motile; generally motile species show peritrichous flagellation. Gram-stain-positive, but staining properties can be lost with age. Non-acid-fast. Colonies are generally ivory, yellow, or orange. Strictly aerobic chemoorganotrophs. Acid is produced weakly from glucose, fructose, and some other carbohydrates. Acetate, pyruvate, and lactate are assimilated in addition to other organic acids. Catalase and DNase-positive; gelatin and esculin are hydrolyzed. Nitrate is not reduced; urease is not produced. **The cell-wall peptiodoglycan, based on the presence of D-ornithine, is type B2β. Acetyl is the peptidoglycan acyl type**. Mycolic acids are not found. Nonhydroxylated fatty acids, specifically **anteiso-methyl branched chains fatty acids predominate**; ω-cyclohexyl undecanoic acid is found in some species. Phosphatidylglycerol, diphosphatidylglycerol, and some glycosyldiacylglycerols are the major polar lipids. Spermidine and spermine are the major polyamines; putrescine and cadaverine are absent. **Isoprenoid quinones, comprising menaquinones with 9 isoprene units (MK-9), predominate.**

DNA G+C content (mol%): 65.8–75.2 (T_m).

Type species: **Curtobacterium citreum** (Komagata and Iizuka, 1964) Yamada and Komagata 1972a, 425 (*Brevibacterium citreum* Komagata and Iizuka 1964, 498).

Further descriptive information

The genus *Curtobacterium*, as described by Yamada and Komagata (1972a), encompasses coryneform bacteria that contain

D-ornithine in their cell-wall peptidoglycan (type B2β of Schleifer and Kandler, 1972). Additional distinguishing characters include the mode of cell division, G+C content, and a number of biochemical and physiological characteristics, principally the weak, slow production of acid from a range of carbohydrates (Yamada and Komagata, 1972a). The genus currently comprises eight species: *Curtobacterium citreum*, *Curtobacterium albidum*, *Curtobacterium ammoniigenes*, *Curtobacterium flaccumfaciens*, *Curtobacterium ginsengisoli*, *Curtobacterium herbarum*, *Curtobacterium luteum*, and *Curtobacterium pusillum*. There is a ninth species, *Curtobacterium plantarum* (Dunleavy, 1989), but genus membership is uncertain as the type strain is almost certainly a member of the family *Enterobacteriaceae* on the basis of biochemical tests (Funke et al., 2005), 16S rRNA gene sequencing, and fatty acid analysis (Evtushenko and Takeuchi, 2006).

Curtobacterium forms a coherent group on the basis of 16S rRNA gene sequencing and is distinct from other Group-B peptidoglycan genera (Rainey et al., 1994). However, the close relationship to *Aureobacterium* uncovered by Park and co-workers (1987), based on 5S rRNA sequencing, is not confirmed by 16S rRNA gene sequence data. Indeed, in a comprehensive analysis of the family *Microbacteriaceace*, based on 16S rRNA gene sequencing and encompassing representatives of 15 genera, *Curtobacterium* was found to be more closely related to *Clavibacter*, *Frigoribacterium*, and *Rathayibacter* (Evtushenko and Takeuchi, 2006). Essentially similar results from a subsequent study confirm this finding; the close relationship between *Curtobacterium* and *Clavibacter* is particularly marked (Chen et al., 2007). The relationship between *Curtobacterium* and its close relatives within the family *Microbacteriaceae*, based on 16S rRNA gene sequence data, is shown Figure 181. It is interesting to note that certain

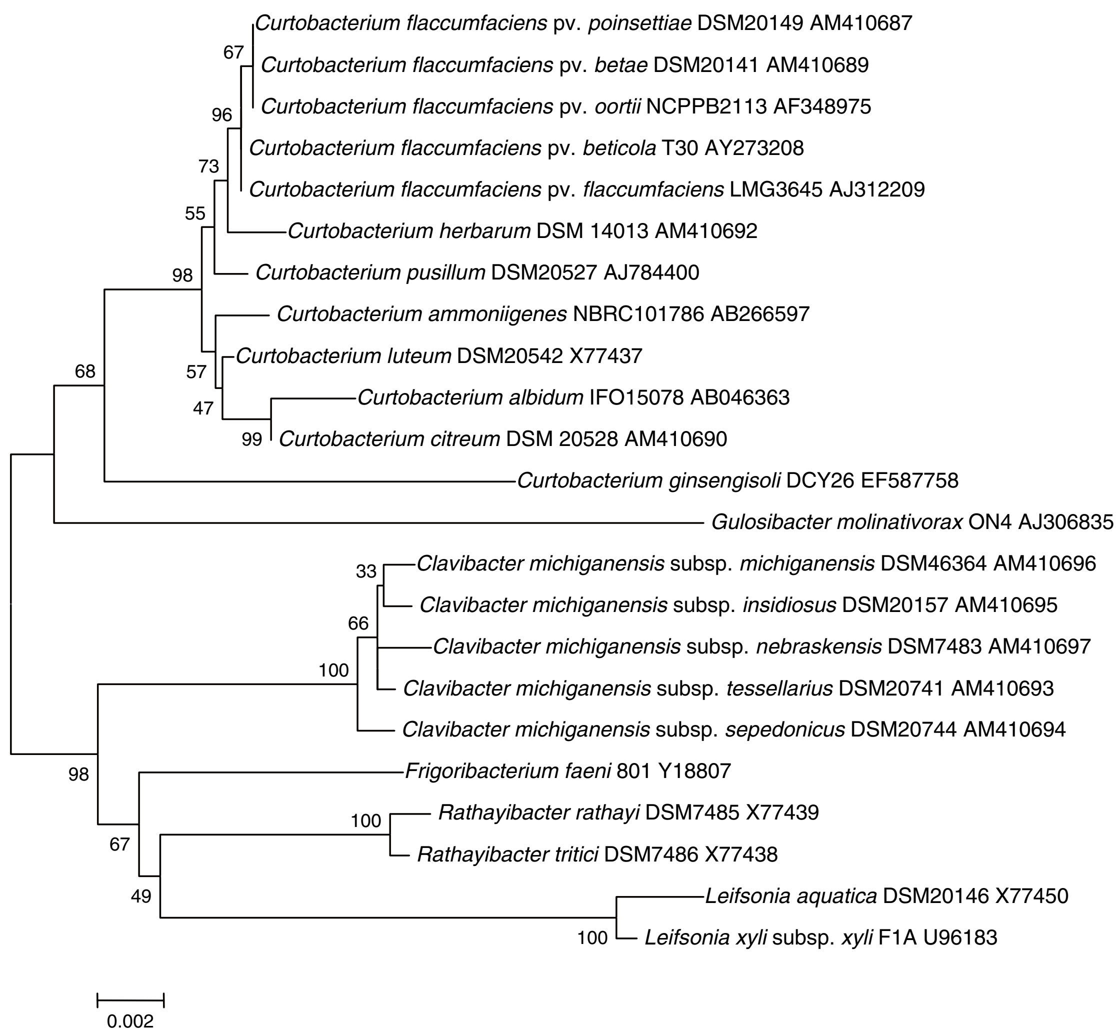

FIGURE 181. Phylogeny of *Curtobacterium* and close relatives drawn from the family *Microbacteriaceae*. Maximum composite likelihood with clustering achieved by the neighbor-joining method to produce a bootstrap consensus tree was performed using MEGA4. Bar = 0.2% difference in the 16S rRNA gene sequences. 500 Bootstrap trees were generated and bootstrap confidence levels (shown as percentages above nodes) were determined.

species within *Curtobacterium*, specifically *Curtobacterium albidum*, *Curtobacterium citreum*, and *Curtobacterium pusillum*, exhibit marked heterogeneity in their multi-copy 16S rRNA gene sequences as determined by temperature-gradient gel electrophoresis (TGGE). As a consequence, there is the potential to distort phylogenetic inference (Felske et al., 1999).

The phylogeny of the family *Microbacteriaceae* has also been studied using alternative genetic markers, namely DNA gyrase subunit B (*gyrB*), RNA-polymerase subunit B (*rpoB*), recombinase A (*recA*), and polyphosphate kinase (*ppk*), in addition to 16S rRNA (Stackebrandt et al., 2007). Analysis of 16S rRNA gene sequence in this study again highlights the close relationship between *Clavibacter* and *Curtobacterium*, but sequence data from *gyrB* and *rpoB* infers a closer relationship to *Frigoribacterium*. Although *Curtobacterium* remains a coherent entity in each phylogenetic tree, the suprageneric relationships vary considerably. One of the significant findings of this study is that in none of the 16 trees generated did the topologies coincide with the key taxonomic marker for this group, specifically the diagnostic diamino acid of the peptidoglycan, suggesting that this characteristic may have evolved independently several times or that it has regularly been subject to horizontal gene transfer. The DNA G+C composition ranges from 65.8–75.2 mol% (T_m) (Aizawa et al., 2007; Behrendt et al., 2002; Chen et al., 2007; Döpfer et al., 1982; Kim et al., 2008b). DNA–DNA hybridizations among representatives of the genus *Curtobacterium* revealed very high relatedness values (≥73%) between pathovars of the species *Curtobacterium flaccumfaciens*, while indices between *Curtobacterium flaccumfaciens* and other members of the genus were 48–54% (Döpfer et al., 1982).

Members of the genus *Curtobacterium* in general produce Gram-stain-positive pleomorphic rods (0.3–0.6 × 0.5–3.0 µm) that show a bending-type cell division, frequently producing V- and Y-pallisade arrangements (Collins and Jones, 1983; Yamada and Komagata, 1972a). Staining properties tend to be lost in older cultures. Rod forms are observed in young cultures, while coccoid forms predominate in older cultures, but there is no marked rod–coccus growth cycle (Komagata and Suzuki, 1986a). Branching is not observed. Motility is facilitated in some species by peritrichous flagella.

Curtobacterium strains possess D-ornithine in the interpeptide bridge and are therefore classed as type B2β, as described by Schleifer and Kandler (1972). Acetyl is the peptidoglycan acyl type. Principal phospholipids are phospatidylglycerol and diphospatidylglycerol, with a number of unidentified glycolipids (Collins et al., 1980). Later, the two major glycolipids were identified in *Curtobacterium flaccumfaciens* pv. *betae* as di- and trimannosyl glyceride (Mordarska et al., 1992). Spermidine and spermine are the major polyamines; putrescine and cadaverine are absent, which contrasts with *Clavibacter* and *Rathayibacter* where minor amounts of the latter two polyamines are present, albeit in small amounts (Altenburger et al., 1997). Anteiso isomers, specifically 14-methylhexadecanoic ($C_{17:0}$ anteiso) and 12-methyltetradecanoic acids ($C_{15:0}$ anteiso), are the predominant components of the fatty acid profile in *Curtobacterium*, comprising approximately 80% of the total (Collins et al., 1980; Henningson and Gudmestad, 1991; Kämpfer and Kroppenstedt, 1996). Significant quantities of 14-methylpentadecanoic ($C_{16:0}$ iso) are also found. Kämpfer and Kroppenstedt (1996) found that it was not possible to separate *Curtobacterium* from *Clavibacter* on the basis of fatty acids, contrasting with the view of Henninson and Gudmestad (1991) who suggested that the ratios between key, minor fatty acid components could even be used to differentiate pathovars of the species *Curtobacterium flaccumfaciens*. Certainly using a commercial identification system based on fatty acids in conjunction with a bespoke identification library, an accuracy of identification of 87.5% was obtained for *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* (Stead et al., 1992). Where misidentifications occurred it was only to other pathovars of the species. *Curtobacterium pusillum* contains an unusual fatty acid, ω-cyclohexyl undecanoic acid (ch-$C_{17:0}$), as its major component (Suzuki et al., 1981). This fatty acid accounts for 26–96% of the cellular fatty acid composition, is strain dependant, and increases in relative amount with increasing growth temperature and glucose concentration. Up until recently it had only ever been found in one other, as yet unnamed, *Curtobacterium* strain (CNF 165), previously "*Brevibacterium helvolum*" isolated from oil-brine (Suzuki and Komagata, 1983), the source of *Curtobacterium pusillum* itself. However, with the recent description of *Curtobacterium ammoniigenes*, isolated from the stem of an aquatic weed, all strains of this species are reported to possess significant amounts of 11-cyclohexyl undecanoic acid (ch-$C_{17:0}$) with more than 80% of the fatty acid profile made up of this single fatty acid (Aizawa et al., 2007). As with previous findings, this component varies with changing growth conditions; the relative concentration of this fatty acid was observed to fall with decreasing pH. These observations highlight the importance of standardizing the growth conditions (temperature, medium composition, pH) if fatty acids are to be analyzed for classification of curtobacteria. All *Curtobacterium* strains possess menaquinones with nine isoprene units (MK-9) (Aizawa et al., 2007; Behrendt et al., 2002; Collins et al., 1980); MK-10 has not been found, in contrast to *Clavibacter*, where minor amounts of this menaquinone have been reported (Sasaki et al., 1998).

Curtobacterium strains grow well on nutrient agar at 25–30°C, however, *Curtobacterium ginsengisoli* has an optimum growth temperature of 30–37°C (Kim et al., 2008b). They are obligate aerobes which may require some amino acids or vitamins for growth (Komagata and Suzuki, 1986a). On nutrient agar, colonies are predominantly yellow/orange, circular, smooth, slightly convex, and glistening (Evtushenko and Takeuchi, 2006). Some strains of *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* produce a purple diffusible pigment on Bacto Soytone Agar (Difco) supplemented with 10% (w/v) glucose (BSG agar) or lactose (BSL agar; Schuster et al., 1968). Strains of *Curtobacterium* produce acid slowly and weakly from various kinds of sugars (Yamada and Komagata, 1972a). All *Curtobacterium* strains produce acid from glucose and fructose, with the exception of *Curtobacterium ginsengisoli* which does not produce acid from glucose (Kim et al., 2008b). Some organic acids are assimilated in addition to acetate, pyruvate, and lactate. *Curtobacerium* strains, which remain to be fully characterized, are known to produce chondroitinase (Takegawa et al., 1991), β-glucuronidase (Tör et al., 1992), and phosphonoacetate hydrolases (McGrath et al., 1999).

Limited information exists on the development of antibodies suitable for the detection of members of the genus *Curtobacterium*. What little there is, focuses primarily on the plant pathogens within the genus and specifically *Curtobacterium flaccumfaciens* pv. *flaccumfaciens*, the causal agent of bacterial wilt of

beans. A comprehensive study reports two monoclonal antibodies raised against *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* (MAb 1527 and 1535), both of which failed to react to all strains of the pathovar and cross-reacted with strains from other *Curtobacterium flaccumfaciens* pathovars (McDonald and Wong, 2000). Similar results were also found with a polyclonal antibody which failed to react with all strains of *Curtobacterium flaccumaciens* pv. *flaccumfaciens*, confirming the earlier findings of Calzolari and co-workers (1987). In contrast, two out of three monoclonal antibodies raised against an isolate of *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* recovered from mungbean were able to detect all strains of the pathovar and showed no cross-reaction to any other organism tested (Diatloff et al., 1993). Members of the genus *Curtobacterium* are known to produce bacteriocins (Gross and Vidaver, 1979a). In this comprehensive study, a wide range of coryneform phytopathogens now members of the genera *Clavibacter*, *Curtobacterium*, *Rathayibacter*, and *Rhodococcus* were examined. A strain of *Curtobacterium flaccumfaciens* pv. *oortti* was found to inhibit a strain of *Curtobacterium flaccumfaciens* pv. *flaccumfaciens*, while *Curtobacterium flaccumfaciens* pv. *flacumfaciens* CV6 showed inhibitory effects on *Curtobacterium flaccumfaciens* pvs *betae*, *oortii* and *poinsettae* as well as other members of *Curtobacterium flaccumfacciens* pv. *flaccumfaciens*. The majority of the bacteriocins produced were resistant to heat but sensitive to proteolytic enzymes.

Most members of the genus *Curtobacterium* have been isolated from plants and their habitats. *Curtobacterium citreum*, *Curtobacterium albidum*, and *Curtobacterium luteum* were isolated from rice paddies (Komagata and Iizuka, 1964), *Curtobacterium ginsengisoli* from soil in a ginseng field (Kim et al., 2008b), while *Curtobacterium herbarum* was isolated from the litter layer of grass (Behrendt et al., 2002), and *Curtobacterium ammoniigenes* was recovered from the stem of an aquatic weed inhabiting acidic swamps in Vietnam (Aizawa et al., 2007). None are known to be phytopathogenic. In contrast, *Curtobacterium flaccumfaciens* is the only species regarded as a plant pathogen and is further subdivided into six pathovars: *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* (*Phaseolus* species and *Vigna* species, beans); *Curtobacterium flaccumfaciens* pv. *betae* (*Beta vulgaris* var. *rubra*, red beet); *Curtobacterium flaccumfaciens* pv. *beticola* (*Beta vulgaris* var. *saccharifera*, sugar beet); *Curtobacterium flaccumfaciens* pv. *ilicis* (*Ilex opaca*, American holly); *Curtobacterium flaccumfaciens* pv. *oortii* (*Tulipa* species, tulips); and *Curtobacterium flaccumfaciens* pv. *poinsettiae* (*Euphorbia pulcherrima*, poinsettia). The only species in the genus not isolated from, or associated with, plants is *Curtobacterium pusillum*, isolated from oil brine in a Japanese oilfield (Iizuka and Komagata, 1965). It is likely that additional *Curtobacterium* species will be described in due course as there are numerous citations in the literature of partially characterized curtobacteria isolated from variety sources, namely agronomic crops and prairie plants (Zinniel et al., 2002), citrus plants (Lacava et al., 2004), apple phyllosphere (Kucheryava et al., 1999), clinical specimens (Funke et al., 2005), reed communities in shallow lakes (Ács et al., 2003), and waste waters (McGrath et al., 1999).

Enrichment and isolation procedures

Few selective media exist for curtobacteria; of these, the majority are used to recover *Curtobacterium flaccumfaciens* strains from suspect, infected plant materials. In situations where asymptomatic infections are suspected, or where problems with overgrowth have been encountered, semi-selective media are required. CNS medium* (Gross and Vidaver, 1979a), which was primarily developed for *Clavibacter michiganensis* subsp. *nebraskensis*, works well with some pathovars of *Curtobacterium flaccumfaciens*. Alternately, a semi-selective media MSCFF† has been reported to allow the growth of a wide variety of *Curtobacterium flaccumfaciens* pv. *flaccumfaciens* strains while inhibiting many saprophytic bacteria commonly found on bean seeds (Maringoni et al., 2006).

Maintenance procedures

Most curtobacteria can be stored on nutrient agar slopes at 5°C for 6 months. However, as with many bacteria, freeze-drying or freezing as a glycerol suspension is recommended for long-term preservation of more than one year (Komagata and Suzuki, 1986a).

Differentiation of the genus *Curtobacterium* from other genera

Curtobacterium is a well-defined genus, with good chemotaxonomic and molecular markers that can be exploited to distinguish it from other menaquinone MK-9 containing genera in the family *Microbacteriaceae* (Table 148). Identification to the genus can be readily achieved using chemotaxonomic methods to identify the presence of D-ornithine in the peptidoglycan of the cell wall. Both *Curtobacterium* and species of the genus *Aureobacterium*, which are all now contained within *Microbacterium*, share a group B peptidoglycan based on D-ornithine (Schleifer and Kandler, 1972). However, *Curtobacterium* species possess a single D-ornithine in the inter-peptide bridge while *Aureobacterium* species contain glycine in addition to the D-ornithine residue. Further, *Microbacterium* strains contain MK-10, MK-11, MK-12, and MK-13. *Gulosibacter*, which also contains D-ornithine and MK-9, can be differentiated from *Curtobacterium* on the basis of a positive oxidase reaction, a higher optimal temperature for growth, and a lower mol% G+C of the DNA (Manaia et al., 2004). Sequence analysis of 16S rRNA genes is also reliable for differentiating *Curtobacterium* from other members of the family *Microbacteriaceae* (Evtushenko and Takeuchi, 2006; Manaia et al., 2004; Stackebrandt et al., 2007). Other genes including; DNA gyrase subunit B (*gyrB*), RNA-polymerase subunit B (*rpoB*), recombinase A (*recA*), and polyphosphate kinase (*ppk*) have also been used successfully to differentiate *Curtobacterium* from other genera within the family (Stackebrandt et al., 2007). Only a small number of studies have been undertaken developing alternative molecular approaches for application in the differentiation and identification of curtobacteria; the bulk of these approaches have focused on *Curtobacterium flaccumfaciens* pv. *flaccumfaciens*. Fingerprinting methods such as RAPD

*CNS Medium (g/liter): Nutrient broth (Difco), 8.0; yeast extract (Difco), 2.0; K_2HPO_4, 2.0; KH_2PO_4, 0.5; agar, 15.0. Added separately: 50 ml of sterile glucose (50%, w/v aq.) and 1 ml of sterile 1M $MgSO_4{\cdot}7H_2O$; lithium chloride, 10.0; nalidixic acid, 25 mg (freshly dissolved in 0.lM NaOH, 10 $mg.ml^{-1}$), polymyxin $B.SO_4$ 32 mg (added as a 10 $mg.ml^{-1}$ freshly prepared aq. solution); Actidione/cycloheximide, 40 mg (added as a 10 $mg.ml^{-1}$ aq. stock solution); Chlorothalonil/Bravo 6F, 0.0625ml. (diluted 1:50 from a stock solution of tetrachloro-isophthalonitrile).

†MSCFF Medium (g/liter): Peptone, 5.0; meat extract, 3.0; sucrose, 5.0; agar, 15.0. Added after autoclaving to the basal medium: skim milk powder, 5.0; Congo red, 0.05; chlorothalonil, 0.01; thiophanate methyl, 0.01; nalidixic acid, 0.01; nitrofurantoin, 0.01; oxacillin, 0.001; sodium azide, 0.001.

(Chen et al., 2007), rep-PCR (McDonald and Wong, 2000), AFLP and pulsed-field gel electrophoresis (Guimarães et al., 2003), highlight differences between *Curtobacterium* and other phytopathogenic members of the family *Microbacteriaceae*, in addition to differentiating pathovars within species and uncovering heterogeneity within the pathovars themselves. Many of the phytopathogenic members of the species *Curtobacterium flaccumfaciens* can be readily detected using a number of different PCR assays. Most of the assays can be applied directly to the suspect plant material, with no cross-reaction to common saprophytes. In the case of *Curtobacterium flaccumfaciens* pv. *flaccumfaciens*, PCR assays have been designed from repetitive sequences (Tegli et al., 2002) or after a process of subtractive hybridization (Guimarães et al., 2001).

Taxonomic comments

Biochemical characteristics useful in distinguishing *Curtobacterium* species are listed in Table 149. Commercial identification systems such as Biolog have been used to identify *Curtobacterium* strains. Using an early version of the identification library (Biolog, release 3.5), Harris-Baldwin and Gudmestad (1996) found that results were highly variable, although 100% of *Curtobacterium flaccumfaciens* pvs *betae*, *flaccumfaciens*, and *oortii* strains were correctly identified to the genus, with this figure dropping dramatically for correct species or pathovar identifications. Indeed, no strains of *Curtobacterium flaccumfaciens* pv. *oortii* were correctly identified to the pathovar even after supplementing the database with additional data in an attempt to improve its accuracy. As the host range of *Curtobacterium flaccumfaciens* pathovars is restricted, it may still be possible to make an effective identification on the basis of knowledge of origin and species-level identification using this method. However, results obtained using API ZYM highlight a great deal of overlap between strains of the genus *Clavibacter* and *Curtobacterium*, with the bulk of curtobacteria indistinguishable from *Clavibacter* using this method (De Bruyne et al., 1992).

An area in need of attention within the genus is the continuing uncertainty over the legitimacy of the species *Curtobacterium plantarum*. On the basis of biochemical tests (Funke et al., 2005), 16S rRNA gene sequencing, and fatty acid analysis (Evtushenko and Takeuchi, 2006), it is evident that the type strain, ATCC 49174, is not a member of the genus *Curtobacterium*, and indeed it is currently listed as *Pantoea agglomerans* by the ATCC. It is possible, however, to identify discrepancies in characteristics as reported in the original description (Dunleavy, 1989) and by Funke and co-workers (2005). The logical conclusion is that an error may have occurred either selecting/depositing the type strain or subsequently. Certainly, it appears from the original description, that other strains assigned to the species may be authentic members of the genus (Evtushenko and Takeuchi, 2006). It is not clear whether these strains are still in existence, and it may be that the only possible solution will be to reject the name *Curtobacterium plantarum* and declare it *nomen dubium*. Since the type strain of *Curtobacterium plantarum* is not a member of the genus *Curtobacterium*, a neotype must be proposed and a request for an opinion submitted to the Judicial Commission of the International Committee for the Systematics of Prokaryotes.

A continuing area of debate also revolves around the subspecific classification within *Curtobacterium flaccumfaciens*. Carlson and Vidaver (1982) argued that differences in biochemical tests, bacteriocin production, and DNA–DNA reassociation experiments, independent of pathogenic specificity, merited recognition at the subspecific-level. This was in marked contrast to subsequent work that challenged the DNA–DNA reassociation experiments and failed to place the same emphasis on other differences suggesting rather that circumscription of these taxa within pathovars was more appropriate (Collins and Jones,

[g]Data from Suzuki et al. (1981).

1983). There is considerable support for the view of Collins and Jones (1983) as numerous subsequent studies have indicated the taxa overlap and differentiating between all strains on the basis of biochemical or chemotaxonomic characters alone is at best problematic. More recently, two strains held in the International Collection of Microorganisms from Plants (ICMP) which represent the type strain of *Arthrobacter ilicis*, a pathogen of American holly, were found not to be identical and that the designated type strain among these two strains was not representative of the pathogen (Young et al., 2004b); one strain, ICMP 2608, which could be sourced back to the original description did appear to be authentic, although it was not a member of the genus *Arthrobacter* based on an earlier comprehensive analysis of biochemical and physiological characteristics (Dye and Kemp, 1977). It was therefore proposed that the description and authority for *Arthrobacter ilicis* be amended to recognize it as novel species, albeit not a plant pathogen. *Curtobacterium flaccumfaciens* pv. *ilicis* was proposed for the pathogen of American holly, although no formal description was given. The description is taken from the earlier work of Dye and Kemp (1977) and lacks details on chemotaxonomic characteristics. Similarly, no 16S rRNA gene sequence data are available for the proposed taxon as yet.

List of species of the genus *Curtobacterium*

1. **Curtobacterium citreum** (Komagata and Iizuka 1964) Yamada and Komagata 1972a, 425[AL] (*Brevibacterium citreum* Komagata and Iizuka 1964, 498)

ci′tre.um. L. neut. adj. *citreum* of or pertaining to the citrus-tree, intended to mean lemon-colored.

The description is as for the genus, and diagnostic tests are listed in Table 149. Dull yellow colonies produced on nutrient agar. Cells are motile. Esculin is hydrolyzed, but casein, gelatin, starch, and Tween 80 are not. Optimum growth at pH 7.

Source: rice paddies.

DNA G+C content (mol%): 70.5–75.2 (T_m).

Type strain: ATCC 15828, CCUG 12163, CCUG 28999, CIP 81.26, DSM 20528, NBRC 12677, JCM 1345, LMG 8786, VKM B-1207.

Sequence accession no. (16S rRNA gene): X77436, AM410690.

[c]Data from Chen et al. (2007).

[d]Results obtained with two basal media, hence two results are given for each characteristic, see Dye and Kemp (1977) for details.

2. **Curtobacterium albidum** (Komagata and Iizuka 1964) Yamada and Komagata 1972a, 425[AL] (*Brevibacterium albidum* Komagata and Iizuka 1964, 500)

al′bi.dum. L. neut. adj. *albidum* white.

The description is as for the genus, and diagnostic tests are listed in Table 149. Colonies on nutrient agar are an ivory color. Cells are nonmotile. Esculin, gelatin, and Tween 80 are hydrolyzed; starch is not. Optimum growth at pH 7.

Source: rice paddies.

DNA G+C content (mol%): 70.0–72.0 (T_m).

Type strain: ATCC 15831, CIP 102693, DSM 20512, HAMBI 2039, NBRC 15078, JCM 1344, VKM B-1206.

Sequence accession no. (16S rRNA gene): AB046363, AM042692, AM410691.

3. **Curtobacterium ammoniigenes** Aizawa, Ve, Kimoto, Iwabuchi, Sumida, Hasegawa, Sasaki, Tamura, Kudo, Suzuki, Nakajima and Sunairi 2007, 1451[VP]

am.mo.ni.i′ge.nes. N.L. n. *ammonia* ammonia; Gr. v. *gennâo* to produce; N.L. part. adj. *ammoniigenes* ammonia-producing.

The description is as for the genus, and diagnostic tests are listed in Table 149. Colonies are pale yellow, smooth, convex, and round with entire margins. Esculin is hydrolyzed; gelatin, and Tween 80 are not. Growth occurs between 15 and 37°C, but not at 4°C or 45°C. The pH range for growth is 3.5–8.0, with optimum growth at pH 4. Ammonia is produced in 10% tryptic soy broth (pH 4.0). The predominant cellular fatty acid is 11-cyclohexyl undecanoic acid (ch-$C_{17:0}$).

Source: creeping waterprimrose (*Ludwigia adscendens*) inhabiting acidic swamps in actual acid sulfate soil areas in Vietnam.

DNA G+C content (mol%): 68.8.

Type strain: B55, JCM 14609, NBRC 101786, VTCC D6-11.

Sequence accession no. (16S rRNA gene): AB266597.

4. **Curtobacterium flaccumfaciens** (Hedges 1922) Collins and Jones 1984, 270[VP] (Effective publication: Collins and Jones 1983, 3546.) (*Bacterium flaccumfaciens* Hedges 1922, 433; *Corynebacterium flaccumfaciens* (Hedges 1922) Dowson 1942, 313)

flac.cum.fa′ci.ens. L. adj. *flaccus* flabby; L. part. adj. *faciens* making; N.L. part. adj. *flaccumfaciens* wilt-making.

The description is as for the genus, and diagnostic tests are listed in Table 149. The colonies are yellow or orange on NBY agar. Some variants may lose pigmentation, and some may produce a blue to purple water-soluble pigment. Generally motile. Optimum growth temperature is 24–27°C and maximum temperature 35–37°C.

DNA G+C content (mol%): 67.5–73.7 (T_m).

Type strain: CIP 107085, ICMP 2584, JCM 9670, LMG 3645, NCPPB 1446.

Sequence accession no. (16S rRNA gene): AJ312209, AF348973, AM410688.

4a. **Curtobacterium flaccumfaciens pv. flaccumfaciens** (Hedges 1922) Collins and Jones 1983, 3547 (*Corynebacterium flaccumfaciens* pv. *flaccumfaciens* Dowson 1942; *Corynebacterium flaccumfaciens* subsp. *flaccumfaciens* Carlson and Vidaver 1982, 322.)

The description is as for the species, and diagnostic tests are listed in Table 150. Colonies can be yellow or orange. Some strains produce a purple diffusible pigment. Casein and gelatin are hydrolyzed; esculin and Tween 80 give variable results. Optimum pH for growth is 7. This organism was isolated from bean (*Phaseolus* species and *Vigna* species), where it causes a vascular wilt.

DNA G+C content (mol%): 72.2 (T_m).

Type strain: ATCC 6887, DSM 20129, ICMP 2584, IFO 12156, JCM 1347, LMG 3645, NBRC 12156, NCPPB 1446, NCTC 4758.

Sequence accession no. (16S rRNA gene): AJ312209, AF348973, AM410688.

4b. **Curtobacterium flaccumfaciens pv. betae** (Keyworth et al. 1956) Collins and Jones 1983, 3547 (*Corynebacterium betae* Keyworth, Howell and Dowson 1956; *Corynebacterium*

flaccumfaciens pv. *betae* Dye and Kemp 1977; *Corynebacterium flaccumfaciens* subsp. *betae* Carlson and Vidaver 1982, 322.)

The description is as for the species, and diagnostic tests are listed in Table 150. Colony color is yellow. Esculin is hydrolyzed; starch and Tween 80 give variable results. Casein and gelatin are not hydrolyzed. This organism was isolated from red beet (*Beta vulgaris* var. *rubra*), where it causes a vascular wilt and leaf spot.

DNA G+C content (mol%): 73.7 (T_m).

Type strain: DSM 20141, ATCC 13437, CFBP 2402, ICMP 2594, LMG 3596, NCPPB 374.

Sequence accession no. (16S rRNA gene): AF348974, AM410689.

4c. **Curtobacterium flaccumfaciens pv. beticola** Chen, Yin, Zhang and Guo 2007, 682

The description is as for the species, and diagnostic tests are listed in Table 150. Colonies are pale yellow with an entire margin, convex, and butyrous. Optimum growth occurs at 24–27°C, but not at 4°C or 37°C. No growth occurs at 10% NaCl with limited growth at 5%. Esculin, casein, starch, and Tween 80 are all hydrolyzed.

Source: sugar beet (*Beta vulgaris* var. *saccharifera*), where it causes bacterial leaf spot.

DNA G+C content (mol%): 67.5 (T_m).

Type strain: ATCC BAA-144.

Sequence accession no. (16S rRNA gene): AY273208.

4d. **Curtobacterium flaccumfaciens pv. ilicis** (Mandel et al. 1961) Young, Watson and Dye 2004b, 303 (*Corynebacterium ilicis* Mandel, Guba and Litsky 1961)

The description is as for the species, and diagnostic tests are listed in Table 150. Esculin is hydrolyzed; starch is not. This organism was isolated from and is a pathogen of American holly (*Ilex opaca*).

DNA G+C content (mol%): not available.

Type strain: ICMP 2608.

Sequence accession no. (16S rRNA gene): not available.

4e. **Curtobacterium flaccumfaciens pv. oortii** (Saaltink and Maas Geesteranus 1969) Collins and Jones 1983, 3547 (*Corynebacterium oortii* Saaltink and Maas Geesteranus 1969; *Corynebacterium flaccumfaciens* pv. *oortii* Dye and Kemp 1977; *Corynebacterium flaccumfaciens* subsp. *oortii* Carlson and Vidaver 1982)

The description is as for the species, and diagnostic tests are listed in Table 150. Colony color is yellow. Casein, esculin, and gelatin are hydrolyzed; starch, and Tween 80 give variable results. This organism was isolated from tulips (*Tulipa* species) where it causes a vascular disease and leaf and bulb spot.

DNA G+C content (mol%): 72.2 (T_m).

Type strain: ATCC 25283, CFBP 1384, ICMP 2632, LMG 3702, NCPPB 2113.

Sequence accession no. (16S rRNA gene): AF348975.

4f. **Curtobacterium flaccumfaciens pv. poinsettiae** (Starr and Pirone 1942) Collins and Jones 1983, 3547 (*Corynebacterium poinsettiae* Burkholder 1948; *Corynebacterium flaccumfaciens* pv. *poinsettiae* Dye and Kemp 1977; *Corynebacterium flaccumfaciens* subsp. *poinsettiae* Carlson and Vidaver 1982

The description is as for the species, and diagnostic tests are listed in Table 150. Colony color is orange. Esculin and Tween 80 are hydrolyzed; casein, gelatin, and starch give variable results.

Source: isolated from and is the cause of a stem canker and leaf spot of the poinsettia (*Euphorbia pulcherrima*).

DNA G+C content (mol%): 72.5 (T_m).

Type strain: ATCC 9682, CFBP 2403, ICMP 2566, LMG 3715, NCPPB 854.

Sequence accession no. (16S rRNA gene): AF348976, AM410687.

5. **Curtobacterium ginsengisoli** Kim, Kim, Kim, Kim, Yi and Yang 2008b, 2394[VP]

gin.sen.gi.so′li. N.L. n. *ginsengum* ginseng; L. n. *solum* soil; N.L. gen. n. *ginsengisoli* of soil of a ginseng field, the source of the type strain.

The description is as for the genus, and diagnostic tests are listed in Table 149. Colonies are pale yellow. Cells are nonmotile short rods. Optimum growth temperature is 30–37°C.

Source: soil of a ginseng field in South Korea.

DNA G+C content (mol%): 65.8 (HPLC).

Type strain: DCY26, JCM 14773, KCTC 13163.

Sequence accession no. (16S rRNA gene): EF587758.

6. **Curtobacterium herbarum** Behrendt, Ulrich, Schumann, Naumann and Suzuki 2002, 1452[VP]

her.ba′rum. L. gen. pl. fem. n. *herbarum* of plants.

The description is as for the genus, and diagnostic tests are listed in Table 149. Colonies are orange, shiny, slightly convex, and round with entire margins. Cells are motile. Esculin and Tween 80 are hydrolyzed; casein and gelatin give variable results; starch is not hydrolyzed. Optimum growth temperature is 25°C.

Source: the phyllosphere of grasses and from the litter layer after mulching the sward.

DNA G+C content (mol%): 71 (HPLC).

Type strain: P 420/07, DSM 14013, JCM 12140, LMG 19917, NBRC 103064.

Sequence accession no. (16S rRNA gene): AJ310413, AM410692.

7. **Curtobacterium luteum** (Komagata and Iizuka 1964) Yamada and Komagata 1972a, 425[AL] (*Brevibacterium luteum* Komagata and Iizuka 1964, 499)

lu′te.um. L. neut. adj. *luteum* saffron or golden yellow.

The description is as for the genus, and diagnostic tests are listed in Table 149.

Colonies on nutrient agar are dark yellow. Cells are motile. Tween 80 is hydrolyzed; casein, esculin, gelatin, and starch are not. Optimum pH for growth is 7.

Source: rice paddies.

DNA G+C content (mol%): 69.8–74.9 (T_m).

Type strain: ATCC 15830, CCUG 23848, CIP 102694, DSM 20542, IAM 1623, NBRC 12676, JCM 1480, LMG 8787, VKM B-1210.

Sequence accession no. (16S rRNA gene): X77437.

8. **Curtobacterium pusillum** (Iizuka and Komagata 1965) Yamada and Komagata 1972a, 425[AL]

(*Brevibacterium*, *pusillum* Iizuka and Komagata 1965, 2)

pu′sil.lum. L. neut. adj. *pusillum* very small.

The description is as for the genus, and diagnostic tests are listed in Table 149.

Colonies on nutrient agar are pale yellow. Cells are motile. Esculin and gelatin are hydrolyzed; casein, starch, and Tween 80 are not. The predominant cellular fatty acid is 11-cyclohexyl undecanoic acid (ch-$C_{17:0}$).

Source: oil brine.

DNA G+C content (mol%): 69.0–74.2 (T_m).

Type strain: ATCC 19096, CIP 81.24, DSM 20527, NBRC 12674, JCM 1350, LMG 8788, VKM Ac-2099.

Sequence accession no. (16S rRNA gene): AJ784400.

Genus VIII. **Frigoribacterium** Kämpfer, Rainey, Andersson, Nurmiaho Lassila, Ulrych, Busse, Weiss, Mikkola and Salkinoja-Salonen 2000, 362[VP]

Peter Kämpfer

Fri.go.ri.bac′te.ri.um. L. n. *frigor* frost, cold; L. neut. n. *bacterium* small rod; N.L. neut. n. *Frigoribacterium* a small rod growing in the cold.

Gram-stain-positive, nonsporeforming, motile, irregular-shaped rods, the **cell division zone being thicker than the poles of the cell**. No mycelium is produced. Catalase-positive. Oxidase-negative. Growth on complex media is observed in a temperature range of 2–25°C. Optimum 4–10°C. **The cell-wall peptidoglycan contains D-lysine as a diamino acid**. The **glycan moiety of the peptidoglycan contains acetyl residues**. The **major isoprenoid quinone is menaquinone MK-9**. Mycolic acids are not present. **Diphosphatidylglycerol, phosphatidylglycerol, and an unknown glycolipid** were detected in the polar lipid extracts. The main cellular fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{16:0}$).

In addition, **1,1 dimethoxy-anteiso-pentadecane ($C_{15:0}$ anteiso DMA = dimethylacetal) is produced in considerable amounts (10–30% of the amount of whole cell fatty substances).** Using standardized fatty acid methyl ester (FAME) analysis, the retention time of this compound is almost identical with that of $C_{14:0}$ 2-OH.

DNA G+C content (mol%): ~71.

Type species: **Frigoribacterium faeni** Kämpfer, Rainey, Andersson, Nurmiaho Lassila, Ulrych, Busse, Weiss, Mikkola and Salkinoja-Salonen 2000, 362[VP].

Further descriptive information

One species, *Frigoribacterium faeni*, has been described so far. Four isolates were obtained during an extensive study of bacteria collected from dust samples and animal sheds (Andersson et al., 1999). An additional strain was isolated from the air in the museum Sainsbury Centre for Visual Arts in Norwich, England. All these isolates showed initially good growth at 2–10°C but only moderate growth at 25°C.

Comparison of the almost complete 16S rRNA gene sequences of 1458–1467 nucleotides in length (which were determined for four isolates) and subsequent phylogenetic analyses based on a dataset comprising 1310 unambiguous nucleotides between positions 38 and 1478 (*Escherichia coli* positions; Brosius et al., 1978) showed that these isolates clustered together as a distinct lineage within the radiation of the actinomycete genera of the family *Microbacteriaceae* (Stackebrandt et al., 1997) (Figure 182). The five strains share 99.3–100% 16S rRNA gene sequence similarity. Highest 16S rRNA gene sequence similarity was shown with species of the genera *Frondicola* (98%), *Yonghaparkia* (97.0%), and *Microcella* (96.8%).

The chemotaxonomic features of *Frigoribacterium* are summarized in comparison to the other genera of the family *Microbacteriaceae* in Table 140. The amino acids found in the cell-wall hydrolysate were glycine, alanine, homoserine, and lysine (molar ratios of 1:1:1:1). The peptidoglycan belongs to the B2β group according to Schleifer and Kandler (1972). It is similar to that found in *Curtobacterium*, but D-lysine is detected instead of ornithine. This type of peptidoglycan is unique among the genera belonging to the B-peptidoglycan group.

Acid hydrolysates of bacterial cells revealed no glycolate, which suggested that muramic acid occurs in the *N*-acetyl form. The major isoprenoid quinone is MK-9. The polar lipid profile consists of diphosphatidylglycerol, phosphatidylglycerol, and an unknown glycolipid which is similar to that designated by Collins and Jones (1980) as glycolipid 2 (G_2). In addition, three unknown lipids were found which were not stained by any of the spray reagents, α-naphthol, molybdenum blue, or ninhydrin. The absence of additional glycolipids, which are found in strains of the phylogenetic neighbors *Clavibacter* and *Rathayibacter* (Collins and Jones, 1980), clearly distinguishes the genus from the representatives of these two genera. The predominant fatty acids were 12-methyltetradecanoic acid ($C_{15:0}$ anteiso), 14-methylpentadecanoic acid ($C_{16:0}$ iso), and hexadecanoic acid ($C_{16:0}$) obtained from cells grown near their maximum tolerable temperature, 28°C. At lower temperatures, a decrease of their contents of $C_{15:0}$ anteiso and (more pronounced) that of $C_{16:0}$ (to <4% at <4°C) was observed.

Fatty acid analysis by the MIDI system resulted in an identification of one peak in all strains as the hydroxylated fatty acid $C_{14:0}$ 2-OH. This peak was found in relatively high amounts (10–26%) of the fatty compounds. Detailed mass spectrometric investigations revealed that this component was 1,1-dimethoxy-12-methyl pentadecane ($C_{15:0}$ anteiso DMA). In spite of the great similarity between the strains in the physiological and chemotaxonomic properties, DNA–DNA reassociation studies showed that the levels of hybridization rates between strain 801 DNA and the DNAs of strains 227 and 301 were 37 and 44%, respectively, and the level of hybridization rate between strain 227 DNA and the 301 DNA was 52%. These data indicate that the strains are similar genomovars of one species.

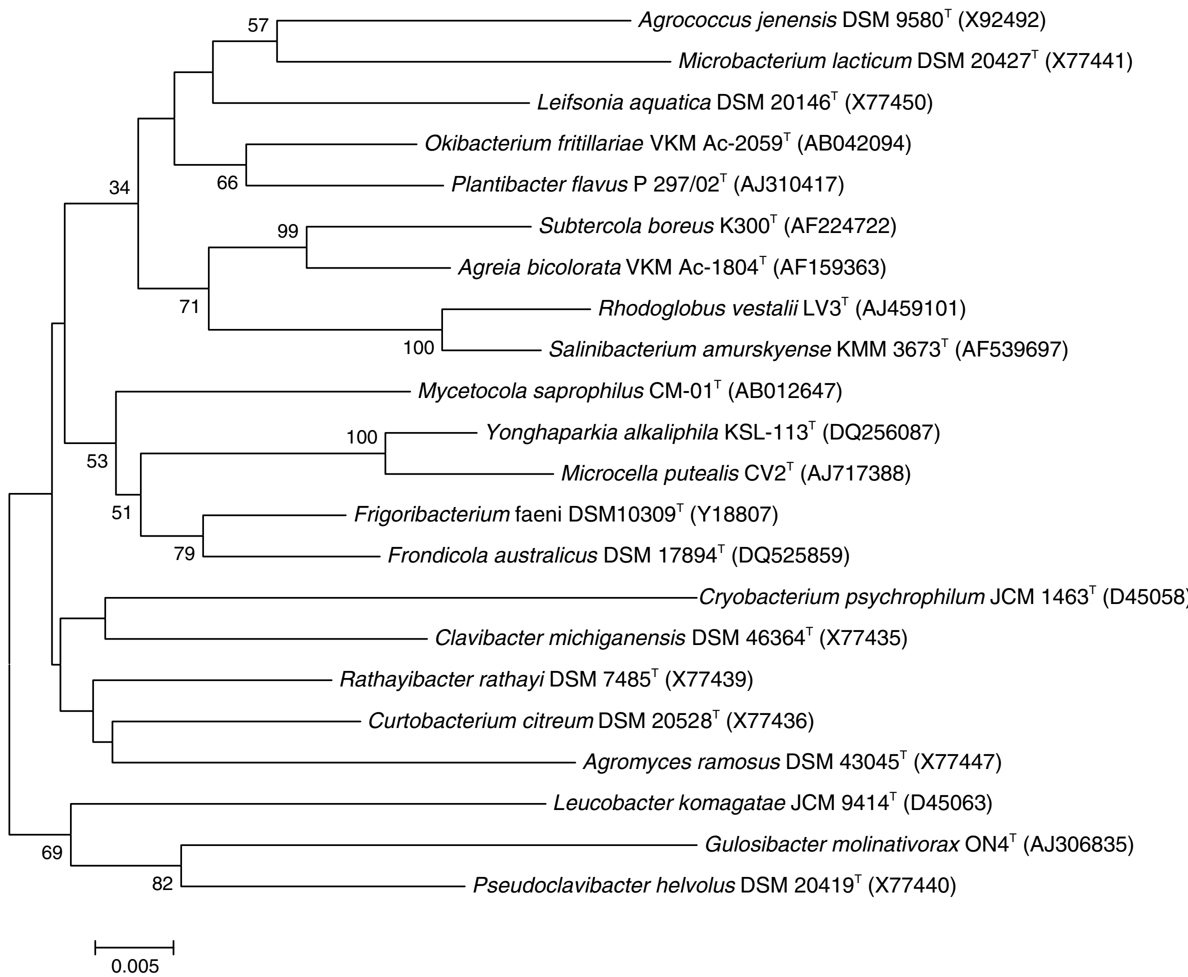

FIGURE 182. Phylogenetic analysis of *Frigoribacterium* and related genera based on 16S rRNA gene sequences available from the European Molecular Biology Laboratory data library (accession numbers are given in brackets) constructed after multiple alignments of data. Distances (distance options according to the Kimura-2 model) and clustering with the neighbor joining method was performed by using the software package MEGA (Molecular Evolutionary Genetics Analysis) version 2.1. Bootstrap values based on 1000 replications are listed as percentages at the branching points. Bar = 0.005 nucleotide substitutions per nucleotide position.

Enrichment and isolation procedures

No specific isolation medium has been described so far. Good growth occurs on complex media like PYES medium (Altenburger et al., 1996) as well as on nutrient agar and TS agar (both BBL Microbiology Systems) at 4–10°C. Growth is observed at 2–25°C.

Maintenance procedures

Frigoribacterium cultures may be lyophilized by common procedures used for many bacteria. In addition, cultures can be maintained by serial transfers on solid complex media. Growth on agar slants in screw-capped tubes can be kept at 4°C for about 2–4 weeks. Long-term preservation of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

Differentiation of the genus *Frigoribacterium* from other genera

Frigoribacterium may be distinguished from other genera in the family *Microbacteriaceae* by cell-wall peptidoglycan, the menaquinone type, the fatty acid composition, the colony pigmentation, the G+C content, and the growth at low temperatures (Table 140).

List of species of the genus *Frigoribacterium*

1. **Frigoribacterium faeni** Kämpfer, Rainey, Andersson, Nurmiaho Lassila, Ulrych, Busse, Weiss, Mikkola and Salkinoja-Salonen 2000, 362[VP]

fae′ni. L. n. *faenum* hay; L. gen. n. *faeni* of hay.

Cells are Gram-stain-positive, irregular rods that are 0.2–0.3 μm × 1.0–1.5 μm. The cells are nonsporeforming and motile in 2-d-old cultures on nutrient agar. No mycelium is produced. The morphology of the species and its chemotaxonomic characteristics are the same as described for the genus. Aerobic. Good carbon sources are sugars including *N*-acetyl-D-glucosamine, L-arabinose, *p*-arbutin, D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-mannose, D-maltose, L-rhamnose, D-ribose, sucrose, D-trehalose, and D-xylose. Only few organic acids were utilized as sole source of carbon (citrate, fumarate). Details of other physiological properties are given in Table 151.

Because of the DNA–DNA similarity data, the genus contains at least two further genomovars. The reference strain for genomovar 2 is 227 (=DSM 10310), the reference strain for genomovar 3 is 301 (= DSM 10311). Details of the physiological chemotaxonomic and properties of representatives of these genomovars are given in Table 151.

Source: hay dust.

DNA G+C content (mol%): 71 (HPLC).

Type strain: 801, ATCC BAA-3, DSM 10309, JCM 11265, NBRC 103066.

Sequence accession no. (16S rRNA gene): AM410686, Y18807.

[a]Symbols: +, positive; –, negative; (+) weak positive; test results given in the table were read after 72 h of incubation at 20°C.

[b]Data from Kämpfer et al. (2000).

[c]Acid formation from the carbohydrates lactose, sucrose, D-mannitol, dulcitol, salicin, inositol, sorbitol, L-arabinose, raffinose, rhamnose, maltose, D-xylose, trehalose, cellobiose, methyl-D-glucoside, erythritol, melibiose, D-arabitol, and D-mannose was negative for all strains. All strains utilized the following substrates as sole source of carbon: *N*-acetylglucosamine, L-arabinose, *p*-arbutin, D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-mannose, D-maltose, α-D-melibiose (weak), D-ribose, sucrose, salicin, D-trehalose, D-xylose, maltitol, and D-mannitol. All strains were negative for the utilization of acetate, propionate, *trans*-aconitate, adipae, 4-aminobutyrate, azelate, glutarate, 3-hydroxybutyrate, itaconate, DL-lactate, L-malate, mesaconate, oxoglutarate, pyruvate, suberate, L-alanine, β-alanine, L-histidine, L-leucine, L-phenylalanine, L-serine, L-tryptophan, 3-hydroxybenzoate, 4-hydroxybenzoate, and phenylacetate. All strains were positive for hydrolysis of esculin, pNP-β-D-galactopyranoside (weak), pNP-β-D-glucopyranoside, pNP-α-D-glucopyranoside, pNP-β-D-xylopyranoside, L-alanine-pNA, and L-proline-pNA. None of the strains hydrolyzed pNP-β-D-glucuronide, bis-pNP-phosphonate, *p*NP-phosphoryl-choline, 2-deoxythymidine-5′- pNP phosphate, and L-glutamate-γ-3-carboxy-pNA (pNP, *para*-nitrophenyl; pNA, *para*-nitroanilide).

Genus IX. **Frondihabitans** Greene, Euzéby, Tindall and Patel 2009, 448[VP]

Anthony C. Greene and Bharat K. C. Patel

Fron.di.ha′bi.tans. L. n. *frons*, *frondis* a leaf, foliage; L. part. adj. *habitans* inhabiting; N.L. part. adj. used as a masc. n. *Frondihabitans* inhabitant of leaves, leaf dweller.

Gram-stain-positive **short irregular-shaped rods.** Nonsporeforming. No mycelium is produced. **Aerobic. Mesophilic**. Temperature range for growth **15–37°C**. **Catalase-positive** and oxidase-negative. Cells are nonmotile with no flagella. A range of carbohydrates, organic acids, and amino acids are metabolized. The cell-wall peptidoglycan **type is B2β and contains L-ornithine. The major cellular fatty acid is $C_{18:1}$ ω7*c*, and menaquinones MK-7 and MK-8** are present. Glycolipids, disphosphatidylglycerol, phosphatidylglycerol, and three unidentified phospholipids are present.

DNA G+C content (mol%): 71–72.

Type species: **Frondihabitans australicus** Greene, Euzéby, Tindall and Patel 2009, 448[VP].

Further descriptive information

Phylogenetic analysis (Figure 183) places *Frondihabitans* (formerly *Frondicola* Zhang et al. 2007c, which is illegitimate because it is a later homonym of a fungal genus name *Frondicola* Hyde 1992) most closely to the psychrophilic genus *Frigoribacterium* in the phylum *Actinobacteria*, class *Actinobacteria*, order *Micrococcales*, and family *Microbacteriaceae*. *Frondihabitans* has a number of significant chemotaxonomic differences from *Frigoribacterium*, particularly in the cell wall and cell membranes and the type of substrates metabolized (Table 152). Furthermore, *Frondihabitans* is unable to grow at psychrophilic temperatures and has a higher optimum pH for growth than *Frigoribacterium*.

Frondihabitans australicus possesses traits that are atypical and have so far not been reported for any of the genera within the family *Microbacteriaceae* These include a high concentration of the mono-unsaturated fatty acid $C_{18:1}$ ω7*c* (78%), cell-wall type B2β peptidoglycan, MK-8 and MK-7 as the major menaquinones, the glycolipids disphosphatidylglycerol, phosphatidylglycerol, and three unidentified phospholipids (Table 152).

Enrichment and isolation procedures

Frondihabitans was isolated from moist leaf litter. It has not been established if this is the only habitat. Isolation can be accomplished by mixing a leaf litter sample with sterile distilled water, serially diluting ten-fold, and spreading aliquots on Trypticase Soy Broth (TSB)-Gelrite plates*. After 6 d incubation at 25°C,

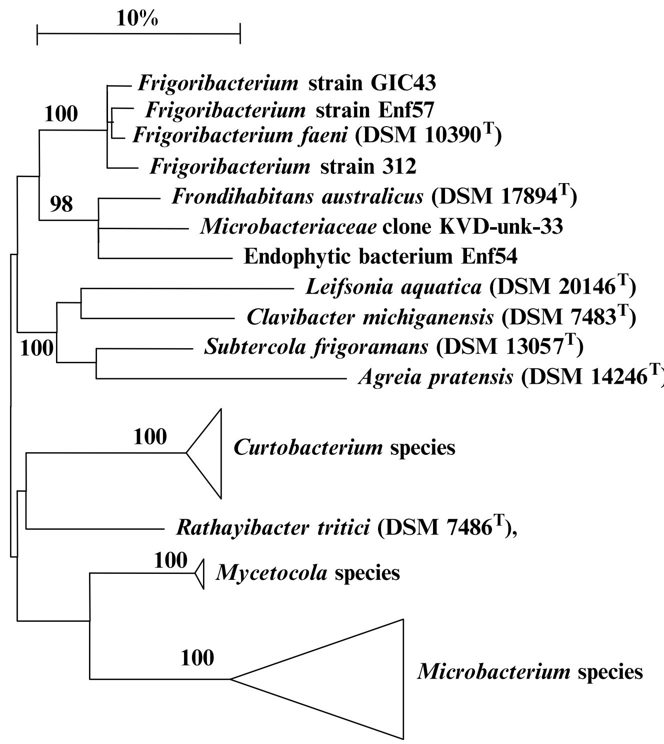

FIGURE 183. Phylogenetic tree showing the position of *Frondihabitans australicus* (DSM 17894[T]) within the family *Microbacteriaceae*. Clusters of members of the same genus are represented as *triangles* and include *Mycetocola saprophilus* (DSM 15178[T]) and *Mycetocola tolaasinivorans* (DSM 15179[T]) for the genus *Mycetocola*, *Microbacterium imperiale* (DSM 20530[T]), *Microbacterium phyllosphaerae* (DSM 13468[T]), *Microbacterium liquefaciens* (DSM 20638[T]), and *Microbacterium thalassium* (DSM 12511[T]) for the genus *Microbacterium*, and *Curtobacterium citreum* (DSM 20528[T]) and *Curtobacterium flaccumfaciens* (LMG 3645[T]) for the genus *Curtobacterium*. The following abbreviations have been used: T, Type culture; DSM, Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH; LMG, Collection of the Laboratorium voor Microbiologie en Microbiele Genetica. Bootstrap values above 95% from 1000 replicates are shown. Bar = 10 nucleotide changes per 100 nucleotides.

cream-colored, round, smooth colonies are picked and individually restreaked onto fresh TSB-Gelrite plates. The purity of the isolate is checked microscopically. Colonies from pure cultures were resuspended in sterile preservation medium (TSB, 0.3 g; glycerol, 15 ml; distilled water, 85 ml) and stored at −80°C.

*(TSB)-Gelrite plates contain (per liter distilled H_2O): TSB, 3 g; $MgCl_2$×$6H_2O$, 2.033 g; $CaCl_2$×$2H_2O$, 0.882 g; Gelrite, 20 g. After pH is adjusted to 7.2, medium is autoclaved and poured into Petri dishes.

Sequence accession no. (16S rRNA gene): DQ525859.

Genus X. **Gulosibacter** Manaia, Nogales, Weiss and Nunes 2004, 786[VP]

Célia M. Manaia, Balbina Nogales and Olga C. Nunes

Gu.lo.si.bac′ter. L. adj. *gulosus* gluttonous, luxurious, dainty, fond of tidbits; N.L. masc. n. *bacter* rod; N.L. masc. n. *Gulosibacter* rod fond of tidbits.

Irregular rod-shaped cells with tendency to form short filaments and branching. Gram-stain-positive. Nonsporeforming. **Nonmotile**. **Obligately aerobic**. Mesophilic. Catalase and oxidase-positive. **Chemo-organotrophic**. Few organic compounds, including amines and nitrogen bases, are used as sole source of carbon and energy. **The diagnostic diamino acid of the peptidoglycan is D-Orn. The major respiratory quinone is MK-9**. The polar lipid pattern is composed of diphosphatidylglycerol, phosphatidylglycerol, and minor amounts of an unknown glycolipid. Major cellular fatty acids are 12-methyl-tetradecanoic acid ($C_{15:0}$ anteiso), 14-methyl-pentadecanoic acid ($C_{16:0}$ iso), and 14-methyl-hexadecanoic acid ($C_{17:0}$ anteiso); $C_{15:0}$ anteiso and $C_{16:0}$ iso are predominant.

DNA G+C content (mol%): 65 (HPLC).

Type species: **Gulosibacter molinativorax** Manaia, Nogales, Weiss and Nunes 2004, 787[VP].

Further descriptive information

Gulosibacter molinativorax is the only species of the genus and is represented by a single strain, *Gulosibacter molinativorax* ON4^T (Manaia et al., 2004). Phylogenetic analysis based on the 16S rRNA gene sequence demonstrates that *Gulosibacter* forms, with *Pseudoclavibacter*, a distinct lineage branching deeply within the family *Microbacteriaceae* (Figure 184). Based on the 16S rRNA gene sequence analysis, the closest relatives of *Gulosibacter molinativorax* ON4^T are members of the genera *Zimmermannella*, *Pseudoclavibacter*, and *Curtobacterium*. *Gulosibacter molinativorax* ON4^T exhibits highest 16S rRNA gene sequence similarities to the type strains of *Zimmermannella bifida* and *Zimmermannella faecalis* (95.7–96.1%) and lower similarity values (~95%) to *Pseudoclavibacter helvolus* (94.6%), *Zimmernannella alba* (94.4%), and *Curtobacterium flaccumfaciens* pv. flaccumfaciens (94.1%). However, the genus *Zimmermannella* (Lin et al., 2004) has to be considered a later homotypic synonym of the genus *Pseudoclavibacter* (Euzéby, 2005) because the type strains of the type species of the genera *Pseudoclavibacter* and *Zimmermannella* are identical, and the validation of the genus *Zimmermannella* was published later than that of *Pseudoclavibacter*.

Gulosibacter molinativorax cells are irregularly rod-shaped, with tendency to branch and to form short filaments (Figure 185 and Figure 186). The cells stain Gram-positive, are non-acid-fast, nonsporeforming, nonmotile, with no visible deposits of poly-beta-hydroxybutyrate (PHB).

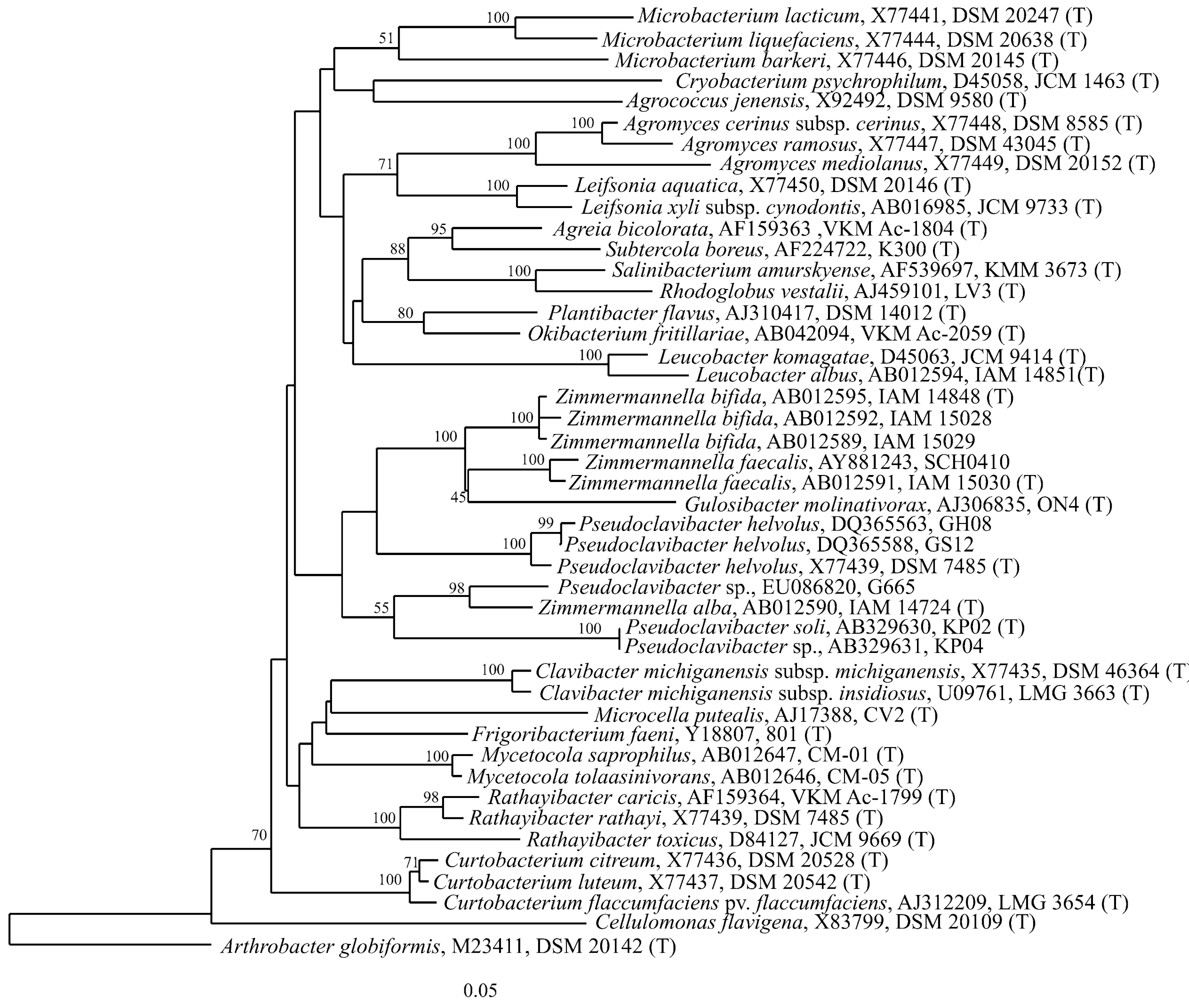

FIGURE 184. Phylogenetic relationships of the 16S rRNA gene sequences of the genera *Gulosibacter* and *Pseudoclavibacter* with sequences of species of related genera within the family *Microbacteriaceae*. Evolutionary distance matrices were calculated using the correction of Jukes and Cantor (1969). The dendrogram was constructed with the neighbor joining algorithm (Saitou and Nei, 1987), using a 50% homology conservation filter. The total number of positions used was 1330 nucleotides. Bootstrap values higher than 50% are indicated in the tree (1000 replicates). The 16S rRNA gene sequence of *Arthrobacter globiformis* DSM 20124^T was used as the outgroup.

The cell-wall peptidoglycan of *Gulosibacter* is of type B, with the diagnostic diamino acid D-ornithine. The major respiratory quinone of *Gulosibacter* is a menaquinone with nine isoprene units (MK-9), with a minor proportion of MK-8. The polar lipid pattern of *Gulosibacter* is composed of diphosphatidylglycerol, phosphatidylglycerol, and minor amounts of an unknown glycolipid. Major cellular fatty acids are 12-methyl-tetradecanoic acid ($C_{15:0}$ anteiso), 14-methyl-pentadecanoic acid ($C_{16:0}$ iso), and 14-methyl-hexadecanoic acid ($C_{17:0}$ anteiso) with $C_{15:0}$ anteiso and $C_{16:0}$ iso predominating. The polyamine pattern of *Gulosibacter* contains spermine and spermidine as predominant compounds (4.4 and 1.1 µmol/g dry wt, respectively) while 1,3-diaminopropane, putrescine, and cadaverine are present in very low amounts (0.2-< 0.1 µmol/g dry wt) (Busse, unpublished results). This polyamine pattern is quite similar to those found in species of *Clavibacter*, *Rathayibacter*, and *Curtobacterium* but, like in *Clavibacter* and *Rathayibacter*, the overall polyamine content is significantly higher than in species of the latter genus (Altenburger et al., 1997).

On complex agar media such as Luria–Bertani agar or Plate Count Agar, *Gulosibacter* forms opaque, white, circular, and convex colonies, 1.0 mm in diameter after 2–3 d of growth.

Gulosibacter is strictly aerobic and chemoorganothrophic. Nitrate is reduced under aerobic or anaerobic conditions, although growth does not occur without oxygen. In complex medium, growth occurs at 10–41°C, pH 5.5–10.5, and 0–7% (w/v) NaCl. *Gulosibacter molinativorax* ON4^T presents a restricted nutritional profile, assimilating few compounds as the only source of carbon and energy. Substrates that support growth include nitrogenated compounds. The Biolog and API 50CH profiles of *Gulosibacter molinativorax* ON4^T revealed that putrescine, L-glutamic acid, nitrogenated bases, 2,3-butanediol, pyruvic acid, methyl pyruvate, and *p*-hydrophenylacetic acid are assimilated by this strain, although Biolog does not directly examine assimilation but

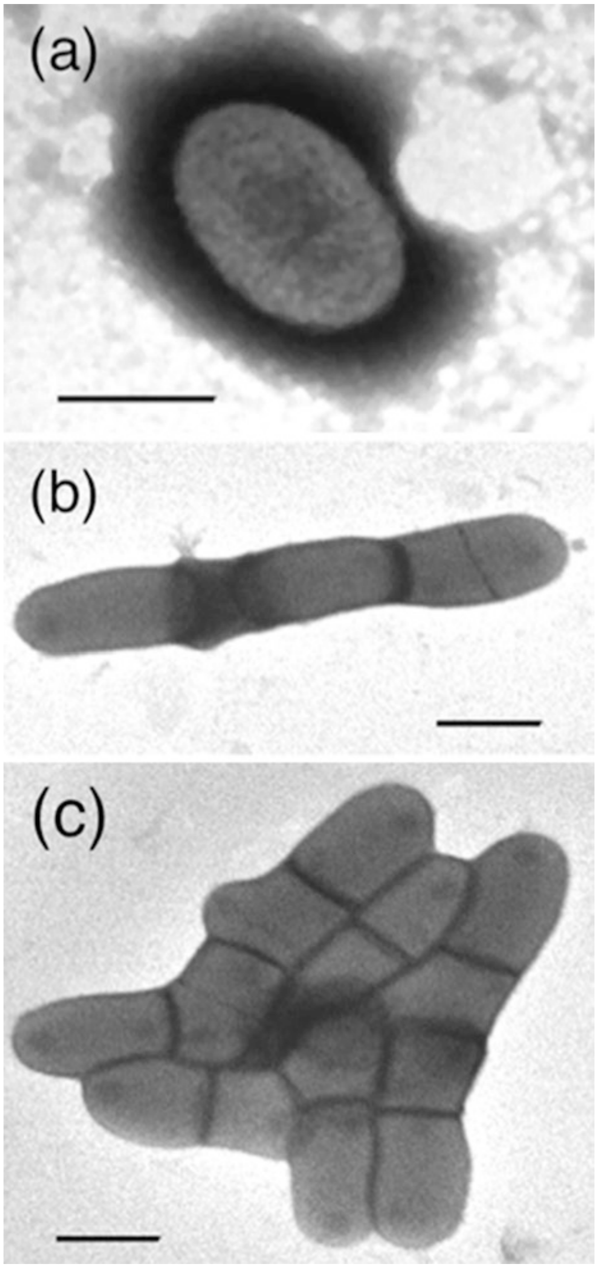

FIGURE 185. Transmission electron micrographs of negatively stained cells of *Gulosibacter molinativorax* ON4^T (a–c) grown on LB medium at 30°C for 24 h. Bar = 0.5 µm. (Reprinted with permission from Manaia et al., 2004. Int. J. Syst. Evol. Microbiol. 54: 783–789; supplementary figure in IJSEM Online.)

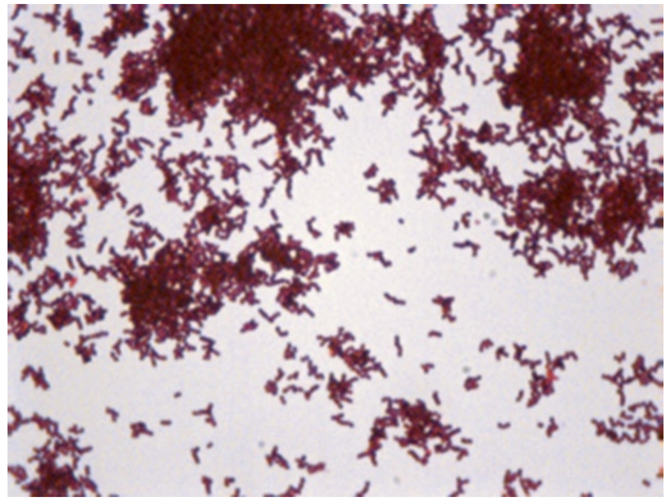

FIGURE 186. Gram-stained smear from a 3-d-old culture of *Gulosibacter molinativorax* ON4^T on Luria–Bertani agar medium at 30°C. Bright field (1000×). (Printed with permission from O.C. Nunes.)

oxidation of the carbon source tested. This microorganism is capable of growth on mineral medium with 2 mM molinate (azepan-1-yl-ethylsulfanyl-methanone), a thiocarbamate herbicide, as the sole source of carbon, energy, and nitrogen (Barreiros et al., 2003). However, other thiocarbamate herbicides such as EPTC (1-ethylsulfanyl-*N*,*N*-dipropyl-formamide), thiobencarb (1-[(4-chlorophenyl)methylsulfanyl]-*N*,*N*-diethyl-methanamide), cycloate (*N*-cyclohexyl-*N*-ethyl-1-ethylsulfanyl-methanamide), and vernolate (*N*,*N*-dipropyl-1-propylsulfanyl-methanamide) are not utilized nor degraded by *Gulosibacter molinativorax* ON4^T. This organism is responsible for the breakdown of the thioester bond of molinate, releasing ethanethiol, which accumulates in the medium, and an azepane moiety derivative of molinate (azepane-1-carboxylic acid) that support its growth (Barreiros et al., 2008). Due to the toxicity of the ethanethiol accumulated in the medium, no growth occurs at molinate concentrations above 3 mM. This toxic effect can be avoided when *Gulosibacter molinativorax* ON4^T grows in a defined mixed culture containing microorganisms co-isolated with strain ON4^T (Barreiros et al., 2003). *Gulosibacter molinativorax* ON4^T produces catalase and cytochrome *c* oxidase. The API ZYM profile shows that this organism also produces acidic and alkaline phosphatase, esterase and lipase (C_4, C_8 and C_{14}), leucine-, valine-, and cystine-arylamidase, and naphthol-AS-BI-phosphohydrolase.

Gulosibacter molinativorax ON4^T is affiliated with the family *Microbacteriaceae* according to phylogenetic analysis based on 16S rRNA gene sequence, constituting a deeply branching group together with the sequences of *Pseudoclavibacter* and *Zimmermannella* species. Irrespective of the treeing method used, and supported by high bootstrap values, the 16S rRNA gene sequence of *Gulosibacter molinativorax* forms a subgroup with *Zimmermannella faecalis* and *Zimmermannella bifida*, and more distant from *Pseudoclavibacter helvolus* and *Zimmermannella alba* (Figure 184). However, *Gulosibacter molinativorax* exhibits a distinctive phenotype including chemotaxonomic characteristics that support its status as a separated genus.

Gulosibacter molinativorax ON4^T was isolated from a microbial mixed culture enriched in molinate. The enrichment culture was obtained from a mixture of soil and water collected at a site where a molinate-containing effluent of a Portuguese pesticide-producing industry was discharged for several years. Several attempts were made to isolate other strains from pesticide contaminated soils (e.g. rice fields). However, *Gulosibacter molinativorax* ON4^T is still the only strain so far isolated and characterized, suggesting that it may be present in low numbers or be a slow grower in such habitats.

TABLE 153. Characteristics differentiating the genus *Gulosibacter* from closely related genera of the family *Microbacteriaceae*[a]

Characteristic	*Gulosibacter*	*Clavibacter*	*Curtobacterium*	*Pseudoclavibacter*[b]

Enrichment and isolation procedures

Although *Gulosibacter molinativorax* ON4[T] grows well in nutritive medium, isolation from environmental samples seems to be difficult. Originally, it was purified from an enrichment culture of a mixture of soil and water contaminated with pesticides. For the enrichment, the sample (10%, v/v) was initially incubated in mineral medium with molinate as carbon and energy source and ammonium sulfate and potassium nitrate as additional nitrogen sources*. After ten successive transfers at 8-d intervals to fresh medium, it was cultivated in a different mineral medium with molinate as the only source of carbon, energy and nitrogen†. The mixed bacterial culture, obtained after three successive transfers in this medium, presented five different morphotypes which were further identified as members of the genera *Pseudomonas* (two isolates), *Achromobacter*, and *Stenotrophomonas*, and the species *Gulosibacter molinativorax* (Barreiros et al., 2003).

Maintenance procedures

The bacteria can be maintained in the laboratory by subculturing on nutritive medium (e.g. Luria–Bertani Agar, Plate Count Agar) or on the same medium supplemented with 1 mM molinate, after 8–10 d at 4°C. Deep freezing (–75°C) is recommended for long-term preservation in 15% glycerol and nutrient broth.

Procedures for testing special characters

Gulosibacter molinativorax ON4[T] is the single organism described as being able to grow and to degrade the thiocarbamate herbicide molinate in complex or in mineral medium with the accumulation of ethanethiol. Molinate depletion may be followed by high performance liquid chromatography (HPLC)‡ (Barreiros et al., 2003).

Differentiation of the genus *Gulosibacter* from other genera

Table 153 shows the characteristics useful to distinguish *Gulosibacter* from other closely related genera of the family *Microbactereaceae*. The major phenotypic and chemotaxonomic characteristics that distinguish the genera within this family include the diagnostic diamino acid of the peptidoglycan and the isoprene chain length of the respiratory menaquinones (Behrendt et al., 2002; Collins and Bradbury, 1992). *Gulosibacter* shares these characteristics with *Curtobacterium*, but can be differentiated from this genus by a lower G+C content, a higher growth temperature, a positive oxidase reaction, and the inability to use several sugars as sole source of carbon. This phenetic differentiation is supported by the 16S rRNA gene sequence based phylogenetic relationship between both genera.

*Mineral medium with 2 mM molinate as carbon and energy source, $(NH_4)_2SO_4$ (3.8 mM), KNO_3 (1.02 mM), $NaNO_3$ (8.21 mM), Na_2HPO_4 (6.0 mM), KH_2PO_4 (4.0 mM), $CaCl_2 \times H_2O$ (0.47 mM), NaCl (0.14 mM), $MgSO_4 \times 7H_2O$ (0.41 mM), nitrilotriacetate (0.52 mM), $FeSO_4 \times 7H_2O$ (2 mg/l), $ZnSO_4 \times 7H_2O$ (0.1 mg/l), $MnSO_4 \times H_2O$ (0.03 mg/l), H_3BO_3 (0.3 mg/l), $CoSO_4 \cdot 7H_2O$ (0.24 mg/l), $CuSO_4 \cdot 5H_2O$ (0.01 mg/l), $NiSO_4 \cdot 7H_2O$ (0.02 mg/l), $NaMoO_4 \times 2H_2O$ (0.03 mg/l), $Ca(OH)_2$ (0.5 mg/l), and EDTA (5 mg/l).

†Mineral medium with 4 mM molinate as carbon, nitrogen, and energy source, phosphate buffer (27 mM, pH 7.2), $CaCl_2 \cdot 2H_2O$ (0.2 mM), NaCl (7.56 mM), $MgCl_2 \cdot 6H_2O$ (0.81 mM), $FeCl_2 \cdot 4H_2O$ (5.19 µM), HCl (1.3 µl, 25%), $ZnCl_2$ (0.07 mg/l), $MnCl_2 \cdot 4H_2O$ (0.1 mg/l), H_3BO_3 (0.062 mg/l), $CoCl_2 \cdot 6H_2O$ (0.19 mg/l), $CuCl_2 \cdot 2H_2O$ (0.017 mg/l), $NiCl_2 \cdot 6H_2O$ (0.024 mg/l), and $NaMoO_4 \cdot 2H_2O$ (0.036 mg/l).

‡Molinate is quantified using a High Performance Liquid Chromatograph with an UV-VIS detector (210 nm), a Lichrosphere 5 µm RP-18 column, and a mixture of methanol:water (80:20, v/v) as mobile phase (flow rate of 0.8 ml/min).

Taxonomic comments

The description of genus *Gulosibacter* was based on the characterization of *Gulosibacter molinativorax* ON4^T. The distinctive chemotaxonomic and physiological characteristics, which include cell-wall composition, menaquinones, optimal growth temperature, and a very restricted nutritional pattern observed for strain ON4^T, along with the low values of 16S rRNA gene sequence similarity with validly named taxa, support the definition of the genus *Gulosibacter*.

List of species of the genus *Gulosibacter*

1. **Gulosibacter molinativorax** Manaia, Nogales, Weiss and Nunes 2004, 787^{VP}

mo.li.na.ti.vo′rax. N.L. masc. n. *molinas -atis* molinate (a herbicide); L. adj. *vorax* devouring, ravenous, voracious; N.L. masc. adj. *molinativorax* molinate-degrading.

General characteristics are those listed in the genus description and in Table 153. Forms irregular rod-shaped cells, 0.8–1.0 µm × 0.5–0.6 µm. The maximal growth rate is observed in the presence of 1% (w/v) NaCl; 8% (w/v) NaCl inhibits growth.

Produces acid phosphatase, alkaline phosphatase, catalase, cystine arylamidase, esterase (C_4), esterase lipase (C_8), leucine arylamidase, lipase (C_{14}), naphthol-AS-BI-phosphohydrolase, and valine arylamidase, but not amylase, chymotrypsin, trypsin, α-fucosidase, α-galactosidase, α-glucosidase, α-mannosidase, β-galactosidase, β-glucosidase, β-glucuronidase, and *N*-acetyl-β-glucosaminidase. Degrades and grows at the expense of the herbicide molinate. Utilizes 2,3- butanediol, 2′-deoxyadenosine, adenosine, adenosine-5′-monophosphate, inosine, L-glutamic acid, *p*-hydroxyphenyl acetic acid, pyruvic acid, methyl pyruvate, putrescine, thymidine, thymidine-5′-monophosphate, uridine, and uridine-5′-monophosphate. Oxidation of α-D-glucose gives a weak reaction. The carbon sources 3-methyl-D-glucose, acetic acid, adonitol, esculin, alaninamide, amygdalin, arbutin, cellobiose, D-alanine, D-arabinose, D-arabitol, D-fucose, dextrin, D-fructose, D-galactose, D-galacturonic acid, D-gluconic acid, D-lactic acid methyl ester, D-lyxose, DL-α-glycerol phosphate D-malic acid, D-mannitol, D-mannose, D-psicose, D-sorbitol, D-tagatose, D-trehalose, dulcitol, D-xylose, erythritol, gentiobiose, glucose 1-phosphate, glucose 6-phosphate, glycerol, glycogen, glycyl-L-glutamic acid, inulin, lactamide, lactulose, L-alanine, L-alanyl-glycine, L-arabinose, L-arabitol, L-asparagine, L-fucose, L-lactic acid, L-malic acid, L-pyroglutamic acid, L-rhamnose, L-serine, fructose 6-phosphate, L-sorbose, L-xylose, maltotriose, mannan, methyl-α-D-galactoside, methyl-α-D-glucoside, methyl-α-D-mannoside, methyl-β-D-galactoside, methyl-β-D-glucoside, methyl-β-xyloside, mono-methyl-succinate, *N*-acetyl-L-glutamic acid, *N*-acetyl-D-glucosamine, *N*-acetyl-D-mannosamine, palatinose, propionic acid, salicin, sedoheptulosan, stachyose, succinamic acid, succinic acid, sucrose, turanose, Tween 40, xylitol, α-cyclodextrin, α-hydroxybutyric acid, α-ketoglutaric acid, α-ketovaleric acid, β-cyclodextrin, β-hydroxybutyric acid, and γ-hydroxybutyric acid are not used.

The major respiratory quinone is MK-9 (95%), with MK-8 as a minor component. The predominant cellular fatty acids are $C_{15:0}$ anteiso (46.9%), $C_{16:0}$ iso (33.2%), and $C_{17:0}$ anteiso (9.7%). Major polyamines are spermine and spermidine.

Source: a mixture of soil and water collected near a molinate-producing industry in Southern Portugal.

DNA G+C content (mol%): 64.5 (HPLC).

Type strain: ON4, CCUG 49965, CIP 108515, DSM 13485, JCM 13320, LMG 21909.

Sequence accession no. (16S rRNA gene): AJ306835.

Genus XI. **Humibacter** Vaz-Moreira, Nobre, Ferreira, Schumann, Nunes and Manaia 2008b, 1016^{VP}

Olga C. Nunes and Célia M. Manaia

Hu.mi.bac′ter. L. masc. n. *humus* earth, soil and, in earth sciences or agriculture, humus; N.L. masc. n. *bacter* rod; N.L. masc. n. *Humibacter* rod living in the humus.

Cells are motile Gram-stain-positive short rods (0.6 × 1.3 µm), forming coryneform V-shape cells only during the early stages of growth. Mesophilic and strictly aerobic chemo-organotroph. Reacts positively for **catalase**, **β-galactosidase**, **urease**, and **Voges–Proskauer** tests. Is able to **hydrolyze esculin** and to **reduce nitrate** but not nitrite. Cytochrome *c* **oxidase** tests **negative**. The peptidoglycan contains the diamino acid **ornithine** in combination with **2,4-diaminobutyric acid**. The major quinones are the **menaquinones 11** and **12**. The 16S rRNA gene sequence analysis positions this genus in a group of Gram-stain-positive bacteria within the family *Microbacteriaceae*. Isolated from sewage sludge compost produced in a municipal wastewater treatment plant in Northern Portugal.

DNA G+C content (mol%): 67.6.

Type species: **Humibacter albus** Vaz-Moreira, Nobre, Ferreira, Schumann, Nunes and Manaia 2008b, 1016^{VP}.

TABLE 154. Relevant chemotaxonomic characteristics differentiating *Humibacter* from closely related genera[a]

Characteristic	*Humibacter*[b]	*Agromyces*[c]	*Curtobacterium*[d]	*Leifsonia*[e]
Major menaquinones (>30%)	MK-11, MK-12	MK-11[f], MK-12, MK-13[f]	MK-9	MK-10, MK-11, MK-12[f]
Diamino acid of peptidoglycan	Orn, DAB	DAB	Orn	DAB

[c]Casida (1986); Takeuchi and Hatano (2001); Behrendt et al. (2002); Jurado et al. (2005a, 2005b, 2005c); and Jung et al. (2007).

[d]Komagata and Suzuki (1986a) and Behrendt et al. (2002).

[e]Suzuki et al. (1999) and Evtushenko et al. (2000).

[f]Only in some species.

[g]Cyclohexyl fatty acids are found only in some species (see text for details).

Further descriptive information

Good growth is observed on Brain Heart Infusion Agar (BHIA, LAB M, United Kingdom); growth is slower and poorer on other media such as Plate Count Agar (PCA, Conda-Pronadisa, Spain) and Luria–Bertani Agar (LBA)*. On BHIA, forms white, opaque, and convex colonies, after 48 h at 30°C. *Humibacter* contains the following major fatty acids: $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, and cyclohexyl $C_{17:0}$. The peptidoglycan is of acetyl type and contains, respectively, ornithine, 2,4-diaminobutyric acid, glycine, alanine, and glutamic acid in a molar ratio of 0.8:0.4:1.0:0.5:1.0. The major respiratory quinones are the menaquinones MK-11 (56%) and MK-12 (32%). MK-10 is a minor component (12%).

The only species in the genus was isolated from final compost produced from anaerobically digested sewage sludge of a domestic wastewater treatment plant. During this process, the anaerobic digest of decanted activated sludge is mixed with granular pine bark and submitted to windrow composting with additional induced aeration for 20 d. Temperatures of about 60°C are reached during this composting process.

Enrichment and isolation procedures

The type strain was isolated from a serial dilution of a suspension containing 10 g of compost per 90 ml of saline solution. The original suspension was shaken for 30 min and 1 ml of each serial dilution was filtered through a membrane of cellulose nitrate with 0.45 µm of pore size. The membranes were placed onto PCA and incubated at 30°C for 24 h. The organism represented a single morphotype in the culture at an estimate of about 7×10^5 colony forming units per gram of compost.

Maintenance procedures

The type strain is maintained in BHIA at 4°C for periods of less than 2 weeks and in nutrient broth with 15% glycerol at −80°C, for long-term storage. Cultures may also be lyophilized.

Differentiation of the genus *Humibacter* from other genera

Table 154 lists characteristics differentiating *Humibacter* from other closely related members of the family *Microbacteriaceae*. The presence of MK-11 as major menaquinone distinguishes *Humibacter* from *Curtobacterium*. The presence of ornithine in combination with 2,4-diaminobutyric acid distinguishes *Humibacter* from *Agromyces*, *Curtobacterium*, and *Leifsonia*. When compared with members of those genera, *Humibacter* presents a lower percentage (more than two times lower) of the fatty acid $C_{15:0}$ anteiso. The presence of cyclohexylundecanoic acid (cyclohexyl $C_{17:0}$), the major fatty acid in the type strain, is another distinctive feature to other taxa, although this same component has been detected in other species of *Curtobacterium* and *Leifsonia*. The presence of cyclohexyl $C_{17:0}$ in the distantly related species *Curtobacterium pusillum*, *Curtobacterium flaccumfaciens* pv. *flaccumfaciens*, *Curtobacterium ammoniigenes* (Aizawa et al., 2007), and in *Leifsonia ginsengi* (Qiu et al., 2007), but not in other members of the respective genera, limits the use of this component as chemotaxonomic marker until more representatives of *Humibacter* are isolated and characterized.

Taxonomic comments

Based on the 16S rRNA gene sequence analysis, the closest related genera are *Agromyces*, *Curtobacterium*, and *Leifsonia*, particularly the species *Leifsonia xyli*, *Leifsonia shinshuensi*, *Leifsonia naganoensis*, *Leifsonia aquatica*, *Agromyces ramosus*, and *Curtobacterium citreum* which have sequence similarities of 95–96%.

List of species of the genus *Humibacter*

1. **Humibacter albus** Vaz-Moreira, Nobre, Ferreira, Schumann, Nunes and Manaia 2008b, 1016[VP]

   al′bus. L. masc. adj. *albus* white.

Colonies on BHIA are white, opaque and 1–2 mm diameter. Growth occurs at 22–36°C, pH 5.5–8.0, and in the presence of 3% NaCl, with optima below 30°C, pH around 7, and less than 1% NaCl. No growth occurs at 15°C or 40°C, at pH 9, or in the presence of 5% NaCl. The type strain assimilates and produces acid from *N*-acetylglucosamine, amygdalin, L-arabinose, D-cellobiose, D-fructose, D-galactose,

*LBA (g/l distilled water): yeast extract, 5.0; tryptone, 10.0; NaCl, 10.0; agar, 15.0.

gentiobiose, glucose, D-lactose, D-maltose, D-mannitol, D-mannose, D-melibiose, methyl-β-D-xylopyranoside, L-rhamnose, D-sucrose, salicin, D-trehalose, and D-xylose. Additionally, inositol, turanose, and D-arabitol are assimilated, and D-arabinose and D-ribose support acid production. Growth occurs in the presence of ceftazidime (30 μg) but not in the presence of amoxicillin (25 μg), gentamicin (10 μg), ciprofloxacin (5 μg), tetracycline (30 μg), sulfamethoxazole (25 μg), cephalothin (30 μg), streptomycin (10 μg), ticarcillin (75 μg), meropenem (10 μg), or colistin sulphate (50 μg).

DNA G+C content (mol%): 67.6 (HPLC).

Type strain: SC-083, CCUG 54538, DSM 18994, LMG 23996.

Sequence accession no. (16S rRNA gene): AM494541.

Genus XII. **Labedella** Lee 2007, 2500[VP]

António Veríssimo

La.be.del′la. N.L. fem. dim. n. *Labedella* named in honor of David P. Labeda, who has made significant contributions to the area of actinomycete taxonomy.

Cells are rod-shaped (0.3–0.38 × 1.0–4.4 μm), **Gram-stain-positive**, nonmotile, and nonsporeforming. Aerobic, oxidase-negative, and catalase-positive. Chemo-organotrophic. Mesophilic. The cell-wall peptidoglycan is of the **B-type containing ornithine** as the diagnostic amino acid. Fatty acids are predominantly iso- and anteiso-branched, namely $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. Mycolic acids are not present. The respiratory quinones are unsaturated **menaquinones, predominantly MK-10 (44%) and MK-11 (31%), but MK-9 and MK-7 are also present in lesser amounts.** The only strain was isolated from dried seaweed.

DNA G+C content (mol%): 68.0.

Type species: **Labedella gwakjiensis** Lee 2007, 2501[VP].

Further descriptive information

Phylogenetic analysis based on the 16S rRNA gene sequences positions the genus *Labedella* as a distinct branch within the radiation of the family *Microbacteriaceae*, forming a coherent cluster with members of genus *Cryobacterium* (Dastager et al., 2008a; Suzuki et al., 1997; Zhang et al., 2007b), *Microcella* (Tiago et al., 2006), and *Yonghaparkia* (Yoon et al., 2006b).

Cells are small and rod shaped. *Labedella* isolates were routinely cultured in TSA, forming translucent and yellow-pigmented colonies. The cellular fatty acids profile, obtained from cultures on TSB for 3 d at 30°C, is characterized by the predominance of $C_{15:0}$ anteiso (49.4%), $C_{16:0}$ iso (20.5%), and $C_{17:0}$ anteiso (11.4%) and includes, as a minor component, a small amount (1.8%) of tuberculostearic acid ($C_{18:0}$ 10 methyl) that has not been found in other species of *Microbacteriaceae*.

Labedella isolates are strictly aerobic mesophiles, and are able to utilize several sugars as sole carbon and energy sources.

The only strain belonging to *Labedella* was isolated from dried seaweed collected at Gwakji Beach in Jeju, Republic of Korea.

Enrichments and Isolation Procedures

The type strain was isolated by direct inoculation of dried seaweed on WAT-SW medium (Lee, 2006) and, after incubation at 30°C for 14 d, then subculturing onto TSA-SW medium. TSA-SW medium is Trypticase Soy Agar in a mixture of 60% (v/v) natural sea water and 40% (v/v) distilled water.

Maintenance procedures

Labedella is maintained in 20% glycerol suspension supplemented with 60% natural sea water at −80°C. Lyophilized cultures are also used.

Differentiation of the genus *Labedella* from closest related taxa

Chemotaxonomic characteristics such as the diagnostic diamino acid ornithine present in the peptidoglycan and the menaquinone composition characterized by the predominance of MK-10 and MK-11 are important distinctive features differentiating *Labedella* from the closest related taxa. Furthermore, growth temperature and some biochemical characters may also be useful differential characteristics.

Table 155 lists the main characteristics differentiating *Labedella* from the closest related *Microbacteriaceae*.

TABLE 155. Characteristics differentiating *Labedella* and closest related genera[a]

Characteristic	*Labedella*	*Cryobacterium*	*Microcella*	*Yonghaparkia*
Motility	−	+/−	−	−

[a]Symbols: +, >85% positive −, 0–15% positive; Orn, Ornithine; Lys, lysine; DAB, diaminobutyric acid.

List of species of the genus *Labedella*

1. **Labedella gwakjiensis** Lee 2007, 2501[VP]

gwak.ji.en′sis. N.L. fem. adj. *gwakjiensis* of or pertaining to Gwakji Beach, Jeju, Republic of Korea, where the type strain was isolated.

The characteristics are as described for the genus with the following additional features. Growth occurs between 10 and 37°C. No growth occurs at 4 or 45°C. The pH range for growth is pH 5.1–10.1, with optimum growth at pH 7.1. Growth occurs in the presence of up to 5% NaCl. Nitrate is not reduced to nitrite. The type strain of this species hydrolyzes esculin, DNA, gelatin, and starch; casein and elastin are not hydrolyzed. Produces H_2S but not indole. D-Glucose, D-arabinose, D-mannose, D-mannitol, and *N*-acetyl-D-glucosamine are utilized as sole carbon and energy sources, but utilization of maltose, gluconate, caproate, adipate, malate, citrate, and phenylacetate is not observed. Under aerobic conditions, acid is produced from: L-arabinose, D-cellobiose, D-fructose, D-galactose, D-glucose, inulin, D-mannose, D-melezitose, methyl a-D-mannoside, D-raffinose, L-rhamnose, salicin, sucrose, D-xylose, glycerol, *myo*-inositol, D-mannitol, and D-sorbitol. Activity of enzymes urease, leucine arylamidase, α-galactosidase, β-galactosidase, α-glucosidase, and β-glucosidase is detected.

Major cellular fatty acids detected after incubation on TSB for 3 d at 30°C are: $C_{15:0}$ anteiso (49.4%), $C_{16:0}$ iso (20.5%), and $C_{17:0}$ anteiso (11.4%). Minor components detected are: $C_{16:0}$ (5.8%), $C_{18:0}$ (1.7%), $C_{14:0}$ iso (2.0%), $C_{15:0}$ iso (2.0%), $C_{18:1}$ ω9*c* (1.8%), $C_{18:0}$ 10-methyl (tuberculostearic acid, 1.8%), and a mixture of $C_{15:0}$ iso 2-OH and/or $C_{16:1}$ ω7*c* (1.6%).

Polar lipids include phosphatidylglycerol and diphosphatidylglycerol. Glycolipids or other phospholipids, namely phosphatidylcholine and ninhydrin-positive phospholipids, were not detected.

Source: dried seaweed collected at Gwakji Beach in Jeju, Republic of Korea.

DNA G+C content (mol%): 68.0 (HPLC).

Type strain: KSW2–17, JCM 14008, KCTC 19176.

Sequence accession no. (16S rRNA gene): DQ533552.

Genus XIII. **Leifsonia** Evtushenko, Dorofeeva, Subbotin, Cole and Tiedje 2000, 377[VP]

Lyudmila I. Evtushenko

Leif.so′ni.a. N.L. fem. n. *Leifsonia* named after Einar Leifson, an American microbiologist who isolated and described the first organism of this genus.

Young cultures produce **slender (mostly 0.3–0.6 µm in diameter) irregular rods or filaments**. **Primary branching and V-forms typically occur.** Cultures a week or more old usually contain shorter rods, but some cells may be coccoid. No aerial mycelium is produced. Nonsporeforming. Some species are **motile by means of peritrichous flagella**. **Gram-stain-positive** cell-wall architecture. **Non-acid-fast. Chemo-organotrophs**, metabolism is primarily respiratory with oxygen as the terminal electron acceptor. Mostly **catalase-positive**. Oxidase reaction varies with strains or experiments. Acids are produced oxidatively rather weakly from carbohydrates. Most species grow well on standard laboratory media at near neutral pH. Some species are nutritionally very exacting. Mesophilic, optimum temperature ~24–30°C; growth range ~4–42°C.

Cell-wall peptidoglycan contains 2,4-diaminobutyric acid as the diamino acid, the structural type of the peptidoglycan is **B2γ, [L-Dab]D-Glu–D-Dab. The muramic acid residue of the peptidoglycan is *N*-acetylated. Menaquinones** are the sole respiratory quinones detected; the predominant component is a **menaquinone with 11 unsaturated isoprene units (MK-11), the second most common major menaquinone is MK-10 or MK-12. Rhamnose** is typically present in the cell-wall polysaccharide(s). The major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. Straight-chain saturated or unsaturated acids are present in small quantities. Mycolic acids are absent. The principal polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and characteristic glycolipids.

Occur in various environments and can be associated with plants, animals, and clinical specimens. Representatives of some species are plant pathogens.

DNA G+C content (mol%): 66–70.7.

Type species: **Leifsonia aquatica** (*ex* Leifson 1962) Evtushenko, Dorofeeva, Subbotin, Cole and Tiedje 2000, 377[VP] ("*Corynebacterium aquaticum*" Leifson 1962, 161).

Further descriptive information

Phylogenetic heterogeneity of the genus *Leifsonia*. The genus *Leifsonia* belongs to the family *Microbacteriaceae*, order *Micrococcales*, and, at the time of writing, includes 11 species and two subspecies with validly published names indicated in Figure 187. The 16S rRNA gene sequence similarities between the species described under the generic name *Leifsonia* range from ~94 to 99.8%, and the inferred phylogenies show that the genus comprises a rather heterogeneous group. The type species *Leifsonia aquatica* together with *Leifsonia naganoensis*, *Leifsonia poae*, *Leifsonia shinshuensis*, and *Leifsonia xyli* with two subspecies (*Leifsonia sensu stricto* species group) compose a coherent cluster with the 16S rRNA gene sequence similarity values exceeding 97.5%. The close phylogenetic relatedness of these species is also supported by analysis of the 16S–23S rRNA intergenic spacer (ITS) region sequences and the partial 23S rRNA gene sequences (approx. 200 bases) available in GenBank. The remaining species (*Leifsonia aurea*, *Leifsonia rubra*, *Leifsonia bigeumensis*, *Leifsonia ginsengi*, *Leifsonia kribbensis*, and *Leifsonia pindariensis*) form

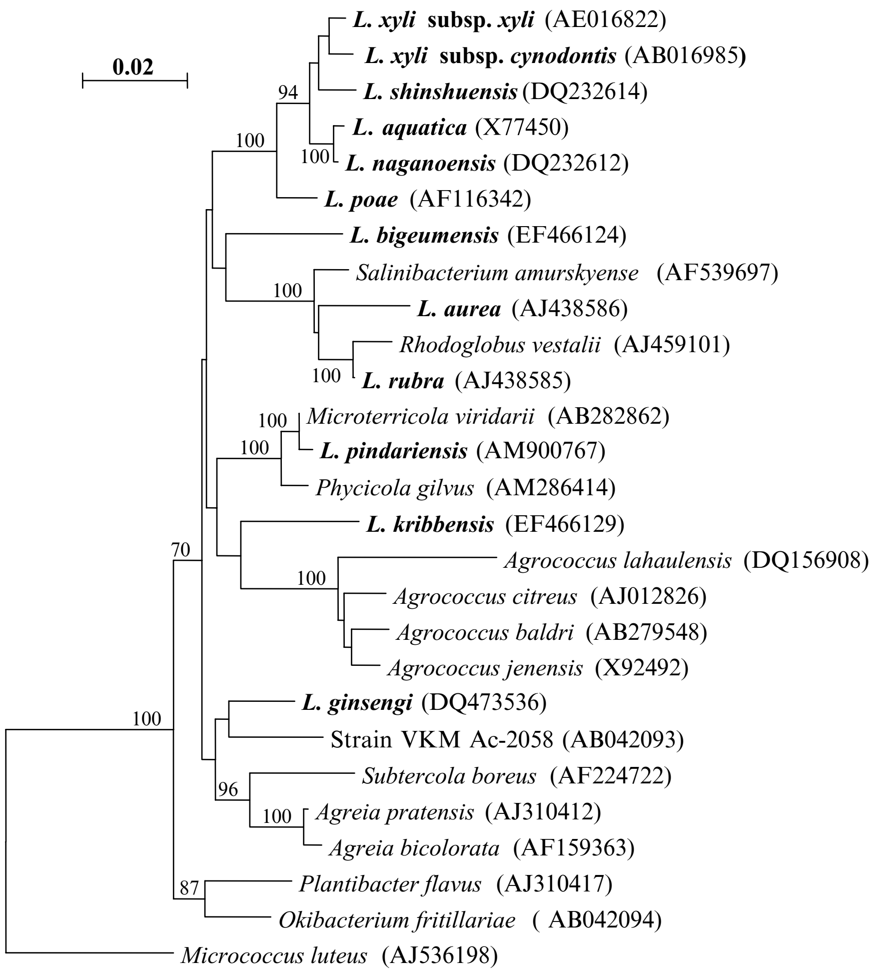

FIGURE 187. Phylogenetic relationship of *Leifsonia* species and related genera based on 16S rRNA gene analysis. The neighbor joining method was used for tree construction. Bar = 0.02 inferred nucleotide substitution per nucleotide. Values at nodes indicate bootstrap values for 500 replicates.

separate lineages outside the coherent *Leifsonia sensu stricto* species group, and the 16S rRNA gene sequence similarity values indicate their approximately equidistant or closer relationship to members of other genera or as yet unclassified microorganisms of the family *Microbacteriaceae*. In the opinion of the author of this chapter, the generic assignment of these six species should be re-examined (see the Taxonomic Comments section). Until their taxonomic status has been clarified, they are dealt with as species *insertae sedis*. The data provided in the genus description and in this section below concern the *Leifsonia sensu stricto* species only.

Cell morphology and motility. Cell morphology of the *Leifsonia* species in young cultures ranges from irregular rods tending to form primary branched cells to the relatively long, occasionally branching filaments resembling rudimentary mycelium of some *Agromyces* species (Figure 188). The mean cell width is 0.3–0.6 μm. Some cells may become thicker on some media and reach up to 0.8–0.9 μm in diameter. The rods or filaments are divided by septum formation, and the rapidly growing cultures a week or more old are usually composed of short rods and coccoid cells. A marked rod–coccoid cycle resembling that in *Arthrobacter* species may be observed in some

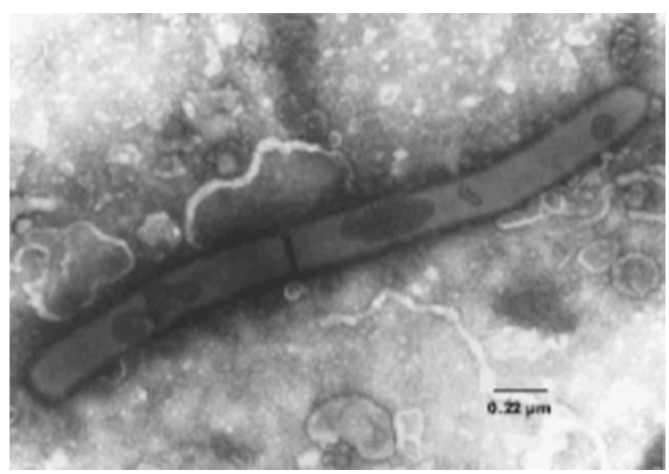

FIGURE 188. Electron micrograph of dividing *Leifsonia xyli* subsp. *xyli* cells isolated from nodal exudates from sugarcane, containing 4 distinct mesosomes. The cell size is most likely smaller than in a living bacterium as the sample was dried during the fixation process. (Reproduced with permission from Brumbley et al., 2006. Austr. Plant Pathol. *35*: 681–689.)

strains during growth on complex agar media, especially in synchronized cultures. No aerial mycelium is produced. Cells of some species are motile by means of 1–3 peritrichous flagella (length, ~10 µm or more) as measured for *Leifsonia aquatica* (Leifson, 1962). It is worth noting that *Leifsonia xyli* subsp. *xyli* reported to be nonmotile (Davis et al., 1984) has homologs of flagellar operons in the genome (Brumbley et al., 2006; Monteiro-Vitorello et al., 2004).

Colony morphology and pigments. Colonies are typically circular, somewhat convex, glossy, opaque, with entire margins. Penetration into agar media was not observed. Most of the *Leifsonia* species usually produce white to light yellow colonies in early growth phase; the color becomes bright yellow to pale brown with age in some species. The yellow pigments of two species (*Leifsonia aquatica* and *Leifsonia poae*) are C_{40}-carotenoids; the pigment biosynthesis is induced by light (Trutko et al., 2005). The pigment production in these two species is inhibited by fosmidomycin at concentrations lower than those inhibiting growth (Trutko et al., 2005) suggesting the nonmevalonate pathway of pigment biosynthesis (Kuzuyama, 2002; Lichtenthaler, 2000). No distinct pigmentation of *Leifsonia xyli* subsp. *xyli* has been reported, but genes for carotenoid biosynthesis (Armstrong, 1997) were identified in the genome of strain *Leifsonia xyli* subsp. *xyli* CTCB07 (Brumbley et al., 2006; Monteiro-Vitorello et al., 2004). The genome of this strain also harbors a gene encoding a member of the delta fatty acid desaturase family which could redirect the carotenoid biosynthetic pathway to the biosynthesis of the plant hormone abscisic acid (Bartley and Scolnik, 1995; Kende and Zeevaart, 1997; Ventura et al., 2007).

Chemotaxonomy. Peptidoglycan is of the B2γ type, [L-Dab]D-Glu–D-Dab, as determined for *Leifsonia aquatica* (Fiedler et al., 1970; Schleifer and Kandler, 1972). All other *Leifsonia sensu stricto* species contain 2,4-diaminobutyric acid (Dab), glycine, glutamic acid, and alanine in a molar ratio close to 2:1:1:1 (Evtushenko et al., 2000; Suzuki et al., 1999). The polymers of *Leifsonia naganoensis*, *Leifsonia shinshuensis*, and *Leifsonia xyli* subsp. *cinodontis* studied in more detail have both D- and L-isomers of Dab in almost equal proportions like that in *Leifsonia aquatica* (Suzuki et al., 1999). The muramic acid is *N*-acetylated (the glycolate test is negative) (Suzuki et al., 1999). The whole cell sugars in *Leifsonia aquatica* and *Leifsonia xyli* subsp. *cinodontis* are similar (glucose, galactose, mannose, fucose, ribose, rhamnose, and traces of xylose). According to Davis et al. (1984), the subspecies *Leifsonia xyli* subsp. *cynodontis* and *Leifsonia xyli* subsp. *xyli s*trains have similar cell-wall sugars (rhamnose, fucose, and trace of galactose). Somewhat different pattern of cell-wall sugars has been revealed in *Leifsonia xyli* subsp. *cinodontis* (rhamnose, galactose, glucose, and a lower content of fucose and mannose) by other authors (Evtushenko et al., 2000), probably due to different method of cell-wall preparation and purification. Cell-wall teichoic acids and related anionic phosphorous-containing polysaccharides have not been found in the type strains of *Leifsonia aquatica* and *Leifsonia poae* (Evtushenko et al., 2000). The major respiratory menaquinone is MK-11; the second most common major component is MK-10 or MK-12 depending on the species (Collins et al., 1979; Evtushenko et al., 2000; Suzuki et al., 1999; Yamada et al., 1976). Concentration of polyamines, as determined in strain *Leifsonia poae* VKM Ac-1401^{T} (DL 89), is low**;** putrescine is the predominant component (Altenburger et al., 1997).

The major fatty acids are represented by $C_{15:0}$ anteiso (24.1–47.3%), $C_{17:0}$ anteiso (32.6–54.4%), and $C_{16:0}$ iso (10–21%) as determined in cells grown at optimal temperatures (Collins and Jones, 1980; Evtushenko et al., 2000; Suzuki and Komagata, 1983; Suzuki et al., 1999). The content of $C_{15:0}$ anteiso may be significantly higher at lower (20°C) growth temperature (Suzuki and Komagata, 1983). The principal polar lipids, as determined in *Leifsonia aquatica*, are diphosphatidylglycerol, phosphatidylglycerol, and two characteristic glycolipids (glycosyldiacylglycerols), G_1 (minor) and G_2 (predominant), both giving green coloration with the anisaldehyde/sulfuric acid reagent indicating the possible presence of mannose (Collins and Jones, 1980). It is worth noting that the glycolipid G_2 as the only glycolipid also occurs in *Agromyces mediolanus* and, along with 1–2 other glycolipids, in some, but not all, members of the family *Microbacteriaceae* (Collins and Jones, 1980; Kämpfer et al., 2000; N.G. Vinokurova and L.I. Evtushenko, unpublished). Khuller and Brennan (1972) reported diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol monomannoside, and dimannosyl diacylglycerol in *"Corynebacterium aquaticum"* B2252. Yanagi et al. (2000) identified two glycoglycerolipids, 1-[α-glucopyranosyl-(1α-3)-(6-*O*-acyl-α-mannopyranosyl)]-3-*O*-acylglycerol and 1-[α-mannopyranosyl-(1α-3)-(6-*O*-acyl-α-mannopyranosyl)]-3-*O*-acylglycerol, in two *"Corynebacterium aquaticum"* strains, S361 and S365, respectively. However, it is not quite clear whether the strains investigated by these authors are actually members of the genus *Leifsonia*.

Nutrition, growth conditions, and metabolic activities. *Leifsonia* species, with exception of xylem-invading *Leifsonia xyli*, usually grow well on standard nutrient media based on yeast-extract and peptone. Knowledge of nutritional requirements of *Leifsonia* species is incomplete. The type strain of *Leifsonia aquatica* can grow readily in simple vitamin-free Casamino acids (Difco) or peptone broth (Leifson, 1962), but not in a basal mineral medium (e.g. Shirling and Gottlieb, 1966) with glucose as a carbon source and ammonium salt as a source of nitrogen. This strain and some other representatives of the genus show growth in the same basal medium with traces of yeast extract. It therefore appears that some growth factors, such as amino acids and probably vitamins, are necessary for certain species. Strains of *Leifsonia xyli* are nutritionally very exacting and require more complex media containing, e.g. bovine serum albumin, bovine hemin chloride, and cysteine (Davis et al., 1984). Extracts of Bermuda grass and maize, as well as xylem fluid from maize, enhance the growth of *Leifsonia xyli* subsp. *cynodontis* (Haapalainen et al., 2000).

Representatives of the genus *Leifsonia* use a wide range of organic compounds as sole sources of carbon for growth and energy and possess various enzymic activities (Table 156 and Table 157). Although *Leifsonia xyli* subsp. *xyli* shows negative reactions in many conventional utilization tests (Davis et al., 1984), strain *Leifsonia xyli* subsp. *xyli* CTCB07 was found to possess a large number of ABC transporter homologs, indicating the potential ability to utilize a broad range of carbohydrates including glucose, arabinose, fructose, galactose, lactose, maltose, maltotriose, ribose, trehalose, and xylose; this strain has also the potential to degrade some organic compounds includ-

[k]Data for reference strain *Leifsonia xyli* subsp. *xyli* CTCB07 from the genome sequence (Monteiro-Vitorello et al., 2004).

ing heteropolysaccharides and peptides (Monteiro-Vitorello et al., 2004; Ventura et al., 2007).

Acids are produced oxidatively rather weakly from carbohydrates; the test results vary with experiments (Evtushenko et al., 2000; Leifson, 1962; Suzuki et al., 1999; Yamada and Komagata, 1972b). No acidification of glucose or other carbohydrates was observed under anaerobic conditions for *Leifsonia aquatica* (Leifson, 1962).

Strains of *Leifsonia naganoensis* and *Leifsonia shinshuensis* were reported to be amine-decomposing bacteria (Suzuki et al., 1999). The type strain of *Leifsonia aquatica* destroys detergent compounds such as tallow-alkyl-sulfate, alkyl-ethoxylate-sulfate,

[a]Data for the type strains; taken from Suzuki at al. (1999) and Qiu et al. (2007).

[b]Symbols: +, positive test reaction; w, weakly positive; −, negative; +/w or w/−, different between experiments.

[c]A negative reaction was observed for all strains with the following carbon sources: L-arabinose, D-arabitol, stachyose, D-tagatose, α- and β-cyclodextrin, *N*-acetyl-β-D-mannosamine, D-alanine sedoeptulosan, α-D-glucose 1-phosphate, D-glucose 6-phosphate, uridine 5′-monophosphate, inulin, lactamide, D-lactic acid methyl ester, D-malic acid, DL-α-glycerol phosphate, glycyl L-glutamic acid, L-pyroglutamic acid, succinamic acid.

and linear-alkyl-benzene-sulfonate (Goodnow and Harrison, 1972). *Leifsonia* species strain S749, reduces phenyl trifluoromethyl ketone to (*S*)-1-phenyltrifluoroethanol (due to production of a novel alcohol dehydrogenase) (Inoue et al., 2005). *Leifsonia* species IS1 (= ATCC BAA-584) isolated from acidic soil is able to grow with naphthalene as a sole carbon source at pH 5.0 and detoxify mercury (Dore et al., 2003).

Two catalase-negative *Leifsonia* strains (ATSB20 and ATSB24) closely related to *Leifsonia shinshuensis* grow on mineral salts medium with D-glucose and some other single carbon sources including methanol (Anandham et al., 2008). The strains are also able to grow chemolithotrophically in a thiosulfate-containing medium, exhibiting growth coupled with thiosulfate oxidation. They accumulate sulfur, sulfite, and trithionate in the spent medium during the time-course of thiosulfate oxidation, and these compounds are finally oxidized into sulfate. The strains possess thiosulfate-metabolizing enzymes such as rhodanese, thiosulfate oxidase, sulfite oxidase, and trithionate hydrolase, suggesting that they use the “S4 intermediate” (S4I) pathway for thiosulfate oxidation which is characteristic of certain obligate and facultative chemolithotrophic S-oxidizing bacteria (Anandham et al., 2008). These examples and some other data available suggest that at least certain representatives of the genus *Leifsonia* are aerobic chemo-organotrophs with a potential for mixotrophy and metabolic flexibility.

Antibiotic susceptibility. The *Leifsonia* species tested to date are sensitive to rifampin (30 μg/ml) (type strain of *Leifsonia aquatica*), doxycycline (5 μg/ml), and erycycline (10 μg/ml) (type strain of *Leifsonia poae*). Both type strains are resistant to the following antibiotics (μg/ml): ampicillin (50), chloramphenicol (10), gentamicin (50), gramicidin G (10), lincomycin (50), neomycin (50), penicillin G (50), rifampin (30), streptomycin (50), and tetracycline (10).

Genomic characteristics. The DNA base ratios reported for *Leifsonia* species ranges from 66 mol% (Davis et al., 1984) to 70.7 mol% (Suzuki et al., 1999). The DNA G+C mol% content for the type strain of *Leifsonia aquatica* is 70.3 as determined by HPLC (Suzuki et al., 1999); in early works, the values 69.3 mol% (T_m) (Yamada and Komagata, 1970) and 73.2 mol% (T_m) (Döpfer et al., 1982) were reported for it. The minimal G+C content, i.e. 66 mol% (T_m), was determined for the type strain of *Leifsonia xyli* subsp. *xyli* (Davis et al., 1984), and 67.7% was calculated for strain *Leifsonia xyli* subsp. *xyli* CTCB07 from the genome sequence (Monteiro-Vitorello et al., 2004). The DNA–DNA hybridization values between the type strains of *Leifsonia* species and subspecies (except for *Leifsonia xyli* subsp. *xyli* for which the data are absent) vary with the technique used, but clearly indicate their separate species status (Evtushenko et al., 2000; Suzuki et al., 1999).

The genome of strain *Leifsonia xyli* subsp. *xyli* CTCB07 consists of a single circular chromosome of 2.58 Mb, of which 70.6% possesses a protein-coding capacity (Monteiro-Vitorello et al., 2004; Ventura et al., 2007). The genome harbors 307 predicted pseudogenes (i.e. gene fragments arising from frame shifts or deletions or caused by point mutations that introduce or remove stop codons, or incomplete genes), which is larger than the numbers of pseudogenes revealed in other actinobacteria, except for *Mycobacterium leprae* (Cole et al., 2001) and all bacterial plant pathogens sequenced to date. The 105 genes for virulence and pathogenicity found in *Leifsonia xyli* subsp. *xyli* present is, by far, the smallest number found in any of the plant-pathogenic bacteria sequenced (Brumbley et al., 2006; Monteiro-Vitorello et al., 2004). The genome of *Leifsonia xyli* subsp. *xyli* CTCB07 has four likely horizontally acquired DNA regions (genomic islands) with deviant G+C contents, codon biases, and dinucleotide signatures, and 3.5% of the genome is occupied by IS-elements of five distinct IS families and transposases (Monteiro-Vitorello et al., 2004; Ventura et al., 2007).

Sequencing of approximately 50% of the *Leifsonia xyli* subsp. *cynodontis* genome identified 56 copies of five distinct IS

elements, which shows that the chromosome contains a larger number of IS copies than the *Leifsonia xyli* subsp. *xyli* genome. Each genome has an unique set of elements although related to the same IS families when considering features such as similarity among transposases, inverted and direct repeats, and element size (Zerillo et al., 2008). A comparative analysis of *Leifsonia xyli* subsp. *cynodontis* and *Leifsonia xyli* subsp. *xyli* IS elements and their detailed characterization have been made by Zerillo et al. (2008). Further information on the *Leifsonia xyli* subsp. *xyli* CTCB07 genome is available from Monteiro-Vitorello et al. (2004); Brumbley et al. (2006), Sutcliffe and Hutchings (2007) and Ventura et al. (2007). Some genomic characteristics of *Leifsonia xyli* subsp. *xyli* related to plant pathogenicity are outlined in the respective section below.

Plasmids. The only known cryptic *Leifsonia* plasmid, pCXC100 (51 kb), has been found in some *Leifsonia xyli* subsp. *cynodontis* strains tested (Li et al., 2004a; Metzler et al., 1992; Taylor et al., 1993). The 5-kb replicon of pCXC100 encodes two proteins essential for plasmid replication and stability; the *RepA* encoding protein is homologous to that of the plasmids in the mycobacterial pLR7 family (Li et al., 2004a; Yin et al., 2006).

Plant pathogenicity and related matters. *Leifsonia xyli* subsp. *xyli* invades vascular systems and causes ratoon stunting (growth-hindering) disease of sugarcane (*Saccharum* interspecific hybrids) worldwide (Davis et al., 1984; Vidaver and Davis, 1988; Young et al., 2006). Infected sugarcane plants show slower growth, look stunted, and have fewer and thinner stalks, while no other reliable external or internal symptoms are typically observed (Davis et al., 1984; Gillaspie and Teakle, 1989). The ratoon stunting disease is difficult to detect in the field, since stunting can be caused by a range of environmental factors (Brumbley et al., 2006; Gillaspie and Teakle, 1989). The disease is considered to be transmitted mechanically or through infected plant materials (Davis et al., 1984; Taylor et al., 1988). This bacterium has not been found to naturally colonize any other grass or to occur free-living in the environment (Brumbley et al., 2006; Gillaspie and Teakle, 1989). In experimental systems, the bacterium was reported to colonize at least 17 plant species, however, with the exception of several *Saccharum spontaneum* clones, these plants remained asymptomatic (Matsuoka, 1971; Mills et al., 2001; Roach and Jackson, 1992; Young et al., 2006). The comprehensive genetic studies of Young et al. (2006) revealed no genetic variation among a large collection of *Leifsonia xyli* subsp. *xyli* isolates, irrespective of sampling time, host cultivar, or country of origin, suggesting the worldwide distribution of a single pathogenic clone (Brumbley et al., 2006; Young et al., 2006).

Exact mechanisms of pathogenicity of *Leifsonia xyli* are largely unknown. The slow growth and other symptoms were believed to be the result of vascular plugging (Kao and Damann, 1978, 1980). It is unclear whether this plugging is caused by substances produced by the bacterium, is a plant defense response, or is a combination thereof (Brumbley et al., 2006). A number of the predicted pathogenicity genes (thought to have been acquired by lateral transfer) encoding, in particular, the cell-wall-degrading enzymes and desaturase, have been found in the genome of *Leifsonia xyli* subsp. *xyli* CTCB07 (Brumbley et al., 2006; Monteiro-Vitorello et al., 2004). The cell-wall-degrading enzymes may be involved in nutrient extraction from the xylem vessels and also may trigger the host defense, the production of the gelatinous material plugging xylem vessels of sugarcane plants infected with *Leifsonia xyli* subsp. *xyli* (Brumbley et al., 2006; Kao and Damann, 1978). A *celA* gene encodes a cellulase similar to CelA of *Clavibacter species*, in which the gene is a plasmid-borne virulence factor (Jahr et al., 2000). The desaturase is assumed to contribute to stunting seen in plants infected with *Leifsonia xyli* subsp. *xyli*, as it may be involved in the synthesis of abscisic acid, a growth inhibitor of plant tissues (Bartley and Scolnik, 1995; Kende and Zeevaart, 1997) which may play a role in the stunting (Brumbley et al., 2006; Ventura et al., 2007). One of the two prophage-like regions in the *Leifsonia xyli* subsp. *xyli* CTCB07 genome carries a homolog of the plasmid-located *pat-1* gene of *Clavibacter michiganensis* subsp. *michiganensis*, which plays a decisive causal role in plant wilting (Dreier et al., 1997). As with other plant pathogens, the *Leifsonia xyli* subsp. *xyli* CTCB07 genome has the potential to encode a number of enzymes (superoxide dismutase, catalase, iron dependent peroxidase, and alkyl hydroperoxide reductase) that would enable the bacterium to resist the reactive oxygen species synthesized as part of the host defense mechanisms (Monteiro-Vitorello et al., 2004). This bacterium also has genes encoding a multidrug efflux pump similar to the AlbF system that allows self-protection of *Xanthomonas albilineans* against the albicidin toxin, presumably aiding survival in the complex ecosystem inhabited by the two organisms (Monteiro-Vitorello et al., 2004).

Leifsonia xyli subsp. *cynodontis* naturally occurs in the xylem vessels of Bermuda grass [*Cynodon dactylon* (L.S. Per)] in Taiwan (Davis et al., 1980, 1984). Under experimental conditions, the bacterium was shown to be pathogenic for Bermudagrass, causing a disease named Bermudagrass stunting disease, which is not known to occur in nature (Davis et al., 1984; Liao and Chen, 1981). In experimental settings, *Leifsonia xyli* subsp. *cynodontis* and its recombinant colonize more than 80 plant species of 26 families without inducing stunting (Fahey et al., 1991; Kostka et al., 1988; Lampel et al., 1994) and may even promote the growth of infected rice plants (Li et al., 2007). *Leifsonia xyli* subsp. *cynodontis* or closely related bacteria identified by the fluorescent antibody direct count on filters were found to be common endophytes of many grasses in eastern Australia (Mills et al., 2001). Several isolates from *Chloris guyana* were shown to be genetically almost identical to the type strain of *Leifsonia xyli* subsp. *cynodontis* (Young et al., 2006).

Although *Leifsonia poae* was isolated from plant galls induced by the plant parasitic nematode *Subanguina radicicola*, there is no clear evidence of plant pathogenic properties of this bacterium per se.

Medically relevant *Leifsonia* species. The genus *Leifsonia* is considered to include some opportunistic pathogens, of which the species *Leifsonia aquatica* ("*Corynebacterium aquaticum*") is most frequently mentioned in publications (Bosshard et al., 2003; Coyle and Lipsky, 1990; D'Amico et al., 2005; Dempsey et al., 2007; Funke and Bernard, 2003; Funke et al., 1994, 1997). *"Corynebacterium aquaticum"* has been described in earlier publications as a cause of disease in humans, e.g. as an etiologic agent of bacteremia, endocarditis, meningitis, peritonitis, and urinary tract infection, or as a cause of pseudobacteremia due to contamination of blood collection tubes (for references, see Funke et al., 1997, 1994). However, many case reports claiming an association of "*Corynebacterium aquaticum*" with human

disease provide inconclusive results. As with other coryneform bacteria of low pathogenicity, the distinction between colonization and infection has not been made in every case (Funke et al., 1997). Further, as shown in numerous studies, both the conventional methods and biochemical panels used for identification give largely ambiguous results with *Leifsonia* species and phenotypically similar organisms (Adderson et al., 2008a; Funke et al., 1994, 1998; Grove et al., 1999; Lau et al., 2002). The assignment of clinical isolates to the genus *Leifsonia* has been supported by 16S rRNA gene analysis in a few cases only. These include clinical strains with 98.2% 16S rRNA gene sequence similarity to *Leifsonia poae* (Bosshard et al., 2003) and isolates from the surface of prosthetic hip joints that are phylogenetically close to *Leifsonia aquatica* and *Leifsonia shinshuensis* (Dempsey et al., 2007). In another case, the sequence determined showed 96.9% sequence similarity to *Leifsonia xyli* (Bosshard et al., 2003). Further taxonomic study of clinical isolates referred to as *Leifsonia* species is necessary to elucidate their generic and species affiliations. Further research is also required for examination of their supposed pathogenicity.

Habitats. Members of the genus *Leifsonia* occur in different environments. The natural habitats of *Leifsonia xyli* subsp. *xyli* and *Leifsonia xyli* subsp. *cynodontis*, as indicated above, are plants (Davis et al., 1984; Mills et al., 2001; Young et al., 2006). *Leifsonia poae* is also associated with plants (Evtushenko et al., 2000) but may occur in plant debris and soil. *Leifsonia aquatica* has been isolated from distilled water supplies and is supposed to occur in natural fresh water (Leifson, 1962). Strains of *Leifsonia naganoensis* and *Leifsonia shinshuensis* have been found in soil (Suzuki et al., 1999). A wide range of unnamed or preliminarily identified organisms exhibiting very high 16S rRNA gene sequence similarities to the recognized *Leifsonia* species have been discovered in various aquatic and terrestrial environments, either neutral, acidic, or alkaline (e.g. Fritz, 2000; Dore et al., 2003; Rickard et al., 2003; Tiago et al., 2004; Otsuka et al., 2008; Graff and Conrad, 2005; Inagaki et al.; (2006). They are also found in association with eukaryotic organisms (e.g. Nakabachi et al., 2003; Evtushenko at al. (2006); Wichels et al., 2006; Nishiwaki et al., 2007) and, as mentioned before, with clinical specimens (Bosshard et al., 2003; Dempsey et al., 2007; Funke et al., 1997).

Enrichment and isolation procedures

The rapidly growing *Leifsonia* strains can be isolated from various environments where they provisionally occur using the dilution plating technique and nutrient media containing peptone and/or yeast extract such as *Corynebacterium* (CB) agar (5 g glucose, 5 g yeast extract, 10 g casein peptone or Casamino acids (Difco), 5 g NaCl, and 15 g agar per liter; pH 7.2), R agar (Yamada and Komagata, 1972b), R2A agar (Difco), the medium developed for cultivation of *Caulobacter* (Leifson, 1962), and some other media. Antibiotics or other growth inhibitors, to which a certain *Leifsonia* species are resistant, may be added to the isolation medium to inhibit the development of other bacteria. Certain media and procedures have been described which were suitable for isolation of not yet identified members of the genus *Leifsonia* or closely related organisms (see, e.g. Janssen et al., 2002; Dore et al., 2003; Nakabachi et al., 2003; Tiago et al., 2004; Wichels et al., 2006; Nishiwaki et al., 2007; Anandham et al., 2008).

For isolation of the slowly growing xylem-associated *Leifsonia xyli*, certain general rules should be followed, among which the choice of suitable material and medium are of primary importance. If nonselective media are used, successful isolation of *Leifsonia xyli* subsp. *xyli* and *Leifsonia xyli* subsp. *cynodontis* requires surface sterilization of plant material and other precautions to avoid or reduce the growth of accompanying bacteria. The nonselective SC medium (Davis et al., 1980) or some selective media (Brumbley et al., 2002; Teakle and Ryan, 1992) can be employed. The following technique has been successfully used for isolation of *Leifsonia xyli* subsp. *xyli* from infected sugarcane (Young et al., 2006). Presumably infected sugarcane is scrubbed clean using scourers and detergent. Stalks are cut into three-eye sets and are immersed in 10% commercial bleach for 10 min, soaked for 10 min in distilled water, rinsed in distilled water, sprayed with 70% ethanol, and flame-sterilized. The end nodes are then excised and the xylem fluid from the central node and internodes is pressed out using positive sterile air pressure and collected in sterile sample tubes. A small amount of the xylem fluid is placed on a microscope slide and examined for *Leifsonia xyli* subsp. *xyli* cells using phase-contrast microscopy, their presence being taken as evidence of infection. Approximately 100 μl of xylem exudate is spread on modified M-SC plates (Brumbley et al., 2002) and incubated at 28°C for 4 weeks or longer. Any contaminants are excised daily and, once visible, *Leifsonia xyli* subsp. *xyli* colonies are restreaked onto fresh medium until only colonies of *Leifsonia xyli* subsp. *xyli* are present. Pure cultures are established by serial plating of single colonies as described by Brumbley et al. (2002). For isolation of *Leifsonia xyli* subsp. *cynodontis*, a selective complex SCMS medium has been developed (Davis and Augustin, 1984).

Maintenance procedures

Strains of the genus *Leifsonia* can be freeze-dried and preserved in liquid nitrogen by standard procedures. Different media, depending on growth requirement of certain species, are used. Pure cultures of *Leifsonia xyli* subsp. *xyli* grown in S8 broth (Davis et al., 1984; Haynes and Britz, 1989) with 0.05–0.1% (w/v) of glycine can be maintained in glycerol stocks at −80°C (Brumbley et al., 2002).

Differentiation of the genus *Leifsonia* from other genera

Phenotypic characteristics that delineate *Leifsonia sensu stricto* species from other genera of the family *Microbacteriaceae* are listed in Table 140. As the *Leifsonia* species are similar to some other genera of the family *Microbacteriaceae* in morphological and key chemotaxonomic characters, a phylogenetic analysis based on 16S rRNA gene sequences is necessary to enable differentiation of *Leifsonia* from other genera and consequently achieve clear-cut identification of an isolate. It should be emphasized that representatives of the genus *Leifsonia sensu stricto* are expected to fall into a coherent 16S rRNA-based phylogenetic cluster which includes the type species *Leifsonia aquatica*. When an isolate is found to be loosely associated with the *Leifsonia sensu stricto* cluster, identification can be achieved by the detailed comparative analysis of other conserved genes, e.g. encoding 23S rRNA or 16S–23S rRNA intergenic spacer sequences (ITS) and the phenotype including chemotaxonomic characteristics. The following chemotaxonomic characteristics are essential: the cell-wall peptidoglycan structure

(or at least the quantitative amino acid composition, including the ratio of D-and L-isomers of Dab), the composition of menaquinones, fatty acids, polar lipids, and, probably, polyamines. The analytical methods to determine such characteristics have been reviewed by Schumann et al. (2009).

Taxonomic comments

As indicated in the *Further descriptive information* section, the genus *Leifsonia* represents a phylogenetically rather heterogeneous taxon. Along with the *Leifsonia sensu stricto* species considered before, the genus includes six species (*Leifsonia aurea*, *Leifsonia bigeumensis*, *Leifsonia ginsengi*, *Leifsonia kribbensis*, *Leifsonia pindariensis* and, *Leifsonia rubra*) branching outside the phylogenetic radiation of *Leifsonia sensu stricto* (Figure 187 and Figure 173). The available data tend to suggest that these species are also distinct from *Leifsonia sensu stricto* at the phenotypic level (Table 158), although the currently available evidence for some species seems inconclusive. Thus, the above-mentioned six species might be regarded as species *insertae sedis* at present, until their taxonomic status has been re-examined. Some details concerned with the taxonomic and nomenclature issues, along with the history of the genus, are outlined below.

The first clearly documented representative of the genus *Leifsonia* was strain 150 (= ATCC 14665), described by E. Leifson (1962) as the type strain of a new species "*Corynebacterium aquaticum*". Subsequent extensive taxonomic studies (Collins et al., 1979; Collins and Jones, 1980; Döpfer et al., 1982; Komura et al., 1975; Park et al., 1987; Schleifer and Kandler, 1972; Yamada and Komagata, 1972a; Yamada et al., 1976) have shown its relatedness to organisms with group B peptidoglycan and hence assigned subsequently to the family *Microbacteriaceae* (Park et al., 1993, 1995). Based on 16S rRNA gene analysis, Rainey et al. (1994) suggested that this bacterium represents the nucleus of a novel genus. Takeuchi and Yokota (1994) and Sasaki et al. (1998) showed its close phylogenetic relatedness to *Clavibacter xyli* subsp. *cynodontis* which, along with *Clavibacter xyli* subsp. *xyli* and other plant-pathogenic bacteria with diamino butyric acid (Dab) in the cell wall, had been described as a member of the genus *Clavibacter* (Davis et al., 1984). The similarity of "*Corynebacterium aquaticum*" JCM 1368 and the type strain of *Clavibacter xyli* subsp. *cynodontis* in the cell-wall peptidoglycan amino acids (in particular, the presence of both L- and D-isomers of Dab) and the predominant menaquinones, which are in fairy good accord with the 16S rRNA phylogeny, led Sasaki and colleagues

TABLE 158. Characteristics differentiating species of the genus *Leifsonia*[a,b,c]

Characteristic	*Leifsonia* spp. (*sensu stricto*)	*L. aurea*	*L. bigeumensis*	*L. ginsengi*	*L. kribbensis*	*L. pindariensis*	*L. rubra*
Colony color	White to yellow or pale brown	Yellow	Yellow	White to yellow	Yellow	Yellow	Red or reddish
Cell morphology[d]	Short rods to filaments[e]	Curved rods	Short rods	Straight or curved rods	Straight to curved rods	Short rods	Curved rods
Motility	D+	−	+	−	+	+	−
Growth temperature (°C)[f]	26–30 (4–42)	22 (0–30)	28 (20–37)	26–30 (4–37)	28 (20–37)	~28	15 (0–22)
Catalase test	+	+	−	+	−	+	+
Salt requirement	−	−	+	−	−	−	−
Rhamnose in cell wall	+	−	+	+	+	+	+
Major menaquinones	MK-11, 10 or MK-11, 12	MK-11	MK-11	MK-11	MK-12, 11	MK-11	MK-11
Major (>10%) fatty acids:[g]							
$C_{15:0}$ anteiso	24.1–47.3[h]	43.7	36.0	19.6	19.7	54.3	37.5
$C_{17:0}$ anteiso	32.6–54.4[h]	28.5	18.2	10.5	(6.8)	19.1	20.3
$C_{16:0}$ iso	10–21	(5.0)	38.9	(8.3)	43.4	(6.8)	11.5

Polar lipids[i]	GPG, PG, GLs		GPG, PG, GLs		DPG, PG, ULs	PG, DPG, UL	
DNA G+C content (mol%)	67.7–70.7[j]	64 (T_m)	69 (T_m)	66.4 (T_m)	73.4 (T_m)		66 (T_m)

[a]Data compiled from publications cited in Table 156 and from Dastager et al. (2008c, 2009); Qiu et al. (2007); and Reddy et al. (2008, 2003c).

[b]See also Figure 187 for phylogenetic clustering.

[c]Symbols: +, positive or present; −, negative or absent; D, different between species (character for the type species is indicated).

[d]Cell morphology is given in accordance with the species descriptions or the micrographs available (*Leifsonia kribbensis*).

[e]Cells or cell ends of some species become thicker and may reach up to 0.8–0.9 µm in diameter.

[f]Optimal temperature and temperature range for growth (in parentheses).

[g]See the species descriptions for details.

[h]Different amounts of $C_{15:0}$ anteiso (66%) and $C_{17:0}$ anteiso (15%) were reported for the type strain of *Leifsonia aquatica* grown at 20°C (below the temperature optimum).

[i]DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; GLs, unknown glycolipids; UL(s), unknown lipid(s).

[j]See Table 156 for details.

(Sasaki et al., 1998) to the conclusion that a new genus should be established to accommodate these two strains. Besides, close phylogenetic relatedness of the two *Clavibacter xyli* subspecies, *Clavibacter xyli* subsp. *xyli* and *Clavibacter xyli* subsp. *cynodontis* was reported (Lee et al., 1997).

The description of the genus *Leifsonia* with the type species *Leifsonia aquatica* was almost simultaneously published by two research groups on the basis of comparative taxonomic study of different strains isolated from soil (Suzuki et al., 1999, 2000) and nematode-induced plant galls on *Poa annua* (Evtushenko et al., 2000). The genus name *Leifsonia* and binominal *Leifsonia aquatica* proposed by Evtushenko et al. (2000) were accepted as having priority according to the Bacteriological Code. Along with the proposal of *Leifsonia aquatica* and *Leifsonia poae*, Evtushenko at al. (2000) formally transferred *Clavibacter xyli* with two subspecies to the genus *Leifsonia* as new combinations (*Leifsonia xyli*, *Leifsonia xyli* subsp. *xyli*, and *Leifsonia xyli* subsp. *cynodontis*). Suzuki and colleagues (Suzuki et al., 1999) described the species *Leifsonia aquatica*, *Leifsonia naganoensis*, and *Leifsonia shinshuensis*, and reclassified *Clavibacter xyli* subsp. *cynodontis* as *Leifsonia cynodontis*. The reclassification was proposed in view of unavailability of the type strain of *Clavibacter xyli* (and *Clavibacter xyli* subsp. *xyli*) strain L1A^T [= NCPPB 3152 = PDDCC 7127 (ICMP 7127) = ATCC 33974 = LMG 7352] either from public culture collections or the authors of the species description (Davis et al., 1984).

Elevation of both subspecies of *Leifsonia xyli* to species level is not in disagreement with the 16S rRNA gene sequence similarity of *Leifsonia xyli* subsp. *xyli* and *Leifsonia xyli* subsp. *cynodontis*. Although rather high (>99.5% identity), similar values have been reported for many closely related species of the family *Microbacteriaceae*. As deduced from analysis of respective sequences available in GenBank, the similarity value (~85%) of the 16S–23S rRNA ITS region and the similarity value (~95.5%) of concatenate sequences of 16S rRNA gene sequences, 16S–23S rRNA ITS, and partial 23S rRNA gene sequences (total of ~2100 nucleotides) of these subspecies are also in the ranks of those found between other *Leifsonia* species. The *Leifsonia xyli* subspecies, according to Davis et al. (1984), are also distinguishable by their characteristic protein bands in polyacrylamide gels, some phenotypic characteristics (Table 156), and their pathogenic properties (each can induce symptoms in its natural host but not in the natural host of the other subspecies). Further taxonomic studies (paying attention to availability/unavailability of the nomenclatural type for *Leifsonia xyli*), could justify the separate species status of *Leifsonia xyli* subsp. *xyli* and *Leifsonia xyli* subsp. *cynodontis*. If the type strain cannot be recovered, a neotype strain of *Leifsonia xyli* has to be described according to the Bacteriological Code. A potential candidate for the neotype could be *Leifsonia xyli* subsp. *xyli* CTCB07 of which the complete genome sequence is now available (Monteiro-Vitorello et al., 2004) or another strain chosen among the genetically almost identical isolates (Young et al., 2006) which is better adapted for growth in culture.

Some other taxonomic and nomenclature comments are concerned with the species *Leifsonia aurea*, *Leifsonia bigeumensis*, *Leifsonia ginsengi*, *Leifsonia kribbensis*, *Leifsonia pindariensis*, and *Leifsonia rubra* which are here regarded as species *insertae sedis*. Among these species, *Leifsonia aurea*, *Leifsonia pindariensis*, and *Leifsonia rubra*, show more close phylogenetic relatedness to other genera: *Leifsonia aurea* and *Leifsonia rubra* are intermixed with species belonging to the genera *Rhodoglobus* (Sheridan et al., 2003) and *Salinibacterium* (Han et al., 2003), while *Leifsonia pindariensis* forms a very tight phylogenetic group with the genera *Microterricola* (Matsumoto et al., 2008) and *Phycicola* (Lee et al., 2008).

Different phenotypic characteristics recorded along with different interpretations of results of the 16S rRNA gene sequence comparisons, lead the authors of the descriptions of above-mentioned *Leifsonia* species and the closely related genera to discrepant taxonomic conclusions. In particular, Reddy et al. (2003c) found their strains to possess key chemotaxonomic characteristic of *Leifsonia* and described two novel species *Leifsonia aurea* and *Leifsonia rubra*. Sheridan et al. (2003), unaware of the above description, decided in favor of creating a novel genus and species, *Rhodoglobus vestalii*, for their isolate that is closely related to *Leifsonia rubra* (>99% 16S rRNA gene sequence identity). Sheridan et al. (2003) revealed a number of phenotypic characteristics that clearly distinguished *Rhodoglobus vestalii* from *Leifsonia* species and related genera. Those include small rods with unusual bulbous protuberances, the cell-wall peptidoglycan with ornithine as the diamino acid, and the menaquinone system with predominant MK-12 (65%) and MK-11 (35%) as well as a low G+C content (62 mol%). Both research groups also indicated the presence of a nearly identical 13 bp and 14 bp insertion in the 16S rRNA gene sequences of their strains that is absent in any of the type strains of *Leifsonia (sensu stricto)* species. They, however, ascribed different taxonomic significance to this fact.

Similarly, without being aware of the recent proposal of *Leifsonia pindariensis* and the emended description of the genus *Leifsonia* (Reddy et al., 2008), two other research groups independently established two different genera, *Phycicola* (Lee et al., 2008) and *Microterricola* (Matsumoto et al., 2008) to accommodate their soil and sewage isolates closely related to *Leifsonia pindariensis*. Along with phylogenetic distinction, the authors, who described the above-mentioned genera, stressed phenotypic differences of their strains from the *Leifsonia sensu stricto* species (Table 140). For instance, the major menaquinone MK-12 (69%), followed by MK-11 (21%) and MK-13 (10%) were indicated for *Microterricola viridari*, and an unusual life cycle with budding-like process and the polar lipid pattern with phosphatidylinositol and phosphatidylcholine were reported for *Phycicola gilvus*. However, re-examination of the polar lipids would be highly desirable because members of the *Microbacteriacea* are quite homogeneous in their polar lipid profiles and the presence of phosphatidylinositol and phosphatidylcholine is so far unique among members of the family. In addition, both *Microterricola viridari* and *Phycicola gilvus*, like *Leifsonia pindargiensis*, appear to differ from the *Leifsonia sensu stricto* species in the predominant fatty acids (increased amounts of $C_{15:0}$ anteiso and lower content of $C_{17:0}$ anteiso and $C_{16:0}$ iso). It is worth noting here that, although the quantitative fatty acid profiles are commonly considered to be unreliable for differentiation of closely related genera, the proportion of predominant fatty acids in *Leifsonia bigeumensis* and *Leifsonia kribbensis* are clearly beyond the range obtained for the *Leifsonia sensu stricto* species determined in cells grown at optimal temperature, irrespectively of the growth medium, culture age, and analytical procedure (Collins and Jones, 1980; Evtushenko et al., 2000; Suzuki and Komagata, 1983; Suzuki et al., 1999). Taken together, all the above data evidence that *Leifsonia aurea*, *Leifsonia pindariensis*,

and *Leifsonia rubra* will be reclassified as members of the phylogenetically closely related genera mentioned.

It should also be emphasized in this context that, according to An and Yokota (2007), the type strain of *Leifsonia rubra* is not available from any established culture collection nor from the authors who described this species (Reddy et al., 2003c). The strains received by An and Yokota (2007) from the culture collections (MTCC 4210, JCM 12417, CIP 107783, DSM 15304) and obtained from the authors (CMS 76r) belong to two different taxa. From the 16S rRNA gene sequence analyses, these are affiliated with *Arthrobacter roseus* (Reddy et al., 2002) and the *Gammaproteobacteria*. It was suggested that the Judicial Commission considers placing the name *Leifsonia rubra* on the list of rejected names if the strain is not found or a neotype is not proposed within 2 years (An and Yokota, 2007).

Note added in proof: after the Request for an Opinion by An and Yokota (2007), the original authors deposited the type strain in the BCCM/LMG culture collection as LMG 24410. According to the LMG, the strain LMG 24410 is authentic. The culture whose authenticity was confirmed by 16S rRNA gene sequencing by the JCM, was also deposited in JCM as JCM 15064. See An and Yokota (2007) and J.P. Euzéby's List of Prokaryotic Names with Standing in Nomenclature (http://www.bacterio.cict.fr/) for more details.

Each of the remaining *insertae sedis* species, i.e. *Leifsonia bigeumensis*, *Leifsonia ginsengi*, and *Leifsonia kribbensis*, does not form a robust 16S rRNA-based phylogenetic cluster with the genus *Leifsonia sensu stricto* or any other genus in the family *Microbacteriaceae*. The phylogenetic distinctness of these species from *Leifsonia sensu stricto* is accompanied by some distinct phenotypic properties, for instance, the negative catalase reaction (indicative of the presence of different factors preventing oxygen damage), major menaquinones, predominant fatty acids, polar lipid pattern, and the DNA base ratio (Table 158). The study of some other characteristics which are not yet determined for *Leifsonia bigeumensis*, *Leifsonia ginsengi*, and *Leifsonia kribbensis*, might provide additional differentiating traits. These include the cell-wall peptidoglycan structure (or at least the quantitative amino acid composition, including the ratio of D-and L-isomers of diaminobutyric acid), acyl type of muramic acid (glycolate test), polyamine amount and composition, detailed polar lipid and menaquinone patterns, and probably some other characteristics at the epigenetic level that delineate genera in other bacterial groups.

It is thus apparent that the current taxonomy of the genus *Leifsonia* is in need of extensive revision, aiming at improvement of phylogenetic and phenotypic coherency in clustering of newly described species. One may note here that the main trend in improving classification schemes of many bacterial groups, including genera of the order *Actinomycetales*, involves the dissecting of polyphyletic and phenotypically heterogeneous genera into monophyletic genera accompanied by more focused circumscription using genomic and epigenetic characteristics (Stackebrandt, 2006, and more recent publications in IJSEM).

Differentiation of species of the genus *Leifsonia*

The phenotypic characteristics useful for the differentiation of the *Leifsonia sensu stricto* species and subspecies are listed in Table 156 and Table 157. The source of isolation (sugarcane with the typical symptoms of stunting disease or other plants where they provisionally occur) and special techniques of purposeful isolation of the xylem-inhabiting *Leifsonia xyli* strains are prerequisites for the assignment of an isolate to *Leifsonia xyli*. Slow growing, slender, elongated Gram-stain-positive rods which show a tendency to coryneform morphology and do not grow on standard nutrient media, e.g. R medium (Suzuki et al., 1999), can be preliminarily and tentatively identified as members of *Leifsonia xyli* subsp. *xyli* or *Leifsonia xyli* subsp. *cynodontis*. The 16S–23S ITS sequence analysis (Fegan et al., 1998; Pan et al., 1998; Young et al., 2006) and the BOX and ERIC PCR fingerprinting (Young et al., 2006) are very useful to achieve a further sharper differentiation of *Leifsonia* species and subspecies. Some techniques and primers developed to detect the ratoon stunting disease of sugarcane (see Brumbley et al., 2006, for references) can be also employed to differentiate *Leifsonia xyli* subsp. *xyli* and *Leifsonia xyli* subsp. *cynodontis*.

The phenotypic characters differentiating the *Leifsonia insertae sedis* species from each other and from the *Leifsonia sensu stricto* group are listed in Table 158. Considering the descriptions of the genera *Microterricola*, *Phycicola*, *Rhodoglobus*, and *Salinimicrobium* is advisable when an isolate is phylogenetically close to *Leifsonia aurea*, *Leifsonia pindariensis*, or *Leifsonia rubra*.

Acknowledgements

This work was supported by the program MCB of the Russian Academy of Sciences. The contribution of Dr V.N. Akimov to the phylogenetic analysis of *Leifsonia* is deeply appreciated.

List of species of the genus *Leifsonia*

1. **Leifsonia aquatica** (*ex* Leifson 1962) Evtushenko, Dorofeeva, Subbotin, Cole and Tiedje 2000, 377[VP] (*Corynebacterium aquaticum* Leifson 1962, 161)

a.qua′ti.ca. L. fem. adj. *aquatica* pertaining to water, the source of isolation of the type strain of this species.

The description is based on information taken from Leifson (1962), Suzuki et al. (1999), and Evtushenko et al. (2000) unless indicated otherwise.

Cells are irregular rods (generally 0.4–0.5 × 1.2–2.5 µm) in 2-d cultures, tending to form primary branching and V-arrangements. In older cultures, short rods and coccoid cells predominate and occur singly, in pairs, or sometimes in short chains or clumps. A distinct rod–coccoid cycle may be observed on some media. Motile by long peritrichous flagella (10 µm or more). Colonies are circular, somewhat convex, glossy, and opaque, with entire margin. The colony color is white to yellowish white in young culture, becoming pale yellow on R agar or deep yellow on CB agar with age due to production of a light-enhanced carotenoid pigment (Trutko et al., 2005).

Obligatory aerobe. Catalase-positive; oxidase reaction is variable. Growth occurs at 7–37°C; optimum is ~26–30°C. Adonitol, cellobiose, dulcitol, D-fructose, D-galactose, D-glucose, glycerol, inositol, lactose, maltose, D-mannitol,

D-mannose, melezitose, melibiose, L-rhamnose, salicin, L-sorbose, sucrose, trehalose, turanose, and D-xylose are used for growth as carbon sources on basal mineral medium (Shirling and Gottlieb, 1966) supplemented with 0.1% (w/v) yeast extract and 0.1% (w/v) casitone. D-Arabinose, D-fucose, inulin, lyxose, *meso*-erythritol, raffinose, ribose, and sorbitol are not used as carbon sources on the same medium. Acids are produced from D-arabinose, D-fructose, D-glucose D-galactose, D-mannose, sucrose, D-xylose, and sorbitol (weakly) but not from D-lactose, melibiose, D-raffinose, tagatose, inositol, and inulin. The acid production from some carbohydrates is rather weak and the test results vary with experiments (Evtushenko et al., 2000; Leifson, 1962; Suzuki et al., 1999; Yamada and Komagata, 1972b). Acetate, citrate, malate, and pyruvate are assimilated, but formate, succinate, oxalate, and tartrate are not. H_2S is produced from peptone. Nitrate is reduced to nitrite. DNA, Tween 40, and starch are hydrolyzed; casein, cellulose, gelatin, hypoxanthine, xanthine, tyrosine, Tween 60, Tween 80, and urea are not hydrolyzed or decomposed. Esculin is decomposed, but the test result may vary with the method used (Evtushenko et al., 2000; Funke et al., 1994; Suzuki et al., 1999). Methyl red and Voges–Proskauer tests are negative. The type strain tolerates up to 5% (w/v) NaCl and 0.02% (w/v) potassium tellurite. The data on utilization of various carbon sources with the Biolog test system are listed in Table 157.

The major menaquinones are MK-11 and MK-10. Cell-wall sugars include a predominant amount of rhamnose and minor amounts of fucose, mannose, glucose, and galactose. The principal polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and two characteristic glycolipids (glycosyldiacylglycerols) (Collins and Bradbury, 1986; Collins and Jones, 1980).

Source (type strain): distilled water.

DNA G+C content (mol%): 70.3 (HPLC), 69.3 (T_m).

Type strain: 150, ATCC 14665, CCUG 27700, CIP 64.13, DSM 20146, JCM 1368, NBRC 15710, NCIMB 9460, VKM Ac-1400.

Sequence accession no. (16S rRNA gene): D45057X77450.

2. **Leifsonia naganoensis** Suzuki, Suzuki, Sasaki, Park and Komagata 2000, 1415[VP] (Effective publication: Suzuki, Suzuki, Sasaki, Park and Komagata 1999, 260.)

na.ga.no.en′sis. N.L. fem. adj. *naganoensis* pertaining to the Nagano Prefecture, Japan, the geographical origin of the type strain of this species.

Cells are irregular rods (generally 0.3–0.5 × 1.8 to 3.0 µm in a 2-d culture). Colonies on R agar are glossy, smooth, with entire margin. White colonies of a 2-d culture become pale brown in old culture at 30°C.

Obligatory aerobe. Catalase-positive; oxidase-negative. Weak growth occurs at 37°C and no growth at 42°C. Acid is produced from glucose, fructose, galactose, maltose, mannose, L-rhamnose, melibiose, sucrose, D-trehalose, D-xylose, glycerol, mannitol, salicin, and amygdalin, but not from inulin. Fumarate, lactate, malate, *n*-butyrate, and pyruvate are assimilated, but formate, citrate, succinate, and propionate are not. Starch and DNA are hydrolyzed. Gelatin is not hydrolyzed. Nitrate is not reduced to nitrite. No growth is observed on R agar containing 5% NaCl. The data on utilization of various carbon sources with the Biolog test system are presented in Table 157. The predominant menaquinones are MK-11 and MK-10.

Source: a forest soil sample, Japan.

DNA G+C content (mol%): 70.5 (HPLC).

Type strain: DB103, CCUG 51931, CIP 106799, DSM 15166, JCM 10592, NBRC 103131.

Sequence accession no. (16S rRNA gene): DQ232612.

3. **Leifsonia poae** Evtushenko, Dorofeeva, Subbotin, Cole and Tiedje 2000, 378[VP]

po′a.e. N.L. gen. n. *poae* of *Poa*, generic name of the annual meadow grass *Poa annua*, the source of the type strain of this species.

The description is based on information taken from Evtushenko et al. (2000) and recent observations unless indicated otherwise.

The young culture (16–24 h) on CB agar displays slender, straight or slightly curved long cells or filaments which are occasionally branching and resemble rudimentary mycelium of some *Agromyces* species. The cell width is generally 0.4–0.6 µm, but sometimes cells appear polymorphic and with swells in the middle or at the ends and reach up to 0.8–0.9 µm in diameter. After 3–4 d cultivation, they break up into shorter irregular fragments (length 2.0–2.5 µm) which are usually motile. The motion type is similar to that of *Leifsonia aquatica*, assuming that *Leifsonia poae* also has peritrichous flagella. In older cultures, short pleomorphic rods are predominant and occur singly, in pairs, or in short chains with diphtheroid arrangements. Colonies are circular, somewhat convex, glistening, opaque, and with entire margins on CB agar. The colony color is white or yellowish white in young cultures to deep yellow with age due to production of a light-enhanced carotenoid pigment (Trutko et al., 2005). Growth occurs at 4–37°C; optimum growth is at 24–28°C.

Aerobic. Catalase-positive; oxidase reaction is variable between experiments (negative or weakly positive). D-Glucose, D-arabinose, cellobiose, D-fructose, D-galactose, lactose, maltose, D-mannose, raffinose, L-rhamnose, sucrose, D-xylose, glycerol, dulcitol, D-mannitol, methyl-α-D-glucopyranoside, and salicin are used as carbon sources on basal mineral medium (Shirling and Gottlieb, 1966) supplemented with 0.1% (w/v) yeast extract and 0.1% (w/v) casitone. D-Fucose, lyxose, melezitose, sorbose, ribose, trehalose, adonitol, *meso*-erythritol, inositol, sorbitol, dextran, and inulin are not assimilated on the same medium. In conventional tests, acids are produced from D-arabinose, D-fructose, D-galactose, mannose, and sucrose, but not from melibiose. Malate, malonate, and propionate are utilized, but no alkaline reaction is registered with citrate, formate, fumarate, gluconate, oxalate, succinate, or tartrate. H_2S is produced from cysteine but not from peptone. Esculin and gelatin (weakly) are decomposed. Casein, hypoxanthine, xanthine, starch, tyrosine, Tweens 40, 60, and 80 are not hydrolyzed. The data on utilization of various carbon sources with the Biolog test system (Qiu et al., 2007) are presented in Table 157. No growth is observed in the presence of up to 5% (w/v) NaCl; tolerant to potassium tellurite at 0.02% (w/v).

Cell-wall sugars are predominantly rhamnose and minor amounts of glucose, galactose, and mannose. The major menaquinone is MK-11 followed by MK-10. The polyamine

pattern includes putrescine (51.6%) as a predominant component and minor amounts of spermine (18.6%), tyramine (12.5%), spermidine (10.9%), and cadaverine (3.1%) (Altenburger et al., 1997).

Source: Poa annua root gall induced by the grass root gall nematode *Subanguina radicicola*.

DNA G+C content (mol%): 69.5 (T_m).

Type strain: DL89, CCUG 47140, CIP 106654, DSM 15202, JCM 11952, NBRC 103069, VKM Ac-1401.

Sequence accession no. (16S rRNA gene): AF116342, AM410682.

4. **Leifsonia shinshuensis** Suzuki, Suzuki, Sasaki, Park and Komagata 2000, 1415[VP] (Effective publication: Suzuki, Suzuki, Sasaki, Park and Komagata 1999, 260.)

shin.shu.en′sis. N.L. fem. adj. *shinshuensis* of or belonging to Shinshu, the old name of Nagano Prefecture, Japan, the geographical origin of the type strain of this species.

Cells are irregular rods, generally 0.3–0.4 × 2.5–3.0 µm in a 2-d culture. Colonies on R agar are glossy, smooth, and with entire margins, having white color in a 2-d culture and becoming pale brown in older culture at 30°C.

Obligatory aerobe. Catalase-positive; oxidase-negative. Growth occurs at 42°C but not at 45°C. Nitrate is not reduced to nitrite. Acid is produced from fructose, glycerol, and inulin, but not from D-glucose, galactose, maltose, mannose, melibiose, L-rhamnose, sucrose, D-trehalose, D-xylose, mannitol, salicin, and amygdalin. Lactate, formate, fumarate, malate, pyruvate, succinate, and propionate are utilized, but citrate and *n*-butyrate are not. Starch is hydrolyzed but casein, gelatin, and DNA are not. The data on utilization of various carbon sources with the Biolog test system are presented in Table 157. The predominant menaquinones are MK-11 and MK-12.

Source: forest soil, Japan.

DNA G+C content (mol%): 70.7 (HPLC).

Type strain: DB 102, CIP 106805, DSM 15165, JCM 10591, NBRC 103132.

Sequence accession no. (16S rRNA gene): DQ232614.

5. **Leifsonia xyli** (Davis et al. 1984) Evtushenko, Dorofeeva, Subbotin, Cole and Tiedje 2000, 378[VP] *(Clavibacter xyli* Davis, Gillespie, Vidaver and Harris 1984, 114)

xy′li. Gr. n. *xulon* wood; N.L. gen. n. *xyli* of wood, intended to mean of the xylem.

The description is based on information taken from Davis et al. (1984) unless indicated otherwise.

Cells are typically slender, straight or slightly curved rods, frequently arranged in V-like forms. Colonies are colorless to yellow on SC agar. Obligate aerobes. Catalase-positive; oxidase-negative. Optimal growth occurs at 26–30°C; no growth is observed at 37°C. Nutritionally very exacting. Acids are produced from oxidative fermentation of glucose and some other carbohydrates. Shows weak hydrolytic activities in conventional tests.

Naturally occurs in sugarcane (*Saccharum* interspecific hybrids), Bermudagrass [*Cynodon dactylon* (L.) Pers.], and some other plants (Davis et al., 1984; Young et al., 2006). Strains of this species are known to be casual agents of stunting (growth-hindering) diseases in their natural host plants.

The species *Leifsonia xyli* is subdivided into the two subspecies, *Leifsonia xyli* subsp. *xyli* and *Leifsonia xyli* subsp. *cynodontis*.

DNA G+C content (mol%): 66 (T_m) – 69 (HPLC).

Type strain: L1A, ATCC 33974, ICMP 7127, LMG 7352, NCPPB 3152, PDDCC 7127.

Sequence accession no. (16S rRNA gene): not available.

Additional comments: according to Suzuki et al. (1999) the type strain of this species and subspecies is not available from the ATCC, ICMP, LMG, and NCPPB collections or from the authors who described this species (see the *Taxonomic comments* section).

5a. **Leifsonia xyli subsp. xyli** (Davis et al. 1984) Evtushenko, Dorofeeva, Subbotin, Cole and Tiedje 2000, 378[VP] (*Clavibacter xyli* subsp. *xyli* Davis, Gillespie, Vidaver and Harris 1984, 114)

xy′li. Gr. n. *xulon* wood; N.L. gen. n. *xyli* of wood, intended to mean of the xylem.

The description is based on information taken from Davis et al. (1984) unless indicated otherwise.

Slender, straight or slightly curved rods, approximately 0.2 µm in diameter and 1.2–2.0 µm in length as measured on electron micrographs (Brumbley et al., 2006; Davis et al., 1984). A living bacterium has most likely slightly larger cells because samples for electron microscopy were dried as part of the fixation process (Brumbley et al., 2006). Longer cells, up to 5–6 µm, have been observed (Davis et al., 1984). These probably consist of divided cells remaining together after septum formation as shown on the micrograph provided by Brumbley et al. (2006) and our own microscopic observation of the other subspecies, *Leifsonia xyli* subsp. *cynodontis*. Cells can have swelling on one end and show V-arrangements. Motility by means of flagella is not observed. Colonies are colorless on SC agar, glossy, smooth, and circular with entire margins.

Obligately aerobic; aerobic growth is not stimulated by increased CO_2 concentration. Catalase-positive; oxidase-negative. Nitrate and nitrite are not reduced. Optimal growth occurs at 26–30°C; no growth is typically observed at 32°C. Acid is produced oxidatively from glucose, maltose, starch, and dextrin in conventional tests; no acid production from arabinose, cellobiose, fructose, galactose, lactose, melibiose, melezitose, raffinose, rhamnose, sucrose, xylose, adonitol, dulcitol, geraniol, inositol, sorbitol, ethanol, propanol, β-methyl-D-glucoside, esculin, arbutin, inulin, and salicin. Indistinct results (weak reactions) were observed with mannose, trehalose, glycerol, and α-methyl-D-glucoside. Casein, corn oil, esculin, gelatin, starch, Tween 20, Tween 80, tyrosine, and urea are not decomposed. KCN is tolerated at a concentration of 0.0075%. Acetoin is produced, but H_2S, indole and ammonium from peptone are not formed. Acetate, acetamide, anthranilate, benzoate, citrate, citroaconate, formate, fumarate, galacturonate, gluconate, glucuronate, glycolate, *p*-hydroxybenzoate, β-hydroxybutyrate, lactate, levulinate, malate, maleic acid, malonate, oxalate, propionate, saccharate, succinate, *m*-tartrate, and tryptamine are not utilized.

Invades vascular systems of sugarcane (*Saccharum* interspecific hybrids) and causes ratoon stunting disease of this

plant. Colonizes many other plants in experimental settings, occasionally inducing similar disease in *Saccharum* species (Gillaspie and Teakle, 1989; Matsuoka, 1971; Mills et al., 2001; Roach and Jackson, 1992; Young et al., 2006).

Source: sugarcane (*Saccharurn* interspecific hybrids), Louisiana, USA.

DNA G+C content (mol%): 66 (T_m).

Type strain: L1A, ATCC 33974, ICMP 7127, LMG 7352, NCPPB 3152, PDDCC 7127.

Sequence accession no. (16S rRNA gene): not available.

Additional comments: according to Suzuki et al. (1999) the type strain of this species and subspecies is not available from the ATCC, ICMP, NCPPB, and LMG collections or from the authors who described this species (see the *Taxonomic comments* section).

5b. **Leifsonia xyli subsp. cynodontis** (Davis et al. 1984) Evtushenko, Dorofeeva, Subbotin, Cole and Tiedje 2000, 378[VP] (*Clavibacter xyli* subsp. *cynodontis* Davis, Gillaspie, Vidaver and Harris 1984, 114)

cy.no.don′tis. N.L. n. *Cynodon* genus of Bermudagrass; N.L. gen. n. *cynodontis* of Bermudagrass.

The description is based on information taken from Davis et al. (1984), Suzuki et al. (1999), Evtushenko et al. (2000), and recent observations, unless indicated otherwise.

Slender, straight or slightly curved rods, generally, 0.4 × 3.0–4.0 µm in a 2-d culture, tending to form primary branching. In older cultures, shorter cells (approximately 1.5–2.0 µm) predominate and occur singly or in pairs, or can be disposed at an angle to each other, giving V-forms. Divided cells frequently remain together after septum formation and thus may look appreciably longer (up to 5–6 µm). Cells can have swelling on one end. Colonies on SC agar are glossy, smooth, circular, with entire margins, and pale yellow in a weak culture at 28–30°C. The pigmentation intensifies with the age of culture.

Obligate aerobes. Growth is not stimulated by increased CO_2 concentration. Catalase-positive. Oxidase-negative. Optimal growth occurs at 26–30°C; no growth is observed at 37°C. Oxidative acid production from glucose, mannose, maltose, trehalose, glycerol, mannitol, dextrin, and starch; no acid production was observed in conventional tests from arabinose, cellobiose, fructose, galactose, lactose, melibiose, melezitose, raffinose, rhamnose, ribose, sucrose, xylose, adonitol, dulcitol, inositol, sorbitol, ethanol, propanol, propylene glycol, α-methyl-D-glucoside, β-methyl-D-glucoside, esculin, arbutin, inulin, and salicin. Starch is hydrolyzed, but casein, corn oil, esculin, gelatin, Tween 20, Tween 80, tyrosine, and urea are not decomposed. KCN is tolerated at a concentration of 0.0075%. Nitrate and nitrite are not reduced. Acetoin is produced, but production of H_2S, indole, or ammonium from peptone is not observed. Citrate and malate are utilized, but acetamide, anthranilate, benzoate, citroaconate, *p*-hydroxybenzoate, β-hydroxybutyrate, formate, fumarate, galacturonate, gluconate glucuronate, glycolate, lactate, levulinate, malate, maleic acid, malonate, oxalate, propionate, saccharate, succinate, *m*-tartrate, and tryptamine are not utilized. The data on utilization of various carbon sources revealed by the Biolog test system are listed in Table 157.

Cell-wall sugars are rhamnose, fucose, and trace amount of galactose (Davis et al., 1984); somewhat different cell-wall sugar pattern, i.e. rhamnose, galactose, glucose, and small quantities of fucose and mannose, was determined using different methods of cell-wall preparation and analysis (Evtushenko et al., 2000). The predominant menaquinones are MK-11 and MK-12.

Naturally occurring in Bermudagrass [*Cynodon dactylon* (L.) Pers.] and probably some other plants (Fahey et al., 1991; Kostka et al., 1988; Lampel et al., 1994; Li et al., 2007). Under experimental settings induces stunting disease in Bermudagrass and colonizes many other plants without producing clear disease symptoms (Davis et al., 1984; Young et al., 2006).

Source: Bermuda grass (*Cynodon dactylon*), Taiwan.

DNA G+C content (mol%): 69.4 (HPLC).

Type strain: TB1A, ATCC 33973, CIP 104615, DSM 46306, ICMP 8790, JCM 9733, LMG 7552, NCIMB 11927, NCPPB 3151, PDDCC 7126, VKM Ac-2041.

Sequence accession no. (16S rRNA gene): AB016985.

Species *incertae sedis*

1. **Leifsonia aurea** Reddy, Prakash, Srinivas, Matsumoto and Shivaji 2003c, 982[VP]

au′re.a. L. fem. adj. *aurea* golden, referring to the yellowish pigment that the bacterium produces.

Cells are curved, nonmotile rods. Colonies are circular, convex, smooth, butyrous, opaque, and yellow-pigmented. The pigment is supposedly a carotenoid (exhibits four peaks at 390, 414, 438, and 468 nm in methanol solution). Gram-stain-positive. Aerobic; catalase-positive. Oxidase-negative (Kovacs, 1956). The temperature range for growth is 0–30°C, optimum 22°C, and the pH range is 6–11, optimum pH 7 (initial pH values). Strains grow at salt concentrations up to 3% NaCl. Nitrate is reduced to nitrite.

The following carbon sources are used for growth and energy on minimal medium: D-glucose, D-fructose, D-galactose, D-mannose, L-rhamnose, D-ribose, D-sorbose, trehalose, glucosamine, erythritol, glycerol, acetate, pyruvate, L-arginine, L-glutamic acid, and L-phenylalanine. Does not grow on the same medium supplemented with L-arabinose, D-cellobiose, cellulose, lactose, D-maltose, D-melibiose, D-raffinose, sucrose, D-xylose, dextran, glycogen, inulin, adonitol, dulcitol, inositol, D-mannitol, melezitol, sorbitol, acetate, citrate, β-hydroxybutyrate, lactate, myristic acid, succinate, L-alanine, L-glycine, L-lysine, L-methionine, L-serine, L-tyrosine, L-tryptophan, L-glutamine, creatinine, and polyethylene glycol phthalate. Does not produce acid from L-arabinose, D-fructose, D-galactose, D-glucose, lactose, D-maltose, D-mannose, L-rhamnose, sucrose, or D-xylose. Strains show positive reactions in the tests for production of acetoin and β-galactosidase; negative for production of H_2S, lipase, phosphatase,

urease, and indole and hydrolysis of esculin, gelatin, and starch. Methyl red test is negative.

Strains are sensitive to the following antibiotics (amount per disk): ampicillin (10 μg), kanamycin (40 μg), novobiocin (30 μg), penicillin (10 U), rifampin (10 μg), streptomycin (10 μg), tetracycline (30 μg) tobramycin (15 μg), vancomycin (30 μg), chloramphenicol (30 μg), as well as amikacin, cefaperazone, cephatoxime, cefazoline, cefuroxime, amoxycillin, ciprofloxacin, and roxithromycin (unknown concentrations). The strains resisted erythromycin (15 μg) and also colistin, nitrofurantoin, cotrimoxazole, nor-floxacin, and lincomycin (unknown concentrations).

The peptidoglycan has been reported to contain DL-diaminobutyric acid as the diamino acid, along with glycine, glutamic acid, and alanine. The sugars determined by the method of Staneck and Roberts (1974) are galactose, glucose, and ribose. The fatty acid profile displays $C_{15:0}$ anteiso (43.7%), $C_{17:0}$ anteiso (28.2%), $C_{16:0}$ iso (5.0%), $C_{15:0}$ iso (3.3%), $C_{17:0}$ iso (6.3%), $C_{14:0}$ iso (0.2%), $C_{14:0}$ (0.2%), $C_{15:0}$ (1.6%), $C_{16:0}$ (1.4%), $C_{18:0}$ (4.3%), and $C_{18:1}$ (4.1%).

Six strains, including the type strain were isolated from a cyanobacterial mat sample, the Wright Valley in McMurdo, Antarctica, by using dilution plating method on Antarctic bacterial medium (ABM) containing 0.5% (w/v) peptone, 0.2% (w/v) yeast extract, and 1.5% (w/v) agar; pH 6.9 with incubation at 5°C.

Source: a cyanobacterial mat sample, the Wright Valley in McMurdo, Antarctica.

DNA G+C content (mol%): 64.0 (T_m).

Type strain: CMS 81y, CIP 107785, DSM 15303, JCM 12762, MTCC 4657.

Sequence accession no. (16S rRNA gene): AJ438586.

Additional comments: the 16S rRNA gene sequence analyses show that *Leifsonia aurea* is clustered with *Leifsonia rubra* and the genera *Rhodoglobus* (Sheridan et al., 2003) and *Salinibacterium* (Han et al., 2003). Based on the studies of nucleic sequences Sheridan et al. (2003) suggested that *Leifsonia aurea* may be included in the genus *Rhodoglobus*. Further studies are required to clarify its phenotypic, including chemotaxonomic, characteristics and taxonomic position.

2. **Leifsonia bigeumensis** Dastager, Lee, Ju, Park and Kim 2008c, 1936[VP]

bi.ge.um.en′sis. N.L. fem. adj. *bigeumensis* of or belonging to Bigeum Island, Korea, the geographical origin of the type strain of this species.

Cells are short, motile rods. Colonies are circular, convex, smooth, butyrous, opaque yellowish-white. Aerobic; catalase and oxidase-negative. Growth of the type strain was reported to occur within a relatively narrow temperature range (20–37°C), with an optimal growth temperature of 28°C, and at pH 6–12, with optimum pH 8 (initial pH values). Slightly halophilic, growing at 3% NaCl, with no growth in the absence of NaCl. Nitrate is reduced to nitrite. Utilizes D-cellobiose, D-melibiose, D-raffinose, D-rhamnose, trehalose, *m*-inositol, and D-mannitol as a sole source of carbon and fails to utilize L-arabinose, D-fructose, D-galactose, D-glucose, D-mannose, and D-ribose. Does not produce acid from L-arabinose, D-fructose, D-galactose, D-glucose, D-maltose, and D-mannose. Hydrolyzes gelatin and starch but not esculin. Negative for urease and H_2S production.

The peptidoglycan contains DL-diaminobutyric acid as the diamino acid, along with alanine, glycine, and glutamic acid. The cell-wall sugars are galactose, glucose, mannose, and rhamnose. The major menaquinone is MK-11. The polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and unidentified glycolipids. The predominant cellular fatty acids are $C_{16:0}$ iso (38.9%), $C_{15:0}$ anteiso (36.0%), and $C_{17:0}$ anteiso (18.2%); other fatty acids detected are $C_{15:0}$ iso (2.4%), $C_{14:0}$ iso (1.9%), $C_{16:0}$ (1.5%), and $C_{17:0}$ iso (1.1%).

The type strain was isolated from a soil sample from the Bigeum Island, Republic of Korea by the standard dilution plating technique at 30°C on ten-fold-diluted R2A agar (Difco) with pH adjusted to 8.0 using Na_2CO_3.

Source: a soil sample from the Bigeum Island, Republic of Korea.

DNA G+C content (mol%): 69 (T_m).

Type strain: MSL-27, DSM 19322, KCTC 19268.

Sequence accession no. (16S rRNA gene): EF466124.

Additional comments: the 16S rRNA-based phylogenetic analysis indicates *Leifsonia bigeumensis* to be phylogenetically distinct from the *Leifsonia sensu stricto* clade (Figure 187). This species is also distinguished by its negative catalase reaction, salt requirement for growth, and a number of other phenotypic characteristics (see Table 158, the Taxonomic Comments section, and the original description of Dastager et al., 2008c, for details). It seems quite likely that this species will be reclassified as a member of a new genus within the family *Microbacteriaceae*.

3. **Leifsonia ginsengi** Qiu, Huang, Sun, Zhang, Liu and Song 2007, 407[VP]

gin.sen′gi. N.L. gen. n. *ginsengi* of ginseng, the source of the type strain of this species.

Cells are straight or curved, nonmotile rods, 0.6–0.8 × 1.2–2.5 μm. Colonies on CB agar are white to yellow, circular, convex, glistening, opaque, butyrous. Aerobic; catalase-positive; oxidase-negative. Growth occurs at 4–37°C; optimum growth is at 26–30°C. Growth occurs at 1% but not at 3% NaCl. Distinct positive reactions are obtained in the Biolog GP test system with the following substrates: D-glucose, D-cellobiose, D-fructose, maltose, D-mannose, D-ribose, D-sorbitol, sucrose, turanose, D-xylose, glycerol, D-mannitol, γ-hydroxybutyric acid, pyruvic acid, pyruvic acid methyl ester, adenosine, 2′-deoxyadenosine, and thymidine. Weak reactions are observed with acetic acid, dextrin, 2,3-butanediol, and Tween 40. Positive for hydrolysis of starch and indole production, but negative for production of urease, acetoin, and hydrolysis of gelatin (results of conventional tests).

Susceptible to the following antibiotics (μg/ml): tetracycline (10), erythromycin (15), rifampin (30), and chloramphenicol (10); resistant to ampicillin (10), lincomycin (15), streptomycin (10), kanamycin (15), and penicillin (10 U/ml).

Cell-wall peptidoglycan has been reported to contain 2,4-diaminobutyric acid along with alanine, glutamic acid and glycine. Cell-wall sugars are galactose, glucose, mannose, and rhamnose. The menaquinone system includes MK-11 as the major menaquinone and minor amount of MK-10 and trace amount of MK-12. The fatty acid profile contains a large amount (52%) of ω-cyclohexyl-undecanoic ($C_{17:0}$ Ch) acid that is unusual for members of the genus *Leifsonia*, and

smaller but significant amounts of $C_{15:0}$ anteiso (19.6%), $C_{17:0}$ anteiso (10.5%), and $C_{16:0}$ iso (8.3%).

The type strain was isolated from a suspension of a surface-sterilized ginseng root using nitrogen-free agar medium (Von Bulow and Dobereiner, 1975) and diluting plating method.

Source: a suspension of a surface-sterilized ginseng root.

DNA G+C content (mol%): 66.4 (T_m).

Type strain: wged11, CGMCC 4.3491, CIP 109552, DSM 19088, JCM 13908.

Sequence accession no. (16S rRNA gene): DQ473536.

Additional comments: as deduced from the 16S rRNA gene sequence analysis, *Leifsonia ginsengi* forms a separate phyletic line outside the *Leifsonia sensu stricto* clade (Figure 187). Besides the fatty acid composition, this species also differs from the *Leifsonia sensu stricto* in many physiological and biochemical characteristics (see the original description of Qiu et al., 2007, for details). It is most likely that *Leifsonia ginsengi* will be reclassified as a member of a new genus within the family *Microbacteriaceae*.

4. **Leifsonia kribbensis** Dastager, Lee, Ju, Park and Kim 2009, 19[VP]

krib.ben′sis. N.L. fem. adj. *kribbensis* pertaining to KRIBB, an arbitrary adjective formed from the acronym of the Korea Research Institute of Bioscience and Biotechnology, where taxonomic studies of this species were performed.

Cells are generally straight to slightly curved rods (approximately 0.6 µm or more × 0.9–1.3 µm) occurring singly or in pairs. Gram-stain-positive (KOH test); non-acid-fast. Colonies are yellow-colored, circular, small (0.6–1.8 mm in diameter), glistening, opaque, and entire on diluted R2A medium. Aerobic. Catalase-negative. Oxidase reaction determined using *N,N,N,N* -tetramethyl-*p*-phenylene diamine dihydrochloride is negative. Nitrate is not reduced to nitrite.

Growth of the type strain was reported to occur within a relatively narrow temperature range (20–37°C), with an optimal growth temperature of 28°C. Growth was observed at initial pH values of 6.0–11.0; with optimum at 8.0. Tolerates up to 3.0% NaCl on tenfold diluted R2A medium.

The type strain uses D-cellobiose, D-melibiose, D-raffinose, D-rhamnose, and *m*-inositol as carbon sources, while D-glucose, D-fructose, D-galactose, D-mannose, and D-ribose are not used for growth. Acid is weakly produced from L-rhamnose and sucrose; no acid production from D-glucose, L-arabinose, D-fructose, D-galactose, D-maltose, and D-mannose. The type strain is positive for decomposition of casein, starch, Tween 80, and tyrosine; negative for degradation of cellulose, elastin, gelatin, pectin, and xylan. No H_2S production is observed. No growth occurs in the presence of phenol (0.3%).

The diagnostic cell-wall diamino acid is diaminobutyric acid. The whole cell sugars are glucose, rhamnose, ribose, and galactose. The major menaquinones are MK-12 and MK-11. The phospholipids detected are diphosphatidylglycerol and phosphatidylglycerol; some unidentified lipids additionally occur. The fatty acid profile includes $C_{16:0}$ iso (43.4%), $C_{15:0}$ anteiso (19.7%), $C_{17:1}$ anteiso ω9c (8.7%), $C_{14:0}$ iso (7.8%), $C_{17:0}$ anteiso (6.8%), $C_{15:0}$ iso (5.3%), and $C_{17:0}$ iso (2.1%).

The type strain was isolated from a soil sample, Bigeum Island, Korea, by the dilution-plating technique on ten-fold diluted R2A medium (Reasoner and Geldreich, 1985; Difco).

Source: a soil sample, Bigeum Island, Korea.

DNA G+C content (mol%): 73.4 (T_m).

Type strain: MSL-13, DSM 19272, KCTC 19267.

Sequence accession no. (16S rRNA gene): EF466129.

Additional comments: the 16S rRNA-based analysis indicates that *Leifsonia kribbensis* is phylogenetically distinct from the *Leifsonia sensu stricto* clade (Figure 187). This species is also distinguished from the *Leifsonia sensu stricto* due to its menaquinone composition, the fatty acid profile with predominant amounts of iso-branched acids making up to nearly 60% of the total, a slightly higher G+C content, and physiological and biochemical characteristics (see Table 158, the Taxonomic Comments section, and the original description of Dastager et al., 2008c, for details). It is most likely that *Leifsonia kribbensis* will be reclassified as a member of a new genus within the family *Microbacteriaceae*.

5. **Leifsonia pindariensis** Reddy, Prabagaran and Shivaji 2008, 2231[VP]

pin.da.ri.en′sis. N.L. fem. adj. *pindariensis* of or belonging to the Pindari glacier of Himalayan region, India, the geographical origin of the type strain of this species.

Cells are curved, short, and motile rods. Colonies are yellow pigmented, convex, and opaque. Gram-stain-positive. Aerobic; catalase-positive. Oxidase reaction is negative. Nitrate is not reduced to nitrite. The type strain of this species as determined by using conventional methods and commercial test systems (HiMedia, Mumbai, India) utilizes D-glucose, lactose, D-maltose, D-mannose, D-melibiose, D-ribose, L-sorbose, dulcitol, glycerol, erythritol, glucosamine, salicin, inulin, D-glucuronic acid, L-arginine, L-asparagine, L-cysteine, L-methionine, and L-valine, but not D- and L-arabinose, D-cellobiose, D-fructose, galactose, maltose, D-melezitose, D-raffinose, rhamnose, sucrose, trehalose, D- and L-xylose, *meso*-inositol, D-mannitol, sorbitol, xylitol, citrate, gluconate, malonate, α-methyl-D-glucoside, α-methyl-D-mannoside, L-alanine, L-aspartic acid, L-glutamine, L-histidine, L-isoleucine, L-leucine, L-lysine, L-phenylalanine, L-proline, L-serine, L-threonine, and L-tyrosine. Produces acid from D-maltose and D-mannose, but not from D-arabinose, D-fructose, D-galactose, D-glucose, D-melibiose, salicin, sucrose, and D-xylose. Shows positive reactions in the tests for phenylalanine deamination, and acetoine and indole production. Produces β-galactosidase and urease, but not phosphatase, ornithine decarboxylase, and lysine decarboxylase.

The type strain was reported to be sensitive to various antibiotics (µg per disc): amikacin (30), ampicillin (10), bacitracin (10), carbenicillin (100), cefazolin (30), cefoperazone (75), cefotaxime (30), cefuroxime (30), chloramphenicol (30), ciprofloxacin (5), co-trimoxazole (25), doxycycline (10), erythromycin (15), gentamicin G (30), kanamycin (30), leukomycin (30), lomefloxacin (30), nitrofurantoin (300), novobiocin (30), oleandomycin (15), penicillinG (10), rifampin (30), roxithromycin (30), spectinomycin (100), streptomycin mycin (10), tetracycline (30), and vancomycin (30). Resistant to colistin (10), nalidixic acid (30), norfloxacin (10), polymixin B (50), and tobramycin (10).

The cell-wall peptidoglycan is based upon 2,4-diaminobutyric acid. The cell-wall sugars include rhamnose and trace

amounts of glucose, galactose, and mannose. The menaquinones are MK-9 (minor), MK-10 and MK-11 (major). Polar lipids are phosphatidylglycerol and diphosphatidylglycerol, with a minor amount of an unknown lipid. The fatty acid profile displays $C_{15:0}$ anteiso (54.3%), $C_{17:0}$ anteiso (19.1%), $C_{16:0}$ iso (6.8%), $C_{15:0}$ iso (5.6%), $C_{16:0}$ (1.9%), and $C_{17:0}$ iso (2.0%) as well as the set of fatty acids constituting 0.5–0.9% ($C_{14:0}$, $C_{11:0}$ anteiso, $C_{12:0}$ anteiso, $C_{13:0}$ anteiso, $C_{14:0}$ iso, and $C_{15:1}$ isoG).

The type strain was isolated from a soil sample collected near the Pindari glacier, Himalayas, by the following procedure. Approximately 200 mg of the soil sample was suspended in 0.9% NaCl; the suspension, after shaking for 1 h, was allowed to settle and plated (100 µl) on agar medium containing 0.03 g of beef extract, 0.05 g of peptone, 0.08 g of NaCl, and 15 g of agar per liter.

Source: a soil sample collected near the Pindari glacier, Himalayas.

DNA G+C content (mol%): no data available

Type strain: PON10, LMG 24222, JCM 15132, MTCC 9128.

Sequence accession no. (16S rRNA gene): AM900767.

Additional comments: the 16S rRNA gene sequence of *Leifsonia pindariensis* is nearly identical to that of *Microterricola viridarii*, but these species exhibit clear difference in a wide range of phenotypical characteristics. It is most likely that *Leifsonia pindariensis* will be reclassified as a new species of the genus *Microterricola.*

6. **Leifsonia rubra** Reddy, Prakash, Srinivas, Matsumoto and Shivaji 2003c, 982[VP]

rub′ra. L. fem. adj. *rubra* reddish, referring to the reddish pigment produced by the bacterium.

Cells are nonmotile, curved rods. Colonies are circular, convex, smooth, butyrous, opaque, red-pigmented, and 1–2 mm in diameter. Catalase-positive. Negative for oxidase activity tested by the method of Kovacs (1956). Growth occurs at 0–22°C and at pH 6–12 (initial pH). Tolerant to 3% NaCl. Optimum growth is observed at 15°C, pH 7. Nitrate is reduced to nitrite. The following carbon sources were reported to be used for growth and energy: D-glucose, D-fructose, D-galactose, L-rhamnose, D-ribose, D-mannose, D-sorbose, trehalose, glycerol, L-glutamate, pyruvate, glucosamine, and L-phenylalanine as sole carbon sources. Fails to utilize L-arabinose, D-cellobiose, lactose, D-maltose, D-melibiose, D-raffinose, sucrose, D-xylose, cellulose, dextran, adonitol, dulcitol, *meso*-erythritol, inositol, D-mannitol, melezitol, sorbitol, citrate, β-hydroxybutyrate, lactate, myristic acid, phthalate, succinate, L-alanine, L-arginine, L-glycine, L-glutamine, L-lysine, L-methionine, L-serine, L-tyrosine, L-tryptophan, glycogen, inulin, polyethylene glycol, and creatinine. Does not produce acid from L-arabinose, D-fructose, D-galactose, glucosamine, lactose, D-maltose, D-mannose, L-rhamnose, sucrose, or D-xylose. Positive for β-galactosidase and negative for urease, lipase, indole production, in methyl red and Voges–Proskauer tests, H_2S production and does not decompose esculin, gelatin, or starch.

Sensitive to the following antibiotics (amount per disk): amikacin (10 µg), ampicillin (10 µg), kanamycin (40 µg), erythromycin (15 µg), novobiocin (30 µg), streptomycin (10 µg), tetracycline (30 µg), tobramycin (15 µg), rifampin (10 µg), and vancomycin (30 µg) as well as cefaperazone, cefazoline, cephatoxime, and lincomycin (unknown concentrations). Strains are resistant to colistin (10 µg), chloramphenicol (30 µg), and penicillin (10 U), as well as to cefuroxime, ciprofloxacin, cotrimoxazole, nitrofurantoin, norfloxacin, and roxithromycin (unknown concentrations).

The cell-wall peptidoglycan was reported to contain DL-diaminobutyric acid as the diamino acid, along with glycine, glutamic acid, and alanine. The whole cell sugars are galactose, glucose, ribose, and rhamnose. The fatty acid profile reported consists of $C_{15:0}$ anteiso (37.5%), $C_{17:0}$ anteiso (20.3%), $C_{16:0}$ iso (11.5%), $C_{15:0}$ iso (7.8%), $C_{17:0}$ iso (1.8%), $C_{14:0}$ iso (0.5%), $C_{14:0}$ (1.3%), $C_{15:0}$ (3.6%), $C_{16:0}$ (1.8%), $C_{18:0}$ (3.7%), and $C_{18:1}$ (5.0%).

The type strain of this species was isolated from a cyanobacterial mat sample, the Wright Valley in McMurdo, Antarctica, using dilution plating method. Isolation medium was Antarctic bacterial medium (ABM) containing 0.5% (w/v) peptone, 0.2% (w/v) yeast extract, and 1.5% (w/v) agar; pH 6.9 with incubation at 5°C.

Source: a cyanobacterial mat sample, the Wright Valley in McMurdo, Antarctica.

DNA G+C content (mol%): 66.0 (T_m).

Type strain: S. Shivaji CMS 76r, LMG 24410, JCM 15064.

Sequence accession no. (16S rRNA gene): AJ438585.

Additional remarks: Leifsonia rubra is closely related to *Rhodoglobus vestalii* (99.4% 16S rRNA gene sequence identity) and most likely belongs to the genus *Rhodoglobus* as suggested by Sheridan et al. (2003). Further studies could clarify its phenotypic, including chemotaxonomic, characteristics and taxonomic position.

Note added in proof: the type strain of *Leifsonia rubra* is now available from the LMG and JCM culture collections (see the *Taxonomic comments* section for details).

Genus XIV. **Leucobacter** Takeuchi, Weiss, Schumann and Yokota 1996, 970[VP]

Akira Yokota

Leu.co.bac′ter. Gr. adj. *leukos* clear, light; N.L. masc. n. *bacter* rod; N.L. masc. n. *Leucobacter* colorless rod.

Gram-stain-positive, nonsporeforming, nonmotile rods. No mycelium is produced. Catalase is produced, but oxidase, arginine dihydrolase, hydrogen sulfide, and urease are not produced. The cell-wall peptidoglycan contains **2,4-diaminobutyric acid (DAB)** as the characteristic diamino acid. **The peptidoglycan acyl type is acetyl.** The quinone system contains either menaquinones MK-10 and MK-11 (*Leucobacter tardus*) or MK-11 only as major isoprenoid quinone. Mycolic acids are not

present. The major cellular fatty acids are **$C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. Diphosphatidylglycerol, phosphatidylglycerol, and one unknown glycolipid** are present.

The genus *Leucobacter* is a member of the family *Microbacteriaceae*.

DNA G+C content (mol%): 62.8–69.5.

Type species: **Leucobacter komagatae** Takeuchi, Weiss, Schumann and Yokota 1996, 970[VP].

Further descriptive information

Phylogenetically, the genus *Leucobacter* belongs to the family *Microbacteriaceae* and presently comprises eleven recognized species (Figure 189). All species of the genus are characterized by 2,4-diaminobutyric acid (DAB) as the diagnostic amino acid in the peptidoglycan. However, some differences in the amino acid composition of the peptidoglycan have been reported; in addition to DAB, glutamic acid, alanine, and glycine, *Leucobacter komagatae*, *Leucobacter albus*, *Leucobacter chironomi*, and *Leucobacter salcicius* contain γ-aminobutyric acid (GABA), and *Leucobacter aerolatus*, *Leucobacter alluvii*, *Leucobacter chironomi*, *Leucobacter chromiireducens*, *Leucobacter iarius*, and *Leucobacter luti* contain threonine. Detailed analysis of the genes encoding these differences might reveal the evolutionary background of these differences.

All species contain MK-11 as the major menaquinone except *Leucobacter tardus* which exhibits a quinone system with MK-10 and MK-11 predominantly; MK-12, MK-10, and/or MK-9 are detectable in minor amounts.

The genus *Leucobacter* can be differentiated from closely related genera of the family *Microbacteriaceae* based on chemotaxonomic and phylogenetic data as shown in Table 159.

Isolation and maintenance procedures

Strains belonging to the genus *Leucobacter* occur in a variety of ecological niches such as airborne (Martin et al., 2010; Takeuchi et al., 1996), soil (Lin et al., 2004), river sediment (Morais et al., 2006b), activated sludge (Morais et al., 2004; Morais et al., 2006b), chironomid egg mass (Halpern et al., 2009), contaminant of *Caenorhabditis elegans* (Muir and Tan, 2007), nematode (Somvanshi et al., 2007), Korean fermented food (Yun et al., 2011), and phylosphere of potato plants (Behrendt et al., 2008b). The majority of *Leucobacter* strains recover well from cultures grown on nutrient agar, Luria–Bertani (LB) agar, or PY-BHI (peptone, 5 g; yeast extract, 1 g; brain heart infusion, 1 g; and water, 1 liter; pH 7.2) agar stored at 5°C for 2 months. Lyophilization or deep freezing (−80°C) in glycerol solution are recommended for long-term preservation.

Differentiation of species of the genus *Leucobacter*

Characteristics distinguishing *Leucobacter* species are presented in Table 160.

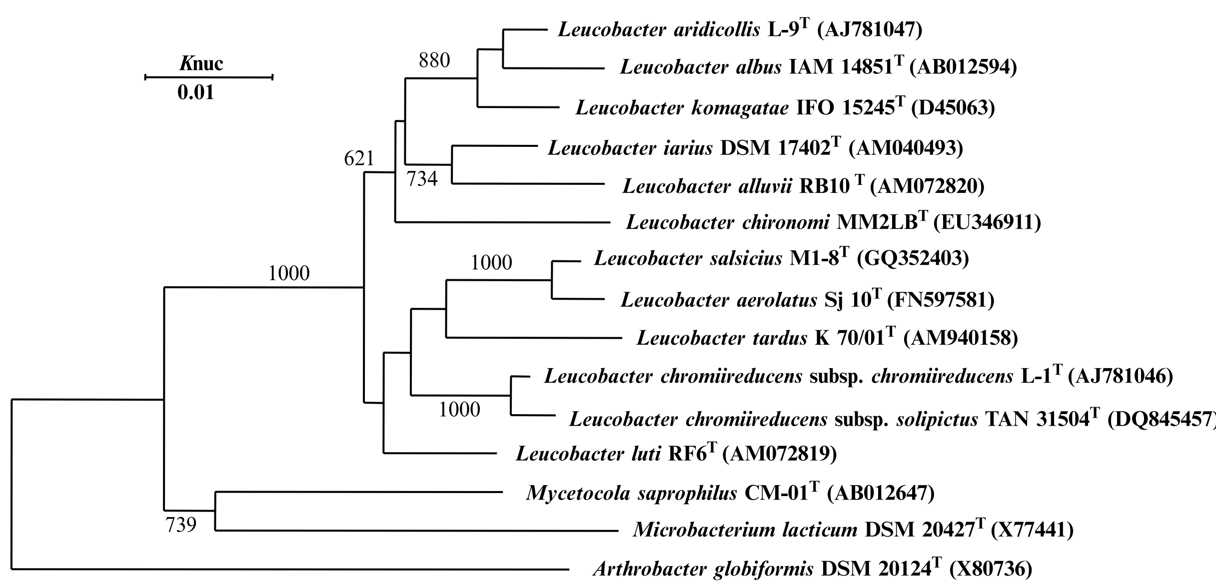

FIGURE 189. Phylogenetic relationships of the named species of the genus *Leucobacter*. The neighbor joining method was used for the tree construction. One thousand bootstrap trees were generated, and bootstrap values (>60%) are indicated at branch points.

List of species of the genus *Leucobacter*

1. **Leucobacter komagatae** Takeuchi, Weiss, Schumann and Yokota 1996, 970[VP]

koma.ga′ta.e. N.L. gen. masc. n. *komagatae* of Komagata, named in honor of Kazuo Komagata, the Japanese microbiologist who first recognized this strain.

Cells are Gram-stain-positive, irregular rods that are 0.2–0.3 µm × 1.0–1.5 µm. The cells are nonsporeforming and nonmotile in 2-d-old cultures on PY-BHI agar. No mycelium is produced. Colonies are circular, entire, low convex, smooth, opaque, and whitish brown. Catalase is produced, but oxidase, arginine dihydrolase, hydrogen sulfide, and urease are not produced. Gelatin, starch, and esculin are not hydrolyzed, but Tween 20, Tween 40, Tween 60, and Tween 80 are hydrolyzed. Nitrate is not reduced. Growth occurs in the presence of 2.0–5.0% NaCl and at pH 10.0. Acetate, D- and L-lactate, malate, succinate, propionate, oxalate, and hippurate are assimilated, but citrate and formate are not assimilated. The G+C content of the DNA is 66 mol%. The cell-wall peptidoglycan contains L-2,4-diaminobutyric acid (L-DAB), alanine, glycine, γ-aminobutyric acid (GABA), and glutamic acid. The acyl type of the cell wall is an acetyl type. The major isoprenoid quinone is menaquinone MK-11. Mycolic acids are not present. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. No diagnostic sugar is present in the cell wall. Diphosphatidylglycerol, phosphatidylglycerol, and one unknown glycolipid are present.

Source: a contaminant on an agar plate.

DNA G+C content (mol%): 66 (HPLC).

Type strain: CCUG 49676, CIP 105084, DSM 8803, IAM 1093, NBRC 15245, JCM 9414, VKM Ac-2073.

Sequence accession no. (16S rRNA gene): AB007419, AJ746337, AM42691, D17751, D45063.

2. **Leucobacter aerolatus** Martin, Lodders, Jäckel, Schumann and Kämpfer 2010, 2840[VP]

a.e.ro.la′tus. Gr. n. *aer* air; L. part. adj. *latus -a -um* carried; N.L. masc. part. adj. *aerolatus* airborne.

Cells are nonmotile, nonsporeforming rods approximately 2 µm in length. Gram-stain-positive, oxidase-positive (weak reaction), aerobic respiratory metabolism. Good growth occurs after 3 d of incubation on tryptone soy agar and nutrient agar at 25–30°C. On TSA, colonies are white and shiny with a diameter of approximately 2 mm. The peptidoglycan contains the amino acids 2,4-diaminobutyric acid (DAB), lysine, threonine, glycine, alanine, and glutamic acid. The quinone system is composed of menaquinone MK-11 as major component and minor amounts of MK-12 and MK-10. The polar lipid profile contains phosphatidylglycerol, diphosphatidylglycerol, one unknown phospholipid, one unknown glycolipid and one unknown aminoglycolipid. Major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso.

The following carbon sources are utilized: *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, D-galactose, D-glucose, L-rhamnose, D-ribose, D-trehalose, i-inositol, putrescine, 4-aminobutyrate, DL-lactate, pyruvate, L-alanine, L-aspartate, L-histidine,L-ornithine, L-proline, and weakly positive are D-maltose and oxoglutarate. Not utilized are L-arabinose, *p*-arbutin, D-cellobiose, D-fructose, gluconate, D-mannose, α-D-melibiose, sucrose, salicin, D-xylose, adonitol, maltitol, D-mannitol, D-sorbitol, acetate, propionate, *cis*-aconitate, *trans*-asconitate, adipate, citrate, fumarate, glutarate, DL-3-hydroxybutyrate, itaconate, L-malate, mesaconate, suberate, β-alanine, L-leucine, L-phenylalanine, L-serine, L-tryptophan, 3-hydroxybenzoate, 4- hydroxybenzoate, and phenylacetate. Following compounds are hydrolyzed (pNP- = *para*-nitrophenyl; oNP = *ortho*-nitrophenyl-; pNA = *para*-nitroanilide): 2-deoxythymidine-5′-pNP-phosphate, L-alanine-pNA and L-proline-pNA. The following compounds are not hydrolyzed: esculin, pNP-β-D-galactopyranoside, pNP-β-D-glucuronide, pNP-α-D- glucopyranoside, pNP-β-D-glucopyranoside, pNP-β-D-xylopyranosid, bis-pNP-phosphate, pNP-phenyl-phosphonate, pNP-phosphoryl-choline, and L-glutamate-γ-3-carboxy-pNA.

Source: the air in a duck barn in Germany.

DNA G+C content (mol%): not available.

Type strain: Sj 10, CCM 7705, DSM 22806.

Sequence accession no. (16S rRNA gene): FN597581.

3. **Leucobacter albus** Lin, Uemori, de Briel, Arunpairojana and Yokota 2004, 1675[VP]

al′bus. L. masc. adj. *albus* white.

Cells are Gram-stain-positive, aerobic rods, 0.3–0.4 × 0.5–1.1 µm, nonsporeforming, and nonmotile. Smooth white colonies are produced on PY-BHI agar. The optimal temperature for growth is 30°C. Catalase is produced, but oxidase is not. Acid is produced from glycerol, ribose, and L-fucose. The following tests are negative: reduction of nitrate or nitrite, nitrate respiration, liquefaction of gelatin, hydrolysis of esculin, urease, alkaline phosphatase, β-galactosidase, and α-glucosidase and acid production from D-glucose, D-fructose, D-mannose, rhamnose, inositol, and mannitol. The cell-wall peptidoglycan contains L-2,4-diaminobutyric acid (L-DAB) and γ-aminobutyric acid (GABA); the muramic acid of the cell wall is of the acetyl type. The major isoprenoid quinone is MK-11. The major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.

Source: soil.

DNA G+C content (mol%): 66 (HPLC).

Type strain: CCUG 50213, IAM 14851, JCM 12888, NBRC 103070, TISTR 1515.

Sequence accession no. (16S rRNA gene): AB012594.

4. **Leucobacter alluvii** Morais, Paulo, Francisco, Branco, Chung and da Costa 2006a, 2507[VP] (Effective publication: Morais, Paulo, Francisco, Branco, Chung and da Costa 2006b, 419.)

al.lu′vi.i. L. neut. gen. n. *alluvii* of an alluvial deposit.

Cells are Gram-stain-positive, irregularly shaped rods. Nonsporeforming; nonmotile in PY-BHI. Colonies are circular, entire, low raised, smooth, opaque, and cream-colored. Optimum growth temperature is 30°C; does not grow at 40°C. Optimum pH for growth is 7.0–8.0. Catalase and urease are produced, but oxidase and arginine dihydrolase are not. Esculin is not hydrolyzed. Tween 20, 40, 60, 80, and gelatin are hydrolyzed. Nitrate is not reduced. Growth occurs in

the presence of 8% NaCl; growth occurs in the presence of 3 mM Cr(VI). The cell-wall peptidoglycan contains alanine, glycine, threonine, 2,4-diaminobutyric acid (DAB), and glutamic acid. The major isoprenoid quinone is menaquinone MK-11. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ and $C_{16:0}$ iso. Chemo-organotrophic, strictly aerobic, and nonfermentative. Growth is observed with D-glucose, D-fructose, D-mannose L-rhamnose, inositol, D-maltose, D-trehalose, and xylitol.

Source: River Alviela sediments, Portugal.

DNA G+C content (mol%): 68.9 (HPLC).

Type strain: RB10, CIP 108819, JCM 14919, LMG 23117.

Sequence accession no. (16S rRNA gene): AM072820.

5. **Leucobacter aridicollis** Morais, Francisco, Branco, Chung and da Costa 2005, 547[VP] (Effective publication: Morais, Francisco, Branco, Chung and da Costa 2004, 650.)

a.ri.di.col′lis. L. adj. *aridus* dry; L. masc. n. *collis* an elevation, high ground, hill; N.L. gen. n. *aridicollis* of a dry hill; referring to the town of Alcanena, which the Moors called al-Kinan, meaning a dry hill.

Cells are Gram-stain-positive, irregularly shaped rods. Nonsporeforming; nonmotile in PY-BHI. Colonies are circular, entire, low raised, smooth, opaque, and cream-colored. Optimum growth temperature is 28°C; does not grow at 40°C. Optimum pH is 7.0–8.0. Catalase and urease are produced, but oxidase and arginine dihydrolase are negative. Esculin and gelatin are not hydrolyzed. Nitrate is not reduced. Growth occurs in the presence of 10% NaCl and 5 mM Cr(VI). The cell-wall peptidoglycan contains 2,4-diaminobutyric acid (DAB), alanine, glutamic acid, and glycine. The major isoprenoid quinone is menaquinone MK-11. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, and $C_{16:0}$. Glucose is not fermented. Weak growth is obtained with D- and L-arabinose, D-fructose, D-mannose, L-sorbose, and D-maltose; D-ribose and L-rhamnose are not assimilated.

Source: activated sludge from chromium polluted wastewater treatment plant in Alcanena, Portugal.

DNA G+C content (mol%): 67.3 (HPLC).

Type strain: L-9, CIP 108388, JCM 13321, LMG 22507.

Sequence accession no. (16S rRNA gene): AJ781047.

6. **Leucobacter chironomi** Halpern, Shakéd, Pukall and Schumann 2009, 667[VP]

chi.ro′no.mi. N.L. gen. n. *chironomi* of *Chironomus*, named after the non-biting midge insect of the genus *Chironomus* (Chironomidae: Diptera) from which the type strain was isolated.

Cells are aerobic, Gram-stain-positive, nonmotile rods measuring 0.5–0.75 μm × 0.95–1.4 μm. Cells occur singly. After 48 h incubation on LB agar at 30°C, colonies are opaque, circular with entire margins, and yellow-colored. Growth is not observed under anaerobic conditions even after 8 d incubation. Growth is observed after 48 h incubation at 17–37°C (optimum 30°C), in the presence of 0–7.0% NaCl (optimum 0–1.0% NaCl) and at pH 4.0–9.5 (optimum pH 6.0–8.0). Good growth occurs on marine agar after 48 h incubation. Growth is not observed on MacConkey or cetrimide agars. Oxidase reaction is negative; catalase reaction is weakly positive. Although the type strain was not isolated from a chromium-enriched environment, it is able to grow in the presence of up to 18.0 mM Cr(VI). On API 50CH strips incubated for 48 h at 30°C, acid is not produced from any of the substrates tested and on API 20NE strips incubated for 48 h at 30°C; all tests are negative. The following results are obtained from API 20E strips after 48 h incubation at 30°C: acetoin is produced; nitrate is reduced to nitrogen; H_2S and indole are not produced; urea and gelatin are not hydrolyzed; citrate is not utilized. Activities of β-galactosidase, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase are detectable. Putrescine and glycerol are oxidized in the Biolog test. Cell-wall amino acids are alanine, glycine, threonine, 2,4-diaminobutyric acid (DAB), γ-aminobutyric acid (GABA), and glutamic acid. The peptidoglycan is of B-type. The major menaquinone is MK-11; MK-10 and MK-12 occur in minor amounts (<10% each). The dominant cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. The following fatty acids are present as minor components (<5%): $C_{16:0}$ and $C_{15:0}$ iso.

Source: a chironomid egg mass in Israel.

DNA G+C content (mol%): not available.

Type strain: MM2LB, DSM 19883, LMG 24399.

Sequence accession no. (16S rRNA gene): EU346911.

7. **Leucobacter chromiireducens** Morais, Francisco, Branco, Chung and da Costa 2005, 547[VP] emend. Muir and Tan 2007, 2774 (Effective publication: Morais, Paulo, Francisco, Brancob, Chung and da Costa 2004, 650.)

chro.mi.i.re.du′cens. N.L. neut. n. *chromium* chromium; L. v. *reducere* to draw backwards, bring back to a state or condition and, in chemistry, converting to a reduced oxidation state; N.L. part. adj. *chromiireducens* chromium reducing.

Gram-stain-positive, irregular rod-shaped cells. Nonsporeforming; nonmotile after growth on PY-BHI. Colonies are circular, entire, low convex, smooth, opaque, and cream-colored. Optimum growth temperature is about 28°C; does not grow at 40°C. Optimum pH is about 7.0. Oxidase-negative and catalase-positive; urease is produced, arginine dihydrolase is not produced. Starch is hydrolized, but esculin and gelatin are not. Nitrate is not reduced. Growth occurs in with the presence of 9% NaCl and 5 mM Cr(VI). The cell-wall peptidoglycan contains 2,4-diaminobutyric acid (DAB), alanine, glycine, glutamic acid, and threonine. The major isoprenoid quinone is menaquinone MK-11. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, and $C_{16:0}$. Glucose is not fermented. L-Rhamnose is assimilated; D-galactose, D-sorbitol, D-cellobiose, D-melezitose, D-raffinose are weakly assimilated. Other carbohydrates are not utilized.

Sequence accession no. (16S rRNA gene): AJ781046.

7b. **Leucobacter chromiireducens subsp. solipictus** Muir and Tan 2007, 2774[VP]

so.li.pic′tus. L. masc. n. *sol* the sun; L. masc. part. adj. *pictus* painted; N.L. masc. part adj. *solipictus* painted by the sun.

Cells are Gram-stain-positive-staining, aerobic, nonmotile, nonsporeforming irregular rods that are 0.4–0.6 µm × 0.8–1.4 µm when grown at 25°C in liquid LB medium and 0.5–0.7 µm × 0.8–4.3 µm when grown at 25°C on solid LB agar for 1–2 d. Cells produce an extracellular material. Colonies are circular, entire, convex, small (0.5–1 µm in diameter), smooth, glistening, yellow-pigmented when grown in the light or cream-colored when grown in the dark (photochromogenic), and opaque on LB agar after 2–5 d growth at 25°C. The light-induced pigment is soluble in methanol and displays characteristic peaks in absorption at 413, 436, and 466 nm. Pigment production is dependent on light quality and temperature. Depigmentation of cells occurs in the combined presence of 0.5 mM fosmidomycin and 0.5 mM mevinolin. Growth occurs at 10–37°C, pH 5.5–9.0, in LB containing 0–8% NaCl. Growth occurs at 4°C, but does not at 40°C, pH 5.0, or in the presence of >9% NaCl. Optimum growth occurs in the range between 25–32°C at pH 7.5–8.5 in aerated LB lacking salt. After 2–5 d incubation at 25°C, growth is observed on solid LB agar containing each of the following metals: 1 mM arsenite, 80 mM cadmium, and 5 mM hexavalent chromium, however, cells are unable to reduce hexavalent chromium to trivalent chromium. Cells are resistant to 50 µg kanamycin/ml, 12.5 µg/ml tetracycline, 10 µg/ml gentamicin, 300 µg/ml streptomycin, and 20 µg/ml chloramphenicol and sensitive to 100 µg/ml ampicillin and 100 µg/ml rifampin. Positive for catalase and alkaline phosphatase activities, but not for cytochrome c oxidase, nitrate reductase, β-galactosidase, urease, gelatinase, amylase, cysteine desulfurase, tryptophanase, phenylalanine deaminase, hemolytic, or lipase activities. No endogenous plasmids are present. After 2–5 d incubation at 25°C, growth can be seen on solid LB agar containing each of the following individually: 1 mM arsenite, 80 µM cadmium, 50 µg kanamycin/ml, 12.5 µg/ml tetracycline, 10 µg/ml gentamicin, and 20 µg/ml chloramphenicol; cells are sensitive to 50 µg/ml streptomycin, 100 µg/ml ampicillin, and 100 µg/ml rifampin. Negative for β-galactosidase, urease, amylase, cysteine desulfurase, tryptophanase, phenylalanine deaminase, hemolytic, and lipase activities. No endogenous plasmids are present.

Cell-wall peptidoglycan contains 2,4-diaminobutyric acid (DAB), alanine, glutamic acid, glycine, and threonine. Galactose is the only cell-wall sugar detected. Major isoprenoid quinones are MK-11 and MK-10. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, and linear $C_{16:0}$. Polar lipids include diphosphatidylglycerol, phosphatidylglycerol, and an unknown glycolipid.

Source: a contaminant from *Caenorhabditis elegan* in Stanford, CA, USA.

Type strain: TAN 31504, ATCC BAA-1336, DSM 18340, JCM 15573.

Sequence accession no. (16S rRNA gene): DQ845457.

8. **Leucobacter iarius** Somvanshi, Lang, Schumann, Pukall, Kroppenstedt, Ganguly and Stackebrandt 2007, 685[VP]

i.a′ri.us. N.L. masc. adj. *iarius* (arbitrary adjective) formed from the acronym IARI (Indian Agricultural Research Institute, New Delhi, India) to commemorate its centenary year.

Gram-stain-positive, straight, nonmotile rods (1.66–2.91 × 0.37–0.49 µm). Neither mycelium nor spores are detected. Colonies are round, 0.4–1 mm in diameter with smooth edges, low-convex, opaque, whitish in color, finely granular and odorless. Optimum temperature for growth is 30°C; growth does not occur at temperatures higher than 37°C or at 4°C. Growth occurs at pH 5.0–9.0. Growth is reduced in the presence of 5–7% NaCl; no growth occurs at 10% NaCl. Urease-negative, nitrate is not reduced, D-glucose is not fermented, and esculin and PNPG (β-galactosidase) are positive in the API 20NE test. Gelatinase-negative. Utilizes *N*-acetylglucosamine and weakly utilizes 5-keto-gluconate, inositol, and salicin. MK-11 is the major menaquinone; MK-10 and MK-9 are present in minor amounts while MK-12 occurs in trace amounts only. Polar lipids are phosphatidylglycerol and diphosphoglycerol. Several unidentified components occur, i.e. a phospholipid, a glycolipid, and an aminophospholipid. Cross-linkage of peptidoglycan is of the B-type; cell-wall amino acids are L-2,4-diaminobutyric acid (L-DAB), alanine, glycine, threonine, and glutamic acid. γ-Aminobutyric acid (GABA) is absent. Major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso; $C_{15:0}$ iso, and $C_{16:0}$ are present in minor amounts.

Source: crushed infective juveniles of *Steinernema thermophilum* collected from soil of the Indian Agricultural Research Institute, New Delhi, India.

DNA G+C content (mol%): not available.

Type strain: 40, CIP 108831, DSM 17402, JCM 14736.

Sequence accession no. (16S rRNA gene): AM040493.

9. **Leucobacter luti** Morais, Paulo, Francisco, Branco, Chung and da Costa 2006a, 2507[VP] (Effective publication: Morais, Paulo, Francisco, Branco, Chung and da Costa 2006b, 419.)

lu.ti. L. gen. n. *luti* of mud.

Cells are Gram-stain-positive, irregular rod-shaped. Nonsporeforming; nonmotile on PY-BHI. Colonies are circular, entire, low convex, smooth, opaque, and cream-colored. Optimum growth temperature is about

25°C; does not grow at 37°C. Optimum pH is 7.0–9.0. Oxidase-negative and catalase-positive; urease is produced, arginine dihydrolase is not produced. Starch is hydrolized, but esculin, gelatin, and Tween 20, 40, 60, and 80 are not. Nitrate is not reduced. Growth occurs in the presence of 8% NaCl and in the presence of 3 mM Cr(VI).

The cell-wall peptidoglycan contains alanine, glycine, threonine, DAB, and glutamic acid. The major isoprenoid quinone is menaquinone MK-11. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, and $C_{16:0}$. Chemo-organotrophic, strictly aerobic and nonfermentative. D-Ribose, L-rhamnose, and inositol are assimilated; glycerol is weakly assimilated.

Source: activated sludge from a chromium polluted wastewater treatment plant in Alcanena, Portugal.

DNA G+C content (mol%): 68.8 (HPLC).

Type strain: RF6, CIP 108818, JCM 14920, LMG 23118.

Sequence accession no. (16S rRNA gene): AM072819.

10. **Leucobacter salsicius** Yun, Roh, Kim, Jung, Park, Shin, Nam and Bae 2011, 505[VP]

sal.si′ci.us. L. masc. adj. *salsicius* salted, salty.

The strain forms circular, cream-colored colonies with entire margins. Cells are aerobic, Gram-stain positive, nonmotile (on semi-solid agar medium) rods that are 1.0–1.5 µm in length. Cells are catalase-positive and oxidase-negative. Optimal growth occurs at 25–30°C and pH 7.0–8.0 and in the presence of 0–4% (w/v) NaCl. The strain can tolerate up to 10.0 mM Cr (VI). In the API ZYM test, positive for esterase C4, leucine arylamidase, valine arylamidase, cystine arylamidase, naphthol-AS-BI-phosphohydrolase, and β-glucosidase. It does not produce alkaline phosphatase, esterase lipase C8, lipase C14, trypsin, α-chymotrypsin, acid phosphatase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, or α-fucosidase. The strain is negative for reduction of nitrate to nitrite. It does not produce indole. The strain hydrolyzes casein, esculin, Tweens 20, 40, 60, and PNPG (*p*-nitrophenyl-β-D-galactopyranoside). It does not hydrolyze starch, urea, gelatin, or Tween 80. It is negative for D-glucose fermentation, L-arginine dihydrolase, and urease. $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso are the dominant cellular fatty acids. The cell-wall peptidoglycan of the strain contains 2,4-diaminobutyric acid (DAB), alanine, glycine, glutamic acid, and γ-aminobutyric acid (GABA). Polar lipids include diphosphatidylglycerol and an unknown glycolipid.

Source: a Korean salt-fermented food containing tiny shrimp.

DNA G+C content (mol%): 62.8 (T_m).

Type strain: M1-8, KACC 21127, JCM 16362.

Sequence accession no. (16S rRNA gene): GQ352403.

11. **Leucobacter tardus** Behrendt, Ulrich and Schumann 2008b, 2577[VP]

tar′dus. L. masc. adj. *tardus* slow, pertaining to the slow reactions in several physiological tests.

Nonsporeforming, nonmotile, short rods (0.4–0.6 × 0.8–1.6 µm), which occur singly or in pairs, sometimes forming small irregular clusters. Gram-stain-positive and strictly aerobic. The lemon-yellow colonies found on nutrient agar are smooth with regular margins. Optimal temperature for growth is 21–30°C; no growth at 4 or 37°C. Catalase activity is present, but urease, β-galactosidase, arginine dihydrolase, lysine decarboxylase, and ornithine decarboxylase activities are absent. Citrate utilization, H_2S production from sodium thiosulfate, tryptophan deaminase, indole production from L-tryptophan and reduction of nitrate are negative. Does not produce acetoin from sodium pyruvate. No growth on MacConkey agar. Weak oxidase reaction. Hydrolyses esculin, but not starch, casein, or gelatin. Oxidative acid production occurs on API 50CH and API 20E substrates for D-fructose, melezitose, raffinose, and L-rhamnose, but not for *N*-acetylglucosamine, D-adonitol, amygdalin, D- or L-arabinose, D- or L-arabitol, arbutin, D-cellobiose, dulcitol, erythritol, D- or L-fucose, D-galactose, gentiobiose, D-glucose, glycerol, glycogen, inositol, inulin, D-lactose, D-lyxose, maltose, D-mannitol, D-mannose, melibiose, methyl α-D-glucopyranoside, methyl α-D-mannopyranoside, methyl β-D-xylopyranoside, potassium gluconate, potassium 2-keto-gluconate, potassium 5-keto-gluconate, D-ribose, sucrose, salicin, D-sorbitol, L-sorbose, starch, D-tagatose, trehalose, turanose, xylitol, or D- or L-xylose. Utilizes *N*-acetyl-L-glutamic acid, adenosine, L-alaninamide, L-arabinose, 2,3-butanediol, 2′-deoxyadenosine, D-gluconic acid, α-D-glucose, D-glucose 6-phosphate, glycerol, DL-α-glycerol phosphate, α-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, L-lactic acid, methyl α-D-galactoside, methyl β-D-galactoside, 3-methyl glucose, methyl α-D-glucoside, methyl pyruvate, putrescine, pyruvic acid, D-ribose, L-serine, D-sorbitol, succinamic acid, succinic acid, thymidine, Tweens 40 and 80, uridine and D-xylose on Biolog GP2 MicroPlates. Weak utilization is observed for D-fructose, *myo*-inositol, α-ketovaleric acid, D-mannitol, palatinose, D-psicose, and D-tagatose. Acetic acid, *N*-acetyl-D-glucosamine, *N*-acetyl-β-D-mannosamine, AMP, D- and L-alanine, L-alanyl glycine, amygdalin, D-arabitol, arbutin, L-asparagine, D-cellobiose, α- and β-cyclodextrin, dextrin, D-fructose 6-phosphate, L-fucose, D-galactose, D-galacturonic acid, gentiobiose, α-D-glucose 1-phosphate, L-glutamic acid, glycogen, glycyl L-glutamic acid, β- and γ-hydroxybutyric acids, inosine, inulin, α-ketoglutaric acid, lactamide, D-lactic acid methyl ester, α-D-lactose, lactulose, D- and L-malic acid, maltose, maltotriose, mannan, D-mannose, melezitose, melibiose, methyl β-D-glucoside, methyl α-D-mannoside, monomethyl succinate, propionic acid, L-pyroglutamic acid, raffinose, L-rhamnose, salicin, sedoheptulosan, stachyose, sucrose, TMP, trehalose, turanose, UMP, and xylitol are not assimilated. Cell-wall amino acids are 2,4-diaminobutyric acid (DAB), alanine, glycine, and glutamic acid. The main menaquinones are MK-10 and MK-11, and MK-9 is present in minor amounts. The fatty acid profile consists predominantly of $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso; $C_{16:0}$, $C_{15:0}$ iso, and $C_{14:0}$ iso are present in minor amounts.

Source: phyllosphere of potato plants in Dahnsdorf (Germany).

DNA G+G content (mol%): not available.

Type strain: K 70/01, DSM 19811, LMG 24388.

Sequence accession no. (16S rRNA gene): AM940158.

Genus XV. **Microcella**, Tiago, Pires, Mendes, Morais, da Costa and Veríssimo 2005a, 1743[VP] (Effective publication: Tiago, Pires, Mendes, Morais, da Costa and Veríssimo 2005b, 484.) emend. Tiago, Morais, da Costa and Veríssimo 2006, 2315[VP]

António Veríssimo

Mi.cro.cel′la. Gr. adj. *mikros* small; L. fem. n. *cella* chamber and in biology a cell; N.L. fem. n. *Microcella* a small cell.

Cells are, rod shaped (0.3–0.4 × 1.6–4 µm), **Gram-stain-positive**, and nonmotile. Nonsporeforming. Aerobic, oxidase-negative, and catalase-positive. Chemo-organotrophic. Mesophilic. Colonies are small and yellow-pigmented. The cell-wall peptidoglycan **is of the B-type containing lysine or ornithine** as the diagnostic amino acid. Fatty acids are predominantly iso- and anteiso-branched, namely $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{14:0}$ iso, and $C_{15:0}$ iso. Mycolic acids are not present. The respiratory quinones are unsaturated **menaquinones with 11–14 isoprene** units, with predominance of MK-12 and MK-13. Phylogenetic analysis based on the16S rRNA gene sequences places the genus *Microcella* in the family *Microbacteriaceae*. The closest phylogenetic neighbor is *Yonghaparkia alkaliphila*. The species of *Microcella* are **alkaliphilic** and the strains were isolated from a non-saline highly alkaline (pH 11.4) groundwater located in Southern Portugal.

DNA G+C content (mol%): 67.1–70.7.

Type species: **Microcella putealis** Tiago, Pires, Mendes, Morais, da Costa and Veríssimo 2005a, 1743[VP] (Effective publication: Tiago, Pires, Mendes, Morais, da Costa and Veríssimo 2005b, 484.).

Further descriptive information

Phylogenetic analysis based on the 16S rRNA gene sequences places the genus *Microcella* within the family *Microbacteriaceae*. The lineage including members of genus *Microcella* is closely related with the type species of genera *Yonghaparkia* and *Frigoribacterium*, regardless of the algorithm used to reconstruct the phylogenetic tree.

The 16S rRNA gene sequence of the type strain *Microcella putealis*, shows the highest pairwise similarity (98.2%) with the type strain of *Yonghaparkia alkaliphila* (Yoon et al., 2006b) and 95.5% with the type strain of *Frigoribacterium faeni* (Kämpfer et al., 2000).

Cells are small and rod shaped. The cell-wall peptidoglycan structure found in members of *Microcella* is of the B-type as in all of the members of the family. However, whereas in *Microcella alkaliphila* the peptidoglycan structure is of the B2β type with D-ornithine as the diagnostic diamino acid, in *Microcella putealis*, a novel B-type peptidoglycan structure was found, with lysine as the diagnostic diamino-acid, but the detailed structure remains unknown. The major respiratory quinones found in *Microcella* strains are unsaturated menaquinones with 11 to 14 isoprene units, but the two species differ in their relative amounts. The cellular fatty acid compositions of *Microcella putealis* and *Microcella alkaliphila* are similar and characterized by the predominance of $C_{15:0}$ anteiso (27.4–32.6%), $C_{16:0}$ iso (34.6–30.8%), $C_{14:0}$ iso (12.1–12.5%), and $C_{15:0}$ iso (10.4–9.8).

Microcella strains were isolated and routinely cultured in Alkaline Buffered Medium 2 (ABM2) adjusted to pH 9.0 (Tiago et al., 2004). ABM2 contains the following components per liter of media: yeast extract (Difco), 5.0 g; triptone (Difco), 5.0 g; α-ketoglutaric acid monopotassium salt (Sigma), 1.0 g; agar (Difco), 15.0 g; 100 ml of a macronutrients solution 10× concentrated; 10 ml of a micronutrients solution 100× concentrated; and 100 ml of a specific buffer solution (listed below) at a concentration of 1 M, autoclaved separately and mixed after cooling. The 10× concentrated macronutrients solution contains per liter: nitrilotriacetic acid, 1.0 g; $CaSO_4 \cdot 2H_2O$, 0.6 g; $MgSO_4 \cdot 7H_2O$, 1.0 g; NaCl, 0.8 g; KNO_3, 1.03 g; $NaNO_3$, 6.89 g; $NaHPO_4$, 1.11 g. The 100× concentrated micronutrients solution contains per liter: $MnSO_4 \cdot H_2O$, 0.22 g; $ZnSO_4 \cdot 7H_2O$, 0.05 g; H_3BO_3, 0.05 g; $CuSO_4 \cdot 5H_2O$, 0.0025 g; $Na_2MoO_4 \cdot 2H_2O$, 0.0025 g; $CoCl_2 \cdot 6H_2O$, 0.0046 g.

The following buffer solutions are used to adjust the medium to different pH values: citrate buffer is used to adjust the pH to 6.5, phosphate buffer is used to adjust the pH to 7.0 and 7.5, tris (hydroxymethyl) aminomethane – Tris buffer is used to adjust pH between 8.0 and 8.5, carbonate-bicarbonate buffer is used to adjust pH between 9.0 and 10.0, and carbonate-KOH is used to adjust pH values higher than 10.0.

Strains belonging to *Microcella* are mesophiles and strictly aerobes, do not reduce nitrate, and are able to utilize several sugars and proteinaceous substances. The known members of the genus *Microcella* are alkaliphilic, growth only occurs at pH above 7, and optimum pH for growth varies from 8.5–9.5.

The type strains of *Microcella putealis* and *Microcella alkaliphila* show a close phylogenetic relationship and a high 16S rRNA gene sequence similarity (99.2%), but the DNA–DNA reassociation value is low.

Strains from both species were isolated from non-saline alkaline groundwater located in Cabeço de Vide in Southern Portugal and constitute the major cultivable population. This groundwater is characterized by a high alkalinity (pH 11.4) associated with an extremely low ionic concentration where Ca^{2+} and OH^- are major chemical constituents. The genesis of this particular environment depends on a complex geological context leading to a geochemical process known as serpentinization (Tiago et al., 2004).

Maintenance procedures

Microcella strains are maintained at −70°C in media used for routine culture (ABM2 adjusted to pH 9.0) supplemented with 15% glycerol. Lyophilized cultures are also used.

Differentiation of the genus *Microcella* from closest related genera

Chemotaxonomic characteristics such as the diagnostic diamino acid (lysine or ornithine) present in the peptidoglycan and the menaquinone composition (MK-11 to MK-14) are important distinctive features to differentiate *Microcella* isolates from the closest related taxa. Furthermore, growth temperature, pH range for growth, and some biochemical characters may also be useful differential characteristics.

Table 161 lists the main characteristics differentiating *Microcella* from closest related *Microbacteriaceae*.

TABLE 161. Characteristics differentiating *Microcella* from closest related bacteria[a]

Characteristic	*Microcella*	*Frigoribacterium faeni*	*Yonghaparkia alkaliphila*
Motility	–	+	–

List of species of the genus *Microcella*

1. **Microcella putealis** Tiago, Pires, Mendes, Morais, da Costa and Veríssimo 2005a, 1743[VP] (Effective publication: Tiago, Pires, Mendes, Morais, da Costa and Veríssimo 2005b, 484.)

pu.te.a′lis. L. fem. adj., *putealis* of or belonging to a well.

Cells are very small, rod shaped (0.4 µm × 0.8–1.6 µm),and nonmotile. Gram-stain-positive. Nonsporeforming. Aerobic and heterotrophic. Colonies are small, smooth, convex, and yellow. Oxidase-negative; catalase-positive.

The diamino acid of peptidoglycan is lysine. Major respiratory quinones are menaquinones 12 (MK-12) and 13 (MK-13), but MK-14 and MK-11 are also present. The predominant fatty acids are $C_{16:0}$ iso, $C_{15:0}$ anteiso, $C_{14:0}$ iso, and $C_{15:0}$ iso comprising about 85% of the total fatty acids.

The optimum temperature for growth is 35°C; no growth occurs at 10°C or 45°C. The optimum pH is between 8.5 and 9.0; no growth occurs at pH 7.0 or 10.5. Growth rate is higher without added NaCl, but grows in media containing up to7.0% NaCl.

The strains of this species do not hydrolyze elastin, esculin, or hippurate, however, they hydrolyze starch, gelatin, arginine, and arbutin. Urease, β-galactosidase, and DNase are present, but xylanase is not. Nitrate is not reduced. The type strain of this species assimilates glycerol, L-arabinose, ribose, D-xylose, galactose, glucose, fructose, mannose, mannitol, cellobiose, maltose, sucrose, inulin, starch, glycogen, gluconate, and 5-ketogluconate.

DNA G+C content (mol%): 68.8.

Type strain: CV-2, CIP 108471, LMG 22692.

Sequence accession no. (16S rRNA gene): AJ717388.

2. **Microcella alkaliphila** Tiago, Morais, da Costa and Veríssimo 2006, 2315[VP]

al.ka.li′phi.la. Arabic article *al* the; Arabic n. *qaliy* ashes of saltwort; N.L. n. *alkali* alkali; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *alkaliphila* loving alkaline environments.

Cells are small, rod shaped (0.3 µm × 3.0 to 4.0 µm), and nonmotile. Gram-stain-positive. Nonsporeforming. Aerobic and heterotrophic. Colonies are small, smooth, convex, and yellow. Oxidase-negative; catalase-positive.

Peptidoglycan is type B2β with D-Orn as the diagnostic diamino acid. The major respiratory quinones are MK-13 and MK-14, but MK-12 is also present. The predominant fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{14:0}$ iso, and $C_{15:0}$ iso comprising more than 85% of the total fatty acids.

The optimum temperature for growth is 35°C; no growth occurs at 20°C or 45°C. The optimum pH is 9.5; no growth occurs at pH 7.5 or 10.5. Growth rate is higher without added NaCl, but grows in medium containing up to 8.0% NaCl.

The type strain of this species does not hydrolyze elastin, esculin, gelatin, arbutin, or casein. Hydrolyzes starch and arginine. Urease, β-galactosidase, and DNase are present; xylanase is not detected. Nitrate is not reduced. The type strain of this species assimilates glycerol, arabinose, ribose, D-xylose, galactose, glucose, fructose, L-rhamnose, mannitol, cellobiose, maltose, sucrose, D-turanose, and 2-ketogluconate.

DNA G+C content (mol%): 67.1 (HPLC).

Type strain: AC4r, CIP 108473, LMG 22690

Sequence accession no. (16S rRNA gene): AJ717385.

Genus XVI. **Microterricola** Matsumoto, Yamada, Ōmura and Takahashi 2008, 1021[VP]

Atsuko Matsumoto and Yōko Takahashi

Mic.ro.ter.ri′co.la. Gr. adj. *mikros* small; L. fem. n. *terricola* dweller in soil; N.L. fem. n. *Microterricola* a small dweller in soil.

Irregular rod-shaped cells, 0.4-0.5 × 0.6-1.2 µm and longer in the early cultures. Gram-stain-positive. **Cells with long flagella have motility** (Figure 190, Figure 191). The color of colonies is pale yellow. Catalase-positive; oxidase-negative. Aerobic. Mesophilic. **The diamino acid in cell wall is diaminobutyric acid (DAB)**. The predominant menaquinone is MK-12. 16S rRNA gene sequence analysis shows that this genus belongs to the family *Microbacteriaceae.*

DNA G+C content (mol%): 70.

Type species: **Microterricola viridarii** Matsumoto, Yamada, Ōmura and Takahashi 2008, 1021[VP].

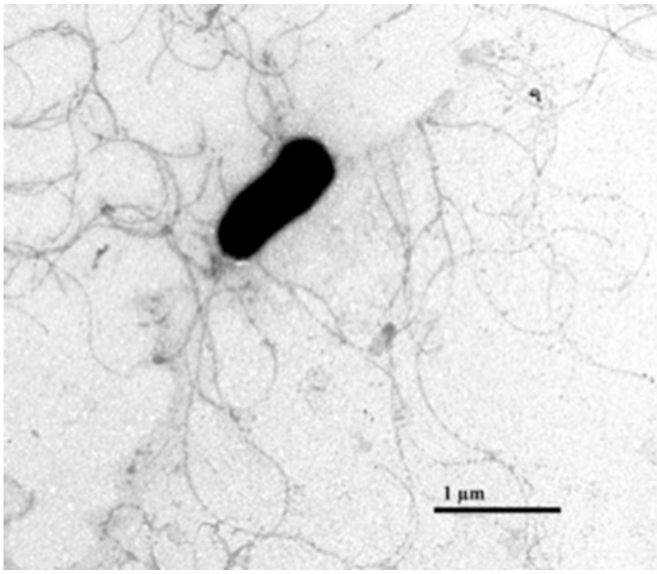

FIGURE 190. Electron micrograph of *Microterricola viridarii* KV-677^T that was negatively stained. Cells cultured on nutrient agar for 2 d at 27°C show long flagella and motility.

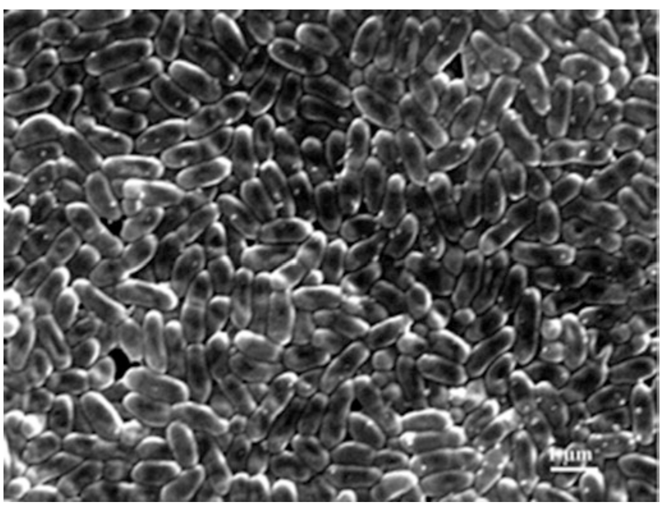

FIGURE 191. Scanning electron micrograph of *Microterricola viridarii* KV-677^T cells cultured on nutrient agar for 10 d at 27°C. Cells are irregular rods and longer in early cultures.

Further descriptive information

The cell-wall peptidoglycan contains DAB, glycine, alanine, and glutamic acid. The acyl type of muramic acid is acetyl. The predominant menaquinone is MK-12. MK-11 and MK-13 are minor menaquinones, however, the amount of total menaquinones in this strain is significantly lower than in other members of the family *Microbacteriaceae*. Mycolic acids are not detected. The dominant cellular fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso, and their total accounts for over 80% in type strain of *Microterricola viridarii*.

Enrichment and isolation procedures

The type strain was isolated using GPM agar* containing 0.002% Benlate (Dupont) and 0.0025% nalidixic acid (Sigma) after incubation for 1 week at 27°C from soil collected at a park in the Tokyo metropolitan area, Japan. The organisms grow well on nutrient agar for 2 d at 27°C.

Maintenance procedures

The type strain is maintained by lyophilization. Cultures may be also stored for several years at −80°C with 15% glycerol.

Differentiation of the genus *Microterricola* from other genera

Microterricola has long flagella and shows motility. Table 162 lists the chemotaxonomic differentiations of *Microterricola* and other genera with cell motility in the family *Microbacteriaceae*. *Microterricola* is distinguished from *Agreia* (Evtushenko et al., 2001), *Curtobacterium* (Yamada and Komagata, 1972b), *Frigoribacterium* (Kämpfer et al., 2000), *Humibacter* (Vaz-Moreira et al., 2008b), *Microbacterium* (Takeuchi and Hatano, 1998b), and *Rhodoglobus* (Sheridan et al., 2003) by the presence of DAB as the sole cell-wall diamino acid. The major menaquinone of *Microterricola* is different from those of *Agreia*, *Curtobacterium*, *Frigoribacterium*, *Leifsonia* (Evtushenko et al., 2000), and *Phycicola* (Lee et al., 2008).

Taxonomic comments

Microterricola is very closely related to *Phycicola* in 16S rRNA gene sequence analysis, and the similarity value is also high (>99%). They are distinguished by the ratio of menaquinones; the type species of *Microterricola* contains MK-12 (69%), MK-11 (21%), and MK-13 (10%), and *Phycicola* contains MK-11 (71%), MK-10 (15%), MK-12 (9%), and MK-9 (5%) (Lee et al., 2008).

List of species of the genus *Microterricola*

1. **Microterricola viridarii** Matsumoto, Yamada, Ōmura and Takahashi 2008, 1021[VP]

vi.ri.da′ri.i. L. gen. n. *viridarii* of a pleasure-garden, the place where the type strain was isolated.

The color of colonies is pale yellow. Cell size is about 0.4-0.5 × 0.6-1.2 µm. The temperature range for growth is 10-38°C, and the optimum range is 15-30°C. Growth occurs at initial pH 6-11. Glycerol, L-arabinose, D-ribose, esculin, D-maltose, and glycogen are utilized as carbon sources. No growth occurs in the presence of 4% (w/v) NaCl.

In disc susceptibility tests, cells are susceptible to tetracycline (30 µg/disc), polymyxin B (300 U/disc), amikacin (30 µg/disc), chloramphenicol (30 µg/disc), erythromycin (15 µg/disc), norfloxacin (10 µg/disc), ciprofloxacin (5 µg/disc), tobramycin (10 µg/disc), vancomycin (30 µg/disc), kanamycin (30 µg/disc), gentamicin (10 µg/disc), ampicillin (10 µg/disc), imipenem (10 µg/disc), and ceftazidime (30 µg/disc).

The predominant components of cellular fatty acid are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso, and other fatty acids are $C_{16:0}$ iso, $C_{15:0}$ iso, and $C_{16:0}$.

DNA G+C content (mol%): 70 (HPLC).

Type strain: KV-677, JCM 15926, NBRC 102123, NRRL B-24538.

Sequence accession no. (16S rRNA gene): AB282862.

Genus XVII. **Mycetocola** Tsukamoto, Takeuchi, Shida, Murata and Shirata 2001, 941[VP]

Takanori Tsukamoto

My.ce.to′co.la. Gr. n. *mukês -etis* a mushroom, fungus; L. suff. *-cola* (from L. masc. or fem. n. *incola*), dweller, inhabitant; N.L. masc. n. *Mycetocola* fungus-dweller.

Aerobic, Gram-stain-positive, nonsporeforming, nonmotile actinomycetes which form irregular rods (0.2–1.1 × 1.5–3.5 µm). Colonies are circular, convex, and smooth on nutrient agar. Growth occurs between 20–30°C, optimally at 25°C, but not at 4°C or 37°C. Catalase-positive, but oxidase-negative. Esculin is hydrolyzed and tributyrin and Tween 40 degraded. Acid is produced from a broad range of sugars and diverse compounds used as sole carbon sources. **Lysine is the diamino acid in the cell-wall peptidoglycan**. **Muramic acid moieties are *N*-acetylated. The polar lipid pattern consists of two phospholipids, a major diphosphatidylglycerol spot, a prominent glycolipid, and a faint phosphatidylglycerol spot; unsaturated menaquinones with ten isoprene units are the predominant isoprenologues. The major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.** The phylogenetic position of *Mycetocola*, as determined by 16S rRNA gene sequence analysis, is in the family *Microbacteriaceae*.

Isolated from rotting fruiting bodies of some cultivated or wild *Agaricales* fungi, such as *Lepista nuda* and *Pleurotus ostreatus*, and from the surfaces of Reblochon cheeses.

DNA G+C content (mol%): 64–70.

Type species: **Mycetocola saprophilus** Tsukamoto, Takeuchi, Shida, Murata and Shirata 2001, 942[VP].

Further descriptive information

Phylogeny. The genus *Mycetocola* is a member of the family *Microbacteriaceae* of the order *Micrococcales* and forms an independent phyletic line in the 16S rRNA *Microbacteriaceae* gene tree (Figure 13 in the Road Map to the present volume), a position supported by a high bootstrap value and several tree-making algorithms (Bora et al., 2008). Phylogenetic trees generated from 16S rRNA gene sequences and those from less conserved genes (*gyr*β, *ppk*, *recA* and *rpoB*) show that the genus is most closely related to the genera *Microbacterium* and *Okibacterium* (Evtushenko and Takeuchi, 2006; Stackebrandt et al., 2007).

Cell morphology. *Mycetocola lacteus*, *Mycetocola saprophilus*, and *Mycetocola tolaasinovorans* strains form irregular rods (0.2–0.4 × 2.0–3.5 µm) when grown in PS broth [$Ca(NO_3)_2$× $4H_2O$, 0.5 g; $Na_2HPO_4 \cdot 12H_2O$, 2 g; peptone, 5 g; sucrose, 15 g; decoction of 300 g potato tuber slices, 1 l] for 24 h at 28°C (Tsukamoto et al., 2001). Similarly, *Mycetocola reblochoni* strains form rod-shaped elements (0.3–1.1 × 1.5 µm) on PY agar after 2 d at 30°C (Bora et al., 2008).

Chemotaxonomy. Cell-wall hydrolysates of *Mycetocola* strains contain major amounts of lysine as the diagnostic

[b]Data taken from Bora et al. (2008).

diamino acid (Bora et al., 2008; Tsukamoto et al., 2001). The type strains of the four species contain lysine, alanine, glycine, and glutamic acid in the molar ratios of 1.0:0.6:1.1:1.6 (*Mycetocola reblochoni*), 1.0:0.6:1.0:1.6 (*Mycetocola lacteus*), 1.0:0.5:0.8:1.7 (*Mycetocola saprophilus*), and 1.0:0.7:1.0:1.7 in the case of *Mycetocola tolaasinivorans* (Bora et al., 2008). These workers found that the type strains of *Mycetocola saprophilus*, *Mycetocola reblochoni*, and *Mycetocola tolaasinovorans* had alanine as the *N*-terminal amino acid of the interpeptide bridge. They also found that the peptide patterns of partially hydrolyzed peptidoglycan of representative *Mycetocola reblochoni* strains were very similar, consisting of the dipeptides L-alanine-D-glutamic acid, glycine-D-glutamic acid, and L-lysine-D-alanine, data which justified the conclusion that the strains have a β-type peptidoglycan (Schleifer, 1985), a finding in line with the phylogenetic position of the organisms.

The type strains of the four *Mycetocola* species have *N*-acetylated muramic acid residues, fatty acid profiles rich in hexadecanoic ($C_{16:0}$), 12-methyltetradecanoic ($C_{15:0}$ anteiso), and 14-methylpentadecanoic ($C_{16:0}$ iso) acids, and major amounts of unsaturated menaquinones with ten isoprene units (Bora et al., 2008; Tsukamoto et al., 2001). These investigators also reported quantitative differences in fatty acid and menaquinone components, as is evident from Table 163. In addition, the type strains share simple polar lipid patterns (Bora et al., 2008), as given in the genus description.

Colony morphology and cultural conditions. *Mycetocola lacteus*, *Mycetocola saprophilus*, and *Mycetocola tolaasinivorans* strains grow optimally at 25°C, but do not grow above 33°C or at 4°C, and form circular, convex, smooth, yellowish-white colonies on PS agar (Tsukamoto et al., 2001). Similarly, *Mycetocola reblochoni* strains grow between 20 and 30°C on PY medium (peptone, 10 g; yeast extract, 2 g; D-glucose, 2 g; NaCl, 2 g; distilled water, 1 liter; Tsukamoto et al., 2001), but not at 37°C (Bora et al., 2008). These workers reported that members of *Mycetocola* species produced smooth, circular, convex colonies on brain heart infusion agar (Difco).

Metabolism. Little is known about the metabolic properties of *Mycetocola* strains though they are obligate aerobes and form acid from a broad range of sugars including cellobiose, fructose, glucose, glycerol, maltose, mannitol, and ribose (Bora et al., 2008; Tsukamoto et al., 2001). They use diverse carbon compounds, such as adonitol, dulcitol, ethanol, fucose, glycogen, melibiose, rhamnose, turanose, xylitol, and xylose (all at 1%, w/v), and sodium salts, including acetate, citrate, pyruvate, and valerate (all at 0.1%, w/v), as well as some sole carbon and nitrogen compounds (Bora et al., 2008). These investigators also noted that *Mycetocola* strains hydrolyzed esculin, but not allantoin, and produced esterase lipase (C8) and naphthol-AS-B1 phosphohydrolase, but not alkaline phosphatase, *N*-acetyl-β-glucosamidase, α-fucosidase, β-glucuronidase, lipase (C14), or α-mannosidase. Similarly, they degraded tributyrin and Tween 40, but not elastin, gelatin, guanine, hypoxanthine, uric acid, or xylan.

Strains of *Mycetocola lacteus*, *Mycetocola saprophilus*, and *Mycetocola tolaasinivorans* grow in peptone water but not in Cohn's, Fermi's, or Uschinsky's solutions, and do not produce hydrogen sulfide, indole, 3-ketolactose or 2-ketogluconate, macerate potato tubers, invoke hypersensitivity reactions in tobacco leaves, or form levan from sucrose, and they are negative for the methyl red and Voges–Proskauer tests (Tsukamoto et al., 2001). In addition, strains of these species detoxify tolaasins, pathogenic toxins (Nutkins et al., 1991; Shirata et al., 1995) which are produced extracellularly by *Pseudomonas tolaasii* (Suyama and Fujii., 1993; Tolaas, 1915) and cause brown blotch disease in the economically important cultivated mushrooms, *Agaricus*

bispora and *Pleurotus ostreatus* (Murata et al., 1998; Nutkins et al., 1991; Rainey et al., 1993; Shirata et al., 1995).

Ecology. The type strains of *Mycetocola lacteus*, *Mycetocola saprophilus*, and *Mycetocola tolaasinivorans*, and additional members of the first two species, were isolated from a rotting fruiting body of *Pleurotus ostreatus* and shown to markedly reduce the levels of extracellular toxins, tolaasins, produced by *Pseudomonas tolaasii*, the most destructive pathogen of cultivated mushrooms (Tsukamoto et al., 1998, 2001). Representatives of these organisms, including the type strains, were shown to suppress the development of brown blotch disease of cultivated mushrooms caused by *Pseudomonas tolaasii* (Tsukamoto et al., 2002). In contrast, *Mycetocola reblochoni* strains were isolated from the surfaces of Reblochon cheeses at the late stage of ripening (Bora et al., 2008).

Tsukamoto et al. (1998) showed that brown blotch disease did not develop on the fruiting bodies of cultivated mushrooms when they were sprayed with *Mycetocola tolaasinivorans* strain 9405^T (= CM-05^T) 1–2 d prior to inoculation with *Pseudomonas tolaasii*. Effective control of the disease required a ratio of 1:10 of the initial cell number of the type strain against those of the pathogen. This positive effect was considered to be due to inactivation of tolaasin by the live cells of the type strain, not to metabolites secreted from the cells into the culture media.

The effect of *Mycetocola tolaasinivorans* strain CM-05^T on *Pseudomonas tolaasii in vitro* was examined by Tsukamoto et al. (1998) who co-inoculated about 2×10^5 cells/ml of these bacteria at 24°C for 48 h on a rotary shaker. Cell pellets resuspended in sterile water were examined to determine viable cell numbers and culture supernatants were assayed for the level of tolaasin activity using a potato tuber slice method (Shirata et al., 1995) in which the presence or absence of strain CM-05^T, though supernatants from the mixed culture failed to induce blackening of tuber slices. The authors suggested that the suppression of the toxin occurred either through inhibition of tolaasin production in the *Pseudomonas tolaasii* strain or by inactivation of tolaasin activity in the medium, not through suppression of growth or viability of the pathogen. Strain CM-05^T was then cultured in PS-TOL broth, a medium which contained tolaasins, in order to establish whether the suppressive effect was due to the inactivation of tolaasin activity. To this end, culture supernatants were periodically harvested by centrifugation, serially diluted, and applied to potato tuber slices to determine tolaasin activity. The activity was found to sharply decrease to half the original level within 3 h of inoculation, with inactivation persisting for up to 24 h without any detectable level of toxicity even in the undiluted sample. *Pseudomonas tolaasii* was then cultured in PS-broth and in broth supplemented with spent culture supernatant of strain CM-05^T to establish whether detoxification could be attributed to secreted metabolites or was associated with live cells of strain CM-05^T. A significant level of tolaasin was detected irrespective of the presence or absence of the culture supernatants. In addition, two strains isolated from wild fungi belonging to the *Agaricales*, namely *Mycetocola lacteus* OM-A1 and *Mycetocola tolassinivorans* OM-F11, were found to detoxify tolaasin effectively and suppress the brown blotch disease of cultivated mushrooms (Tsukamoto et al., 2002).

Isolation procedures

The tolaasin-detoxifying *Mycetocola* species can be isolated on potato synthetic agar ($Ca(NO_3)_2 \cdot 4H_2O$, 0.5 g; $Na_2HPO_4 \cdot 12H_2O$, 2 g; peptone, 5 g; sucrose, 15 g; agar, 15 g; decoction of 300 g potato tuber slices, 1 liter; pH 7.0; Wakimoto, 1955) and T-PAF medium (Suyama et al., 1995); the latter formulation is based on *Pseudomonas* agar F (PAF) with the addition of tartrate, 2 g; 0.1% crystal violet, 5 ml; 0.2% BTB, 15 ml; cycloheximide, 100 μg in 1 liter (Suyama et al., 1995). *Mycetocola* strains form yellow colonies on these media, whereas those of *Pseudomonas tolaasii* are a distinctly blue color (Suyama et al., 1995; Wakimoto, 1955). Tolaasin-detoxifying mycetocolae can also be isolated by using the potato tuber slice method (Shirata et al., 1995). Target strains growing on isolation plates should be cultured aerobically at 28°C in PY agar or other media based on glucose, peptone, and yeast extract.

Bora et al. (2008) isolated *Mycetocola reblochoni* strains from Reblochon cheeses by suspending and homogenizing samples of the red smear surface in 2%, w/v, sodium citrate prior to plating tenfold dilutions onto plate count agar (PCA; Biokar Diagnostics) supplemented with 3% w/v sodium chloride. Purified cultures derived from the PCA plates were screened using a *rep*-PCR procedure and the *Mycetocola reblochoni* strains recognized by their distinctive banding patterns following agarose gel electrophoresis.

Maintenance procedures

Short-term preservation can be accomplished by serial transfer every few weeks in appropriate media, such as PS agar (Tsukamoto et al., 2001) and trypticase soy agar (Difco). Longer term preservation can be achieved as frozen stocks in 20%, v/v aqueous glycerol at −20°C and/or at 80°C, or by using standard lyophilization procedures.

Differentiation of the genus *Mycetocola* from other genera

Mycetocola strains form a distinct phyletic line in the 16S rRNA *Microbacteriaceae* gene tree (Figure 13 in the Road Map to the present volume). They can also be distinguished from other genera classified in this family using a combination of chemical markers (Table 163). In addition, peptidoglycan data distinguish them from all other known peptidoglycans based on lysine (Bora et al., 2008).

Differentiation of species of the genus *Mycetocola*

Mycetocola species can be distinguished from one another by using a combination of phenotypic properties (Table 164). They can also be separated by DNA:DNA relatedness data and by quantitative differences in fatty acid and menaquinone components (Bora et al., 2008; Tsukamoto et al., 2001).

[b]Data taken from Tsukamoto et al. (2001) and Bora et al. (2008).

List of species of the genus *Mycetocola*

1. **Mycetocola saprophilus** Tsukamoto, Takeuchi, Shida, Murata and Shirata 2001, 942[VP]

sa.pro′phi.lus. Gr. adj. *sapros* putrid; N.L. masc. adj. *philus* (from Gr. masc. adj. *philos*) friend, loving; N.L. masc. adj. *saprophilus* putrid-loving.

Obligately aerobic, nonsporeforming, nonmotile, Gram-stain-positive actinomycetes which form irregular rods (0.2–0.4 × 2.0–3.5 μm) and smooth yellowish-white colonies on PS agar. Grows optimally at 25°C in PS broth. Maximum temperature for growth is 33°C, but does not grow at 4°C.

Additional phenotypic properties are cited either in the text or are shown in Table 164.

Forms a distinct phyletic line in the 16S rRNA gene tree and has chemotaxonomic properties typical of the genus *Mycetocola*.

Source: a rotting fruiting body of the cultivated mushroom *Pleurotus ostreatus*.

DNA G+C content (mol%): 65.2 (HPLC).

Type strain: CM-01, DSM 15178, NBRC 16274, JCM 11655, MAFF 211324, NRRL B-24119.

Sequence accession no. (16S rRNA gene): AB012647, AM410677.

2. **Mycetocola lacteus** Tsukamoto, Takeuchi, Shida, Murata and Shirata 2001, 942[VP]

lac.te′us. L. masc. adj. *lacteus* milky.

Obligately aerobic, nonsporeforming, nonmotile, Gram-stain-positive actinomycetes which form irregular rods (0.2–0.4 × 2.0–3.5 μm), and smooth yellowish-white colonies on PS agar. Grows optimally at 25°C in PS broth. Maximum temperature for growth is 33°C, but does not grow at 4°C.

Additional phenotypic properties are cited either in the text or are shown in Table 164.

Forms a distinct phyletic line in the 16S rRNA gene tree and has chemotaxonomic properties typical of the genus *Mycetocola*.

Source: a rotting fruiting body of the cultivated mushroom *Pleurotus ostreatus*.

DNA G+C content (mol%): 63.9–64.7 (HPLC).

Type strain: CM-10, DSM 15177, NBRC16278, JCM 11654, MAFF 211326, NRRL B-24121.

Sequence accession no. (16S rRNA gene): AB012648, AM410678.

3. **Mycetocola reblochoni** Bora, Vancanneyt, Gelsomino, Snauwaert, Swings, Jones, Ward, Chamba, Kroppenstedt, Schumann and Goodfellow 2008, 2691[VP]

re.blo.cho′ni. N.L. neut. n. *reblochonum* Reblochon cheese; N.L. gen. n. *reblochoni* of a Reblochon cheese, to denote that the first strains were isolated from the surface of Reblochon cheese.

Aerobic, Gram-stain-positive, nonsporeforming, rod-shaped actinomycetes (0.3 × 1.1–1.5 µm) which form circular, convex, smooth, shiny colonies on PY agar. Grows between 20–30°C, but not at 37°C, and from pH 7.0–10.0, but not at pH 12.0.

Additional phenotypic properties are cited either in the text or are shown in Table 164.

Forms a distinct phyletic line in the 16S rRNA gene tree and has chemotaxonomic properties typical of the genus *Mycetocola*.

Source: the surfaces of Reblochon cheeses at the late stage of ripening.

DNA G+C content (mol%): 70.0 (HPLC).

Type strain: R-20377, BRB-1L41, DSM 18580, LMG 22367.

Sequence accession no. (16S rRNA gene): DQ062097.

4. **Mycetocola tolaasinivorans** Tsukamoto, Takeuchi, Shida, Murata and Shirata 2001, 942[VP]

to.la.a.si.ni.vo′rans. N.L. neut. n. *tolaasinum* tolaasin, type of toxin produced by *Pseudomonas tolaasii*; L. part. adj. *vorans* devouring; N.L. part. adj. *tolaasinivorans* tolaasin-devouring (tolaasin-decomposing).

Obligately aerobic, nonsporeforming, nonmotile, Gram-stain-positive actinomycete which form irregular rods (0.2–0.4–2.0 × 3.5 µm), and smooth yellowish-white colonies on PS agar. Grows optimally at 25°C in PS broth. Maximum temperature for growth is 33°C, but does not grow at 4°C.

Additional phenotypic properties are cited either in the text or are shown in Table 164.

Forms a distinct phyletic line in the 16S rRNA gene tree and has chemotaxonomic properties typical of the genus *Mycetocola*.

Source: a rotting fruiting body of the cultivated mushroom *Pleurotus ostreatus*.

DNA G+C content (mol%): 65.1 (HPLC).

Type strain: CM-05, 9405, DSM 15179, NBRC 16277, JCM 11656, MAFF 211325, NRRL B-24120.

Sequence accession no. (16S rRNA gene): AB012646.

Genus XVIII. **Okibacterium** Evtushenko, Dorofeeva, Krausova, Gavrish, Yashina and Takeuchi 2002, 991[VP]

Lyudmila I. Evtushenko

O.ki.bac.te′ri.um. N.L. n. *Oka* the name of the river; L. neut. n. *bacterium* small rod and, in biology, a bacterium (so called because the first ones observed were rod-shaped); N.L. neut. n. *Okibacterium* a bacterium isolated from plants collected near the river Oka.

Small irregular rods (mean 0.4–0.6 × 0.7–1.5 µm). **In older cultures, ovoid or irregular coccoid cells predominate and occur mostly singly or in pairs.** A distinct rod–coccus growth cycle is not observed. No marked motility or primary branching. Cell-wall architecture is typical of **Gram-stain-positive** bacteria, **but cells are readily decolorized.** Nonsporeforming. Non-acid-fast. **Chemo-organotroph with a respiratory type of metabolism.** Catalase and oxidase-positive. Oxidative acid production from some carbohydrates. Mesophilic; optimum temperature ~24–27°C. **The cell-wall peptidoglycan contains lysine as the diamino acid** along with alanine, glycine, glutamic acid, **homoserine, and** the **glycolyl type of muramic acid. Major menaquinones are MK-10 and MK-11**. Saturated fatty acids with anteiso-methyl branched chains predominate (more than 70%). Mycolic acids are absent. Polar lipids comprise diphosphatidylglycerol, phosphatidylglycerol, and a variety of glycolipids.

DNA G+C content (mol%): 67.

Type species: **Okibacterium fritillariae** Evtushenko, Dorofeeva, Krausova, Gavrish, Yashina and Takeuchi 2002, 992[VP].

Further descriptive information

The genus *Okibacterium* belongs to the family *Microbacteriaceae*, order *Micrococcales*. Based on the 16S rRNA gene sequence analysis, *Okibacterium* forms a tight phylogenetic group with the genus *Plantibacter* (see Figure 173). Moreover, the genes encoding DNA gyrase subunit B (*gyrB*), RNA-polymerase subunit B (*rpoB*), recombinase A (*recA*), and polyphosphate kinase (*ppk*) of *Okibacterium fritillariae*, in the absence of the respective data on *Plantibacter* species, do not form robust clusters with representatives of 12 other genera of the family (Stackebrandt et al., 2007).

In young culture, cells are irregular, straight or sometimes slightly curved, short rods, mostly 0.4–0.6 µm × 0.7–1.5 µm (Figure 192). In older cultures (4–7 d), the cells become shorter rods or coccoid forms and usually occur singly or in pairs. A distinct rod–coccus growth cycle like that in *Arthrobacter* species is typically not observed. Reproduction is by fission with the formation of a transverse septum. The electron microscopic

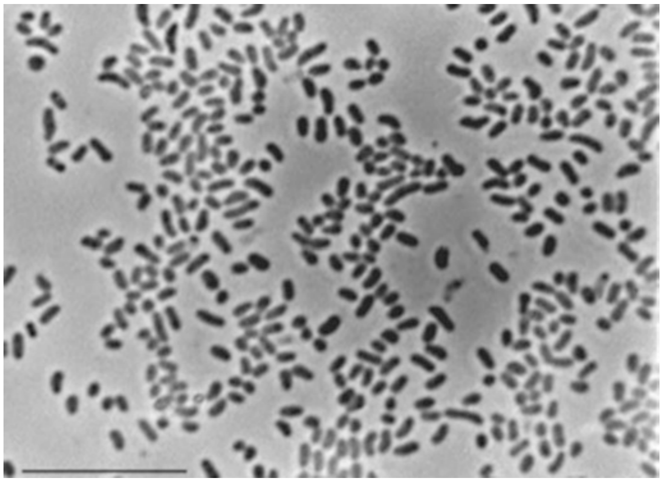

FIGURE 192. Cellular morphology of *Okibacterium fritillariae*. Cells from a 2-d-old slide culture on CB agar were imaged by phase-contrast microscopy. Bar = 10 μm. (Courtesy of N.E. Suzina.)

studies have shown that the cell-wall structure is typical of Gram-stain-positive bacteria. The wall contains a nearly homogeneous electron-dense thick coat (peptidoglycan) around the cytoplasmatic membrane and an irregular outer layer of less density. The tests with Gram-staining and KOH are indistinct or negative (cells frequently fail to retain the Gram stain; the KOH test also shows a reaction typical of Gram-stain-negative bacteria).

Cell-wall hydrolysates contain lysine, alanine, glycine, glutamate, and homoserine in a molar ratio close to 1:1:1:1:0.5 (the reduced content of homoserine is due to formation of the lactone from some portion of homoserine). The amino acid composition is similar to that of *Frigoribacterium faeni* which possesses the B2β type of peptidoglycan (Kämpfer et al., 2000). The glycan moiety of the peptidoglycan preferably contains *N*-glycolyl residues as determined by the method of Uchida and Aida (1977). The cell-wall sugars of both *Okibacterium frutillarim* strains examined are similar and include rhamnose as the predominant component and a minor quantity of glucose. The fatty acid profiles of the two *Okibacterium frutillarim* strains tested contain saturated $C_{15:0}$ anteiso (48% and 54%), $C_{17:0}$ anteiso (23% and 19%), and $C_{16:0}$ iso (29% and 20%) as predominant components; other branched ($C_{14:0}$ iso, $C_{15:0}$ iso, and $C_{17:0}$ iso), straight-chain, and unidentified fatty acids each make up 1–3% of the total. No ω-cyclohexyl or 10-methyl branched acids were detected. The principal polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and a characteristic unknown predominant glycolipid; in addition, one unidentified minor and a few glycolipids in trace amounts have been revealed (N.G. Vinokurova and L.I. Evtushenko, recent observation). The predominant glycolipid showed the same chromatographic behavior as the glycolipid 3 (G_3) reported for representatives of *Rathayibacter* and *Clavibacter* (Collins and Jones, 1980). The major respiratory menaquinone is MK-10, followed by MK-11 and minor amounts of MK-9 and MK-8, as determined by mass spectrometry. Oxidase test with tetramethyl-*p*-phenylendiamine is positive. Both strains have the aa_3- types of cytochrome oxidase; oxidase *bd* is additionally synthesized under oxygen limitation (Trutko et al., 2003).

Colonies of *Okibacterium fritillariae* are yellow-pigmented due to the presence of C_{40}-carotenoids (Trutko et al., 2005). The suppression of pigmentation by fosmidomycin in the concentrations of 0.1–0.3 mg/ml, which are lower than those inhibitory for growth, suggests that the pigment is synthesized via the nonmevalonate pathway (Kuzuyama, 2002; Lichtenthaler, 2000).

Strains usually grow well on standard laboratory media based on yeast extract, peptone, and glucose at near neutral pH and use a wide range of carbon sources for growth and energy in a mineral medium supplemented with 0.1% (w/v) of yeast extract and 0.1% (w/v) of casitone.

Okibacterium fritillariae srains VKM Ac-2059 and VKM Ac-2062 are sensitive to the following antibiotics [inhibitory concentration (μg/ml) in parentheses]: erythromycin (15), levomycetin (30), neomycin (30), streptomycin (30), and tetracycline (30). Strain VKM Ac-2059 is also inhibited by kanamycin (30) and linkomycin (15), while VKM Ac-2062 tolerates these antibiotics.

Little information is available on the habitat and ecology of members of the genus *Okibacterium*. The bacteria are often associated with plants and can be endophytes. The two strains of *Okibacterium fritillariae* were isolated from nearly matured seeds removed aseptically from the seed pods of *Fritillaria ruthenica* Wikstr. and *Clematis recta* L. The seeds were not surface sterilized. On the basis of partial rRNA gene sequences, bacteria similar to *Okibacterium fritillariae* were revealed in endophytic bacterial communities in poplar grown under field conditions (Ulrich et al., 2008) and the shoots and rhizosphere of the Ni-hyperaccumulator *Thlaspi goesingense* (Idris et al., 2004). Most of these *Thlaspi goesingense*-associated strains formed siderophores and tolerated Ni at concentrations of 1–10 mM. Some strains produced 1-aminocyclopropane-1-carboxylic acid deaminase, an enzyme proposed to have no function in bacteria, but able to modulate ethylene levels in developing plants by reducing the amount of the precursor and lowering the levels of "stress" ethylene biosynthesized (Glick et al., 1998; Idris et al., 2004). *Okibacterium* sp. strain GIC 24y was recovered from a deep ice core from a Greenland glacier which was at least 120,000 years old. The strain had small yellow colonies, was able to grow at the temperature range of 2–25°C, and displayed the activities for amylases, β-galactosidases, and DNase (Miteva et al., 2004b). Representatives of the genus were also associated with sponge (*Petrosia ficiformis*) collected along the Mediterranean coast (Bourrain, M., R. Belbes, L. Intertaglia and P. Lebaron, GenBank accession no. AM990749) and with feces of giant panda (*Ailuropoda melanoleuca*) (Ley et al., 2008). There is also a clinical isolate among members of the genus *Okibacterium*. Strain VA8728_00 was discovered in the central venous catheter of a heart-transplant patient (Geissdoerfer, W., I. Wittmann, C. Schoerner, and M. Roellinghoff, GenBank accession no. AF306834).

Enrichment and isolation procedures

Several procedures and media commonly used for isolation of plant-associated bacteria can be used for the isolation of *Okibacterium*. For isolation of strains of *Okibacterium fritillariae*, the seeds of *Fritillaria ruthenica* and *Clematis recta* were cut into pieces, added to 1 ml of 0.85% NaCl (w/v) solution, and ground with a pestle. One drop of the suspension was plated onto CB agar (glucose, 5 g; peptone 5 g; Casamino acids, 3 g;

NaCl, 5 g; agar, 15 g, tap water 1 liter, pH 7.0) and incubated up to 3 weeks at room temperature (18–24°C) under daylight. Tenfold-diluted Trypticase soy agar (Difco) supplemented with $NiCl_2$ (up to 10 mM) and cycloheximide (100 mg/l) was used to isolate *Okibacterium*-like strains associated with the Ni-hyperaccumulator *Thlaspi goesingense* (Idris et al. (2004). Enrichment and subsequent isolation of *Okibacterium* strains can be carried out using MM1 medium supplemented with acetate as described by Miteva et al. (2004b).

Maintenance procedures

Okibacterium strains can be maintained on CB or R2A agar for up to 3 months at 10°C. For long-term preservation, strains can be lyophilized by standard procedures. The two strains of *Okibacterium fritillariae* have been safely maintained for 10 years in lyophilized state with skim milk as a cryoprotectant.

Differentiation of the genus *Okibacterium* from other genera

Characteristics useful for phenotypic delineation of *Okibacterium* from other genera of the family are discussed in the chapter on the family *Microbacteriaceae* (see Table 140). The salient characteristics which differentiate *Okibacterium* strains from the phylogenetically closest genus *Plantibacter* include the presence of lysine as the diamino acid in cell-wall peptidoglycan and the glycolyl type of muramic acid. *Okibacterium* is also clearly distinguished from *Plantibacter* and many other genera of the family by its cellular morphology, particularly in older cultures where coccobacillary forms dominate.

List of species of the genus *Okibacterium*

1. **Okibacterium fritillariae** Evtushenko, Dorofeeva, Krausova, Gavrish, Yashina and Takeuchi 2002, 992[VP]

fri.til.la.ri′a.e. N.L. gen. n. *fritillariae* of *Fritillaria* generic name of the plant, the source of isolation of the type strain of the species.

Visible growth is observed at 26°C after 3–4 d on CB medium. The colonies are yellow, circular, somewhat convex, glistening, and opaque. Pigment formation is not induced by daylight. No primary branching or distinct motility by flagella. Growth is observed at 7–37°C. The optimum is 24–27°C. H_2S is produced weakly from peptone. D-Arabinose, cellobiose, D-fructose, D-galactose, D-glucose, inositol, inulin, lyxose, maltose, D-mannitol, D-mannose, L-rhamnose, salicin, sorbitol, sucrose, trehalose, and D-xylose are used as carbon and energy sources. Adonitol, dextrin, dulcitol, *meso*-erythritol, and ribose are not used as carbon sources. Growth in the presence of D-melibiose and salicin is weak or absent. Acids are produced during aerobic growth from D-arabinose, D-glucose, mannose, L-rhamnose, sucrose, trehalose, and D-xylose, but not from D-melibiose, melezitose, L-rhamnose, raffinose, D-sorbose, and sorbitol. Starch and esculin are decomposed; hypoxanthine, tyrosine, xanthine, casein, Tween 40, Tween 60, and Tween 80 are not. Tolerates 6% (w/v) NaCl. The chemotaxonomic characteristics are listed in the genus description.

Source (type strain): seeds of *Fritillaria ruthenica* Wikstr. collected in Priosko-Terrasny Biosphere Park, Moscow Region, Russia.

DNA G+C content (mol%): 67 (T_m).

Type strain: DE-504, DSM 15271, NBRC 16404, JCM 12284, VKM Ac-2059.

Sequence accession no. (16S rRNA gene): AM410675.

Genus XIX. **Phycicola** Lee, Lee, Seo, Schumann, Kim and Lee 2008, 1321[VP]

António Veríssimo

Phy.ci′co.la. L. n. *phycos -i* seaweed; L. masc. suffix. *-cola* inhabitant; N.L. masc. n. *Phycicola* inhabitant of seaweed.

Cell morphology varies from rod-shaped (0.4–0.5 × 0.8–1.2 μm) to coccoid cells (0.18–0.33 μm in diameter). **Gram-stain-positive**. Rod-shaped cells are motile whereas the coccoid forms are nonmotile. Nonsporeforming. Chemo-organotrophic. Oxidase-negative and catalase-positive. The cell-wall peptidoglycan is of the **B-type containing 2,4-diaminobutyric acid** (DAB) as the diagnostic amino acid. Fatty acids are predominantly anteiso-branched, namely $C_{15:0}$ anteiso and $C_{17:0}$ anteiso. Mycolic acids are not present. The respiratory quinones are unsaturated **menaquinones, predominantly MK-11 (71%)**, but MK-10 (15%), MK-12 (9%), and MK-9 (5%) are also present in lesser amounts.

DNA G+C content (mol%): 69.8.

Type species: **Phycicola gilvus** Lee, Lee, Seo, Schumann, Kim and Lee 2008, 1321[VP].

Further descriptive information

Phylogenetic analysis based on the 16S rRNA gene sequences show that genus *Phycicola* is closely related with the type strain of *Microterricola viridarii* (Matsumoto et al., 2008), forming a coherent cluster within the radiation of the family *Microbacteriaceae*. The pairwise 16S rRNA gene sequence similarity between *Phycicola gilvus* and *Microterricola viridarii* is 99.5%.

Cell are rod shaped or coccoid depending on the culture age; while in young cultures rod-shaped cells are observed, in older cultures the coccoid forms are predominant. Colonies

are circular, smooth, entire, and the color is variable. The major fatty acids are $C_{15:0}$ anteiso (49.7%) and $C_{17:0}$ anteiso (27.3%) comprising about 77% of the total fatty acids. Polar lipids contain phosphatidylcholine, phosphatidylglycerol, phosphatidylinositol, and diphosphatidylglycerol.

Phycicola isolate is strictly aerobic and is able to utilize several sugars as sole carbon and energy sources.

The only strain belonging to *Phycicola* was isolated from a living seaweed collected at Samyang Beach in Jeju, Republic of Korea.

Maintenance procedures

Phycicola strain is maintained in 20% glycerol suspension supplemented with 60% natural seawater at −80°C. Lyophilized cultures are also used.

Differentiation of the genus *Phycicola* from other genera

The menaquinone composition characterized by the predominance of MK-11, the growth temperature, and some biochemical characteristics may be useful in differentiating *Phycicola* from the closest related taxa (Table 165).

TABLE 165. Characteristics differentiating *Phycicola* from closest related *Microbacteriaceae*[a]

Characteristic	*Phycicola*	*Microterricola*
Cell morphology	Rod/coccoid	Irregular
Motility	−/+	+
Growth temperature (°C)	4–30	10–38
Optimal temperature (°C)	25	15–30
Major menaquinones (MK)	11	12
DNA G+C content (mol%)	69.8	70.0

[a]Symbols: +, >85% positive; −, 0–15% positive.

Taxonomic comments

The close phylogenetic relationship between *Phycicola gilvus* and *Microterricola viridarii* confirmed by the formation of a very coherent cluster supported by bootstrap analysis at a confidence level of 100%, regardless the algorithm used to reconstruct the phylogenetic tree; the high pairwise 16S rRNA gene sequence similarity value (99.5%) between the two species; and the resemblance of some chemotaxonomic characteristics such as the diamino acid in the peptidoglycan, fatty acid profiles, and other physiological features, may raise doubts about the coherence of these two taxa as true distinct genera. An accurate comparison of the chemotaxonomic and biochemical characteristics of the two strains, as well as the determination of the DNA–DNA reassociation value, would be helpful to clarify the taxonomic position of these isolates.

List of species of the genus *Phycicola*

1. **Phycicola gilvus** Lee, Lee, Seo, Schumann, Kim and Lee 2008, 1321[VP]

gil′vus. L. masc. adj. *gilvus* pale yellow-colored.

The characteristics are as described for the genus with the following additional features.

The colony color is variable; colonies are white when cultures are incubated in the dark but yellow when incubated in the light. The optimum temperature for growth is 25°C, but growth occurs at 4–30°C, and no growth occurs at or above 37°C. The pH range for growth is pH 6.1–10.1 with optimum of pH 7.1–8.1. Growth occurs in the presence of up to 2% NaCl. Nitrate is reduced to nitrite. The type strain of this species hydrolyzes esculin, however, casein, elastin, starch, and gelatin are not hydrolyzed. Indole and H_2S are not produced. Citrate is not used. Acid is produced from same substrates such as L-arabinose, D-cellobiose, dextran, D-galactose, D-glucose, glycerol, maltose, L-rhamnose, D-ribose, salicin, and sucrose. Activity of the enzymes urease, alkaline phosphatase, leucine arylamidase, naphthol-AS-BI-phosphohydrolase, acid phosphatase, and α-glucosidase was detected

Major cellular fatty acids detected after incubation on TSA for 3 d at 30°C are $C_{15:0}$ anteiso (49.7%) and $C_{17:0}$ anteiso (27.3%), but $C_{16:0}$ iso (6.1%), $C_{16:0}$ (5.1%), $C_{18:0}$ (5.0%), $C_{15:0}$ iso (3.6%), and $C_{17:0}$ (2.6%) are also detected.

DNA G+C content (mol%): 69.8 (HPLC).

Type strain: SSWW-21, DSM 18319, KCTC 19185.

Sequence accession no. (16S rRNA gene): AM286414, DQ788720.

Genus XX. **Plantibacter** Behrendt, Ulrich, Schumann, Naumann and Suzuki 2002, 1451[VP]

Undine Behrendt, Andreas Ulrich and Peter Schumann

Plan.ti.bac′ter. L. fem. n. *planta* plant; N.L. masc. n. *bacter* rod; N.L. masc. n. *Plantibacter* rod of/from plants.

Pleomorphic cells which are sometimes arranged in an angle to give V-formations, 0.3–0.8 × 0.5–1.5 µm. **Nonmotile**. Nonsporeforming. Cells are **Gram-stain-positive**. Growth is **obligatory aerobic**. **Cell-wall peptidoglycan contains L-DAB, D-Glu, D-Ala, and Gly** corresponding to the **type B2γ**. The muramic acid is **acetylated**. Rhamnose is the predominant cell-wall sugar. **Fatty acid profiles** are characterized by nonhydroxylated fatty acids in which **anteiso- and iso-methyl-branched forms are predominant**. Minor amounts of straight-chain saturated acids are found. Predominant respiratory quinones are menaquinones MK-10 and MK-11, MK-10 or MK-10 and MK-9, depending on the species.

DNA G+C content (mol%): 66–70.

Type species: **Plantibacter flavus** Behrendt, Ulrich, Schumann, Naumann and Suzuki 2002, 1451[VP].

Further descriptive information

The genus comprises two established species, *Plantibacter flavus* (Behrendt et al., 2002) and *Plantibacter auratus* (Lin and Yokota, 2006). "*Plantibacter agrosticola*", "*Plantibacter elymi*", and "*Plantibacter cousiniae*" are three further species for which the names have not yet been validated (Evtushenko and Takeuchi, 2006). The analyses of the 16S rRNA gene sequences of the intended type strains reveal a clear clustering in the branch of the genus *Plantibacter* (Figure 193). Therefore, characteristics of the putative species are likewise considered in the definition of the genus.

The nature of the terminal oxidase of the respiratory chain in the genus *Plantibacter* was investigated by Trutko et al. (2003). It was shown that the studied species (Table 166) contains the aa_3-type cytochrome oxidase. Some species synthesize the quinole oxidases bo_3 or bb_3. Oxygen deficiency in the cultivation medium induces the synthesis of the *bd*-type oxidase. Another characteristic of the genus *Plantibacter* is its ability to synthesize isoprenoid pigments through the non-mevalonate pathway (Trutko et al., 2005). The spectral analysis of the pigments reveals that they are typically C_{40}-carotenoids. The suitability of polyamine patterns for the classification of actinobacterial taxa was studied by Altenburger et al. (1997). The investigations included two strains of the genus *Plantibacter* isolated from plant gall which were tentatively assigned to *Rathayibacter* species. In comparison with established *Rathayibacter* species, the polyamine content of both strains is relatively low and spermine is predominant. These characteristics support their classification separate from the genus *Rathayibacter*. One strain that belongs to the species "*Plantibacter agrosticola*" additionally contains 1,3-diaminopropane, whereas only traces of this polyamine was found in the type strain of "*Plantibacter cousiniae*".

Plantibacteria seem to be widely distributed in the environment, but plants and related sources are their main habitats. The species *Plantibacter flavus* has been isolated from the phyllosphere of grass and the surface litter from sward mulching (Behrendt et al., 2002), where it forms a significant portion of the actinobacterial community. Furthermore, it has been shown that strains of the genus *Plantibacter* are endophytic bacteria living on several plant species. Ulrich et al. (2008) found a multitude of endophytic strains inhabiting hybrid poplar clones. Zinniel et al. (2002) isolated an endophytic strain (LB030) from the above-ground plant tissue of agronomic plants. This strain, formerly classified as *Microbacterium* sp., showed a close relationship to species of *Plantibacter* in the 16S rRNA gene sequence comparison (data not shown). Endophytic

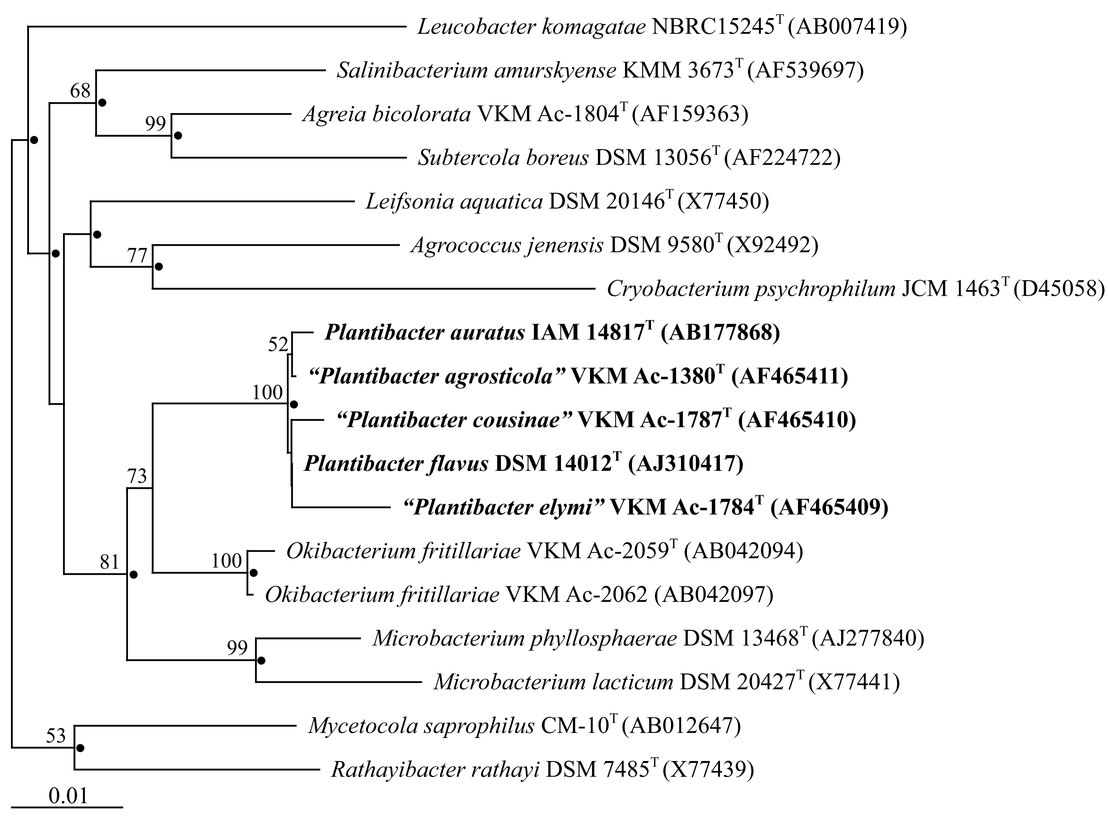

FIGURE 193. Phylogenetic tree showing the relationship of *Plantibacter flavus*, *Plantibacter auratus*, and the putative species "*Plantibacter agrosticola*", "*Plantibacter elymi*", and "*Plantibacter cousiniae*" within the circle of the closely related genera of the family *Microbacteriaceae*. The tree is based on a 1406 bp alignment of 16S rRNA gene sequences and was constructed using the neighbor joining method (Saitou and Nei, 1987). *Dots* indicate branches of the tree that were also formed using the maximum-likelihood method (Felsenstein, 1981). To estimate the root position of the tree, *Brevibacterium linens* (ATCC 9172T; X77451) was used as an outgroup. The values are the relative number that a branch appeared in 1000 bootstrap replications. Bar = relative sequence divergence.

plantibacteria isolated from flowering plants of the Ni hyperaccumulator *Thlaspi goesingense* Hálácsy are of particular interest (Idris et al., 2004). They are able to live in the shoots of *Thlaspi goesingense* despite the extreme high Ni concentrations. Endophytic bacteria are known for their beneficial effects on plant growth (Lodewyckx et al., 2002), and the functional analysis of the isolates accordingly reveals characteristics that potentially support the plant's uptake of heavy metal and the reduction of stress symptoms (Idris et al., 2004). A strain belonging to the genus *Plantibacter*, which displayed antagonistic properties against fungal pathogens, was isolated from *Sphagnum fallax* H. Klinggr. by Opelt et al. (2007) and demonstrates the potential of this bacterial group in the biological control of plant pathogens. An example of the association of plantibacteria with the rhizosphere of plants was shown by Heuer et al. (2002). They described an uncultured clone in the rhizosphere of potato plants that is highly related to the established species of the genus through 16S rRNA gene sequence analysis. The plant colonization of another group of *Plantibacter* species depends on the infection of the plant with highly specialized plant parasitic nematodes. As pointed out by Evtushenko and Takeuchi (2006), strains assigned to "*Plantibacter agrosticola*", "*Plantibacter elymi*", and "*Plantibacter cousiniae*" seem to be strictly associated with *Agrostis* sp. (probably *Agrostis capllaris* L.), *Elymus repens* (L.) Gould., and *Cousinia onopordioides* Ledeb, which are host plants for the nematodes *Anguina agropyri*, *Anguina agrostis*, and *Mesoanguina picridis*, respectively. The bacteria seem to only inhabit the inside of the galls, as they have not been recovered from samples outside of the galls, from plants without nematode infections, or from galls induced by other nematodes. Evtushenko and Takeuchi (2006) concluded from these findings that these *Plantibacter* species use plant parasitic anguinid species as vectors, similar to certain species of *Rathayibacter* (Riley, 1987). Examples of plant pathogenic properties of the strains belonging to the genus *Plantibacter* have not been convincingly demonstrated. Evtushenko and Takeuchi (2006) concluded from the phenotypic characteristics of "*Corynebacterium agropyri*" reported by O'Gara (1915), Cummins et al. (1974), and Riley et al. (1988), that the causative agent of gumming disease might be related to the species of *Plantibacter*.

A strain highly related to the species *Plantibacter auratus* was described after being isolated from an aquatic environment. Schulze et al. (2006) isolated this strain from oysters during a study of the bacterial diversity in a marine hatchery, whereas the type strain of *Plantibacter auratus* arose from a misidentified strain deposited in the National Collection of Industrial and Marine Bacteria (NCIMB) in 1964 (Lin and Yokota, 2006).

Pathogenicity. The clinical significance of the strains of the genus *Plantibacter* was demonstrated by Hirji et al. (2003) in the context of bacterial contamination of transplant products. A strain related by 16S rRNA gene investigations to *Plantibacter flavus* was isolated from peripheral blood or bone marrow stem cell products. The nosocomial outbreak of bacteremia in immunocompromised patients after reinfusion showed the pathogenic potential of otherwise harmless organisms.

Isolation and maintenance procedures

Strains of the species *Plantibacter flavus* can be isolated from plants and plant related sources by the approaches described by Behrendt et al. (1997), Heuer et al. (2002), Opelt et al. (2007), Ulrich et al. (2008), and Zinniel et al. (2002). The bacteria are able to grow on complex media such as Nutrient Agar II (Merck), Trypticase Soy Agar, R2A Agar (Difco), or Medium B from King et al. (1954)* without special requirements for growth factors. Furthermore, they can be cultured on CNS medium (Vidaver and Davis, 1994)†, a medium with selective properties for coryneform bacteria. This medium can be used for the semi-selective isolation of *Plantibacter*, accompanied by the growth of actinobacteria belonging to the genera *Curtobacterium*, *Microbacterium*, *Frigoribacterium*, *Agreia*, and *Clavibacter*, which are ubiquitous on plant material. A genus specific method for isolation has not been described so far.

The procedure for preparing a sample to isolate bacteria from plant galls was described by Evtushenko et al. (2001) and Evtushenko and Takeuchi (2006). The suspension of ground galls were plated on NWG Agar‡, *Corynebacterium* (CB) Agar§, or R2A Agar (Difco) for the first isolation. The media could also be used for further cultivation.

Stocks of the cultures could be maintained for a short period of about 4 weeks on agar slants at 4°C. The bacteria may be preserved for longer periods at subzero temperatures by various methods. There have been good results with preservation on glass beads at −80°C as described by Stead (1990) or the Microbank storage system (Pro-Lab Diagnostics). Recommended procedures for long-term preservation also include lyophilization.

Differentiation of the genus *Plantibacter* from other genera

The phylogenetic analyses on the basis of the 16S rRNA gene sequence comparison clearly demonstrate the separate genus status of *Plantibacter*. As shown in Figure 193, species of the genus constitute a monophyletic branch in the family *Microbacteriaceae*. The closest phylogenetic neighbors are the genera *Okibacterium* and *Microbacterium* which cluster with *Plantibacter* in both the maximum likelihood and the neighbor joining method supported by a high bootstrap value.

The 16S rRNA gene sequence analysis is the most frequently used method for studying the phylogenetic relationship between bacteria (Stackebrandt and Goebel, 1994). However, genes encoding proteins with higher sequence substitution rates than that of 16S rRNA genes are able to provide a better insight into intrageneric phylogenies. Richert et al. (2005) selected the gene encoding DNA gyrase B (*gyrB*) for testing the 16S rRNA gene phylogeny of members of the family *Microbacteriaceae* including the genus *Plantibacter*. It was shown that the nucleotide

*Medium B g/l aqua demin.: proteose-peptone (Difco), 20.0; agar, 15.0; glycerol, 10.0; KH_2PO_4, 1.5; and $MgSO_4 \cdot 7H_2O$, 1.5 (pH 7.2).

†CNS medium g/480 ml: nutrient broth, 8.0; yeast extract, 2.0; potassium phosphate (dibasic), 2.0; potassium phosphate (monobasic), 0.5; agar, 6.5 (pH 6.9 after autoclaving). Add the following ingredients to the medium (g) after autoclaving at 50°C: cycloheximide, 0.020 (2.0 ml of a 1%, w/v, solution); nalidixic acid, 0.0125 (1.25 ml of a solution of 0.1 g nalidixic acid in 7 ml aqua demineralized and 3 ml 1N NaOH); polymyxin B sulfate (8000 USP units/mg), 0.016 (1.6 ml of a solution of 1.0 g in 100 ml aqua demineralized); Daconil 2787-F (530 mg/ml chlorothalonil ml – the active ingredient is tetrachloroisophtalonitrile), 0.00048 (0.03 ml of a solution of 1.2 ml Daconil in 38.8 ml); glucose, 2.5 (25 ml of 10% w/v sterile solution); magnesium sulfate, 0.062 (0.25 ml of a 1.0 M sterile solution).

[e]Evtushenko and Takeuchi (2006) and Trutko et al. (2003).

substitution of *gyrB* is significantly higher than that of the 16S rRNA gene. Thus, the similarity of *Plantibacter* compared to the other genera on the basis of *gyrB* was reduced by approximately 10–15%, in comparison to its relatedness based on 16S rRNA gene sequences. However, it must be stated that a correlation between both gene similarities has not been elaborated and thus, sequence analyses of *gyrB* and 16S rRNA genes result in different insights into the phylogenetic relationship within the family *Microbacteriaceae*. Nevertheless, this higher heterogeneity enables one to discriminate between closely related strains.

A polyphasic approach for describing a taxon requires, in addition to the phylogenetic analysis, a convincing differentiation on the phenotypic level. Chemotaxonomic characteristics were widely used in the classification and identification of actinobacterial genera. Peptidoglycan typing is a prominent feature used for distinguishing the majority of genera from one another. Thus, the phylogenetically closely related genera *Okibacterium* and *Microbacterium* differ distinctly from *Plantibacter* in the structure of their peptidoglycan (Evtushenko et al., 2002; Takeuchi and Hatano, 1998b). The comparison of the peptidoglycan composition of *Plantibacter*, which corresponds to the type B2γ from Schleifer and Kandler (1972), with those of the remaining genera of the family *Microbacteriaceae* reveals its accordance to the genera given in Table 167. While *Clavibacter*, *Leifsonia*, *Pseudoclavibacter*, and *Yonghaparkia* represent a subgroup because they display the isomers L and D of DAB to almost equal amounts, the genera *Plantibacter*, *Rathayibacter*, *Cryobacterium*, *Agromyces*, and certain species of *Zimmermannella* share another subgroup in which the isomer L-DAB predominates (Behrendt et al., 2002; Evtushenko et al., 2000; Lin et al., 2004; Manaia et al., 2004; Sasaki et al., 1998). Within the latter subgroup, species of *Agromyces* are characterized by filamentous cells fragmenting into coccoid forms in older cultures and by the predominant menaquinones MK-12 and MK-11. Thus, they can easily be distinguished from the genus *Plantibacter* through phenotypic features without the need of phylogenetic studies. Another genus that contains L-DAB in its peptidoglycan is *Agrococcus* (Groth et al., 1996; Wieser et al., 1999). Threonine and aspartic acid were found in the peptidoglycan of certain *Agrococcus* species in addition to the amino acids determined in *Plantibacter*. The species *Agrococcus casei* (Bora et al., 2007) exhibit the same amino acid composition of the peptidoglycan as determined in the genus *Plantibacter* but differ in the occurrence of the main menaquinone MK-12. The different menaquinone composition is an additional feature for phenotypic distinction (Table 167). *Cryobacterium psychrophilum* is an obligatory psychrophile and can be differentiated from *Plantibacter* by a significant amount of $C_{15:1}$ anteiso in the fatty acid profile (Suzuki et al., 1997).

In contrast, the genus *Rathayibacter* is similar in its morphology and main chemotaxonomic characteristics to *Plantibacter* (Behrendt et al., 2002; Dorofeeva et al., 2002; Riley and Ophel, 1992; Zgurskaya et al., 1993) and thus, *Rathayibacter* isolates

[b]Schleifer and Kandler (1972).

[c]Data obtained from following references: Behrendt et al. (2002); Davis et al. (1984); Evtushenko et al. (2000); Groth et al. (1996); Kämpfer et al. (2000); Lin et al. (2004); Mayilraj et al. (2006); Sasaki et al. (1998); Takeuchi et al. (1996); Takeuchi and Hatano (1998); Tsukamoto et al. (2001); Wieser et al. (1999); and Yoon et al. (2006b).

associated with grasses and nematodes in particular might be confused in their genus affiliation with *Plantibacter*. The application of the Fourier-transform infrared (FT-IR) spectroscopy, as a physico-chemical whole-cell fingerprint technique, in the classification of coryneform bacteria with special reference to plant-associated species shows that this method is reliable in differentiating members of *Plantibacter* and *Rathayibacter* effectively (Behrendt et al., 2002; Evtushenko and Takeuchi, 2006). Furthermore, Trutko et al. (2003) showed in a comparative study of the terminal oxidase composition, the potential of this parameter as a chemotaxonomic marker. Species of the genus *Plantibacter* produce cytochrome oxidase aa_3, while *Rathayibacter* species synthesize mainly cytochrome oxidase bb_3 or, depending on growth conditions, both bb_3 and aa_3.

The search by Trutko et al. (2005) for additional chemotaxonomic markers for differentiating actinobacterial genera on a phenotypic level reveals the taxonomic significance of pigment formation. The absorption spectra of pigments are virtually identical for the *Plantibacter* and *Okibacterium* strains tested and similar to *Rathayibacter*. However, the susceptibility to fosmidomycin, an inhibitor of the synthesis of isoprenoid pigments is different. At a concentration of 0.1 mg/ml fosmidomycin, the pigment synthesis in *Plantibacter* bacteria is suppressed, whereas, even at a concentration of 1.0 mg/ml, the growth of these bacteria is not inhibited. In the case of the investigated *Okibacterium* and *Rathayibacter* species, fosmidomycin inhibits not only the synthesis of pigments but also the growth of these bacteria in a concentration-dependent manner. These differences in their tolerance to fosmidomycin make it not only possible to differentiate between them, but also to formulate a selective medium for *Plantibacter* species on this basis. However, the latter will need to be proven in further studies.

Lastly, *Plantibacter* should be differentiated from the genus *Zimmermannella*, as proposed by Lin et al. (2004). The type species of the genus, *Zimmermannella helvola*, is a later homotypic synonym of *Pseudoclavibacter helvolus* and therefore, the genus *Zimmermannella* is illegitimate. However, Lin et al. (2004) described three novel species assigned to *Zimmermannella*. In aberrance to the type species, it was shown that their predominant isomer in the peptidoglycan is L-DAB, just as in the genus *Plantibacter*. The major isoprenoid quinones differ between species from MK-8 to MK-10 and thus, on this basis, only single species of *Plantibacter* and *Zimmermannella* could be differentiated. Fatty acid profiles are similar, but show differences in the amount of their straight-chain saturated fatty acid $C_{16:0}$. Since a clear discrimination based solely on a morphological and chemotaxonomic characterization appears to be difficult for certain genera, the analysis of the 16S rRNA gene sequences is an essential procedure for the clear affiliation of unknown isolates to the genus *Plantibacter*. However, the phenotypic characterization and differentiation is a prerequisite in taxonomic studies if new taxa are to be proposed.

Differentiation of the species of the genus *Plantibacter*

The differential characteristics of the species of *Plantibacter* are given in Table 166.

List of species of the genus *Plantibacter*

1. **Plantibacter flavus** Behrendt, Ulrich, Schumann, Naumann and Suzuki 2002, 1451[VP]

fla′vus L. masc. adj. *flavus* yellow, referring to the colony color.

Characteristics distinguishing the species from other organisms of the genus are shown in Table 166. Morphological and physiological description is based on five strains. Cells are Gram-stain-positive, strictly aerobic, nonsporeforming, nonmotile, irregularly shaped rods, which sometimes form V-shapes. Colonies are yellow, shiny, slightly convex, and round with entire margins. Voges–Proskauer reaction is negative, while catalase is positive. Esculin, DNA, Tween 60, and Tween 80 are hydrolyzed. The type strain is positive for the hydrolysis of starch, while the utilization of starch is strain dependent. None of the strains hydrolyzes casein, gelatin, or cellulose. Formation of levan from sucrose is negative. Strains produce oxidative acid from L-arabinose, D-fructose, D-galactose, D-glucose, lactose, D-maltose, D-mannitol, D-mannose, D-melezitose, raffinose, L-rhamnose, sucrose, D-trehalose, ribose, and D-xylose. Acid formation from inulin, melibiose, D-sorbitol, and L-sorbose is strain dependent while the type strain is negative for these carbohydrates. All strains are negative for adonitol and inositol. Optimum growth temperature is about 25°C. At 4°C, they grow slowly and at −2°C growth still occurs but much slower. The fatty acid profile of the type strain consists of the predominant compounds $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso, whereas $C_{16:0}$ and $C_{14:0}$ iso are present in minor amounts and $C_{14:0}$ iso in traces.

Source: the phyllosphere of grasses and from the litter layer from sward mulching. The type strain was isolated from the phyllosphere.

DNA G+C content (mol%): 68–70 (HPLC).

Type strain: P 297/02, DSM 14012, JCM 12144, LMG 19919, NBRC 103081.

Sequence accession no. (16S rRNA gene): AJ310417.

2. **Plantibacter auratus** Lin and Yokota, 2006, 2338[VP]

au.ra′tus L. masc. part. adj. *auratus* gold-colored, yellow.

Characteristics that differentiate the species from the other organisms of the genus are shown in Table 166. The morphology and cell-wall composition are as described for the genus. Colonies are circular, convex, smooth, and pale yellow on PY-BHI agar. The optimal temperature for growth is generally 30°C. Catalase and α- and β-galactosidase are produced. The hydrolysis of esculin is positive. Nitrate reduction and alkaline phosphatase are negative. Oxidative acid production from rhamnose, maltose, lactose, and melezitose is positive but negative for L-sorbose, sorbitol, melibiose, and inulin. The major fatty acids are $C_{15:0}$ anteiso, followed by $C_{17:0}$ anteiso, and $C_{16:0}$ iso, whereas minor amounts of $C_{16:0}$ and $C_{14:0}$ iso are present.

DNA G+C content (mol%): 68 (HPLC).

Type strain: IAM 14817, JCM 23192, NBRC 15702, NCDO2317, NCIMB 9991.

Sequence accession no. (16S rRNA gene): AB177868.

Other organisms

1. **"Plantibacter agrosticola"** Evtushenko and Takeuchi 2006

Characteristics differing from those of the other organisms of the genus are given in Table 166. Furthermore the utilization of DL-alanine and L-asparagine as nitrogen source is positive for 80% of the strains tested. Glutamic acid is not used as a nitrogen source. Hydrogen sulfide formation from cysteine is positive for 20% of the tested strains.

DNA G+C content (mol%): 67.

Type strain: VKM Ac-1380.

Sequence accession no. (16S rRNA gene): AF465411.

2. **"Plantibacter cousiniae"** Evtushenko and Takeuchi 2006

Characteristics that are different from the other organisms of the genus are given in Table 166. The utilization of DL-alanine, L-asparagine, and glutamic acid as nitrogen source is positive. Hydrogen sulfide formation is positive.

DNA G+C content (mol%): 68.

Type strain: VKM Ac-1787.

Sequence accession no. (16S rRNA gene): AF465410.

3. **"Plantibacter elymi"** Evtushenko and Takeuchi 2006

In addition to the differential characteristics given in Table 166, all tested strains are negative for the utilization of DL-alanine, L-aparagine, and glutamic acid as nitrogen sources. Formation of H_2S from cysteine is positive.

DNA G+C content (mol%): 66.

Type strain: VKM Ac-1784.

Sequence accession no. (16S rRNA gene): AF465409.

Genus XXI. **Pseudoclavibacter** Manaia, Nogales, Weiss and Nunes 2004, 787[VP]

Célia M. Manaia, Balbina Nogales and Olga C. Nunes

Pseu.do.cla.vi.bac′ter. Gr. adj. *pseudês* false; N. L. masc. n. *Clavibacter* a bacterial generic name; N.L. masc. n. *Pseudoclavibacter* false *Clavibacter*.

Rod-shaped cells. Gram-stain-positive. Nonsporeforming. **Nonmotile**. **Strictly aerobic**. The optimal growth temperature is 30°C. Catalase-positive. **Chemo-organotrophic**. Nitrate is not reduced. **The diamino acid 2,4-diaminobutyric acid (DAB) is present in the peptidoglycan**. The muramic acid of the peptidoglycan is of the acetyl type. **The major respiratory quinone is MK-9**. The major polar lipids are diphosphatidylglycerol and phosphatidylglycerol. The major cellular fatty acids are 12-methyl-tetradecanoic acid ($C_{15:0}$ anteiso), 14-methyl-pentadecanoic acid ($C_{16:0}$ iso), and 14-methyl-hexadecanoic acid ($C_{17:0}$ anteiso).

DNA G+C content (mol%): 67.

Type species: **Pseudoclavibacter helvolus** Manaia, Nogales, Weiss and Nunes 2004, 787[VP].

Further descriptive information

The genus *Pseudoclavibacter* was described based on *Pseudoclavibacter helvolus* DSM 20419[T] (Manaia et al., 2004), previously known as "*Brevibacterium helvolum*" (Zimmermann 1890) Lochhead 1955, and is an earlier homotypic synonym of *Zimmermannella helvola* Lin et al. 2004. Phylogenetic analysis based on the 16S rRNA gene sequence demonstrated that *Pseudoclavibacter* forms a distinct lineage adjacent to *Gulosibacter*, branching deeply within the family *Microbacteriaceae* (Figure 184). *Pseudoclavibacter helvolus* exhibits highest 16S rRNA gene sequence similarities to organisms belonging to the species *Zimmermannella alba* (95.6%), *Zimmermannella faecalis* (95.7%), and *Zimmermannella bifida* (95.6%) (Lin et al., 2004). The closest phylogenetic neighbors belonging to other genera are the species *Gulosibacter molinativorax* (~95%) and *Curtobacterium luteum* (~95%). The recently described species *Pseudoclavibacter soli* (Kim and Jung, 2009), shares with *Pseudoclavibacter helvolus* 93.7% 16S rRNA gene sequence similarity. The distant relatedness of *Pseudoclavibacter soli* to *Pseudoclavibacter helvolus* is also reflected by the quinone system, which, in addition to menaquinone MK-9, also contains major amounts of MK-8.

The cells of *Pseudoclavibacter helvolus* are Gram-stain-positive, irregular rods, non-acid-fast, and nonmotile (Figure 194). Endospores and granules of poly-β-hydroxybutyrate (PHB) are not produced. The cell-wall peptidoglycan of type B2γ, [L-DAB]-D-Glu–D-DAB was reported for *Pseudoclavibacter helvolus* (Schleifer and Kandler, 1972), with L- and D-DAB present in nearly equal proportions (Sasaki et al., 1998). In the species *Pseudoclavibacter helvolus*, the molar ratios of the amino acids glutamate, glycine, alanine, and DAB are approximately 1.0:1.0:0.8:1.8 (Sasaki et al., 1998); Lin et al. (2004) reported a similar composition, although only L-DAB was referred. The muramic acid in the peptidoglycan is of the acetyl type (Lin et al., 2004). In *Pseudoclavibacter soli*, the diagnostic diamino acid is also DAB; in addition, it contains alanine, glutamate, and glycine (Kim and Jung, 2009). The cell-wall sugars of *Pseudoclavibacter helvolus* are reported to be rhamnose and 6-deoxytalose (Lin et al., 2004) while *Pseudoclavibacter soli* contains rhamnose and ribose (Kim and Jung, 2009).

The peptidoglycan of all species of the genus *Zimmermannella* contains L-DAB as diamino acid and rhamnose as cell-wall sugar as well. In the species *Zimmermannella bifida* and *Zimmermannella alba*, the molar ratios of the amino acids glutamate, glycine, alanine, and L-DAB are similar to those found in *Pseudoclavibacter helvolus* (Lin et al., 2004). According to Lin et al. (2004), in the species *Zimmermannella faecalis* described based on strain ATCC 13722[T], the peptidoglycan contains glutamate, glycine, alanine, L-DAB, and homoserine in the molar ratios of 1.0:1.9:0.8:0.9:0.2. However, in a previous study the same strain was reported to exhibit a peptidoglycan composed of [L-Hsr]–D-Glu–D-DAB (Döpfer et al., 1982). Except for *Zimmermannella faecalis*, other sugars are also present in the cell wall of *Zimmermannella* species; *Zimmermannella bifida* contains glucose and *Zimmermannella alba* contains glucose and 6-deoxytalose.

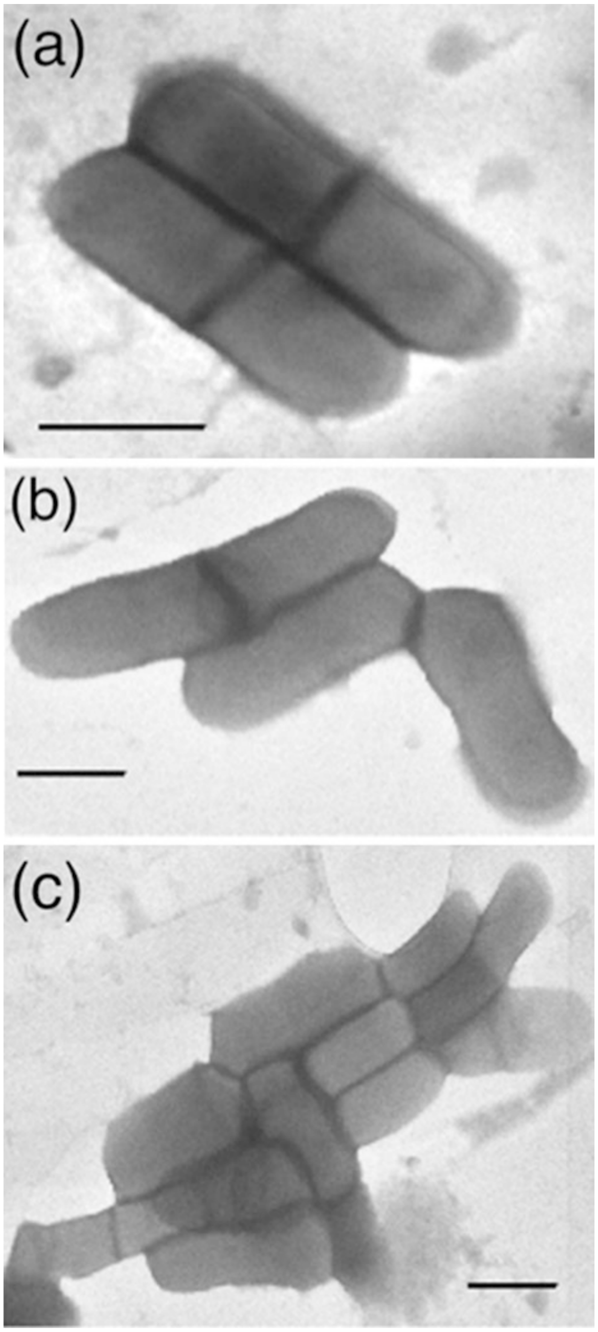

FIGURE 194. Transmission electron micrographs of negatively stained cells of *Pseudoclavibacter helvolus* DSM 20419[T] (a–c) grown on LB medium at 30°C for 24 h. Bar = 0.5 μm. (Reprinted with permission from Manaia et al., 2004. Int. J. Syst. Evol. Microbiol. 54: 783–789.)

The major respiratory quinones of *Pseudoclavibacter* are menaquinones. In *Pseudoclavibacter helvolus* MK-9 accounts for approximately 90%, whereas MK-8 and MK-10 are minor components (Lin et al., 2004; Manaia et al., 2004; Sasaki et al., 1998). In *Pseudoclavibacter soli*, both MK-9 and MK-8 are major components (Kim and Jung, 2009).

The quinone composition of *Zimmermannella faecalis* is similar to that of *Pseudoclavibacter helvolus*. In *Zimmermannella bifida*, MK-8 and MK-9 are in approximately equal proportions, with MK-7 as minor component. *Zimmermannella alba* is characterized by the predominance of MK-10, with minor proportions of MK-9, MK-8, and MK-7 (Lin et al., 2004).

The polyamine pattern of *Pseudoclavibacter helvolus* includes cadaverine as the predominant polyamine (74%), while 1,3-diamino propane is present in a minor proportion (23%) (Altenburger et al., 1997). Like in other members of the *Microbacteriaceae*, the major polar lipids of *Pseudoclavibacter helvolus* are diphosphatidylglycerol and phosphatidylglycerol. Minor amounts of an unknown glycolipid have been reported (Manaia et al., 2004). The major cellular fatty acids are 12-methyl-tetradecanoic acid ($C_{15:0}$ anteiso), 14-methyl-pentadecanoic acid ($C_{16:0}$ iso), and 14-methyl-hexadecanoic acid ($C_{17:0}$ anteiso) (Lin et al., 2004; Manaia et al., 2004). Slightly discrepant results for the relative proportions of hexadecanoic acid ($C_{16:0}$) were reported by Lin et al. (2004) and by Manaia et al. (2004), respectively 6% and 17%. This is probably due to differences in the growth conditions used to produce the biomass from which fatty acids were extracted. A similar fatty acid pattern is found in *Pseudoclavibacter soli* (Kim and Jung, 2009) and in *Zimmermannella* species (Lin et al., 2004). According to Lin et al. (2004), $C_{16:0}$ represents 10–31% of the total fatty acids in the *Zimmermannella* species.

On Luria–Bertani agar, *Pseudoclavibacter helvolus* DSM 20419[T] forms colonies that are yellow, circular, convex, with 2–3 mm in diameter after 2–3 d of growth (Manaia et al., 2004), and on peptone/yeast extract supplemented with brain heart infusion agar (PY-BHI agar) forms smooth white colonies (Lin et al., 2004). *Pseudoclavibacter soli* forms pale-yellow, circular, slightly convex colonies in R2A agar after 4 d of growth (Kim and Jung, 2009).

Pseudoclavibacter helvolus is aerobic and chemoorganothrophic. Nitrate is not reduced under aerobic or anaerobic conditions (Lin et al., 2004; Manaia et al., 2004). In nutritive medium, the range of growth of *Pseudoclavibacter helvolus* is 10–35°C, pH 6–10, and 0–6% (w/v) NaCl (Manaia et al., 2004). The optimal temperature of growth is 30°C (Lin et al., 2004; Manaia et al., 2004). In the characterization of the nutritional pattern, different methodologies were used by Manaia et al. (2004) and Lin et al. (2004). The first analyzed carbon source assimilation, whereas the latter tested acid production. Using the multi-test systems Biolog GP and API 50CH, *Pseudoclavibacter helvolus* presents a versatile nutritional profile, oxidizing a variety of organic compounds including nucleotides, amino acids, organic acids, alcohols, and sugars (Manaia et al., 2004). According to Lin et al. (2004), *Pseudoclavibacter helvolus* produces acid from rhamnose. *Pseudoclavibacter helvolus* is catalase and cytochrome *c* oxidase-positive (Lin et al., 2004; Manaia et al., 2004). The API ZYM profile of *Pseudoclavibacter helvolus* (Manaia et al., 2004) shows that this organism produces acid- and alkaline phosphatase, esterase, and lipase (C_4, C_8, and C_{14}), leucine-, valine-, and cystine-arylamidase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, and α-glucosidase.

Analysis of 16S rRNA gene sequence permitted the affiliation of the genus *Pseudoclavibacter* to the family *Microbacteriaceae*, with *Zimmermannella*, *Gulosibacter*, and *Curtobacterium* as the closest relatives in terms of sequence similarities. Phylogenetic analysis including the sequences of representatives of the different gen-

era in the *Microbacteriaceae* indicates that the 16S rRNA gene sequences of *Pseudoclavibacter* form a deeply branching group within the family, also including *Zimmermannella* species and *Gulosibacter molinativorax*, which groups consistently with the sequences of *Zimmermannella bifida* and *Zimmermannella faecalis* (Figure 184).

Pseudoclavibacter helvolus and *Pseudoclavibacter soli* have high DNA G+C contents (67 and 64 mol%, respectively) (Kim and Jung, 2009; Lin et al., 2004; Manaia et al., 2004).

Pseudoclavibacter helvolus was isolated from butter, and *Pseudoclavibacter soli* was isolated from a ginseng field soil in South Korea (Kim and Jung, 2009).

Enrichment and isolation procedures

Scarce information about the isolation procedures of *Pseudoclavibacter* organisms is available.

Maintenance procedures

The microorganisms can be maintained in the laboratory on nutritive medium (e.g. Luria–Bertani agar* or PY-BHI agar†) for ~10 d at 4°C. Deep freezing (−75°C) or lyophilization are recommended for long-term preservation.

Differentiation of the genus *Pseudoclavibacter* from other genera

Characteristics useful for the differentiation of *Pseudoclavibacter* from other related organisms of *Microbacteriaceae* are indicated in Table 153. The majority of the genera of this family are characterized by having DAB as diamino acid and acetyl-type muramic acid in the peptidoglycan. *Pseudoclavibacter* can be differentiated from other closely related genera by a low phylogenetic relationship, the presence of both L- and D-DAB in the peptidoglycan (rare in *Microbacteriaceae*), the presence of MK-9 as major menaquinone, a distinctive polyamine pattern, and some physiological properties (Table 153 and Table 168).

Taxonomic comments

The circumscription of the genus *Pseudoclavibacter* was based on 16S rRNA gene sequence analysis and on the distinctive chemotaxonomic characteristics, which include cell wall, menaquinones, and polyamines composition. This genus comprises only two validly named species, *Pseudoclavibacter helvolus* and *Pseudoclavibacter soli*, although the 16S rRNA gene sequence-based phylogenetic analysis and the phenotypic and chemotaxonomic characterization indicate that *Pseudoclavibacter* and *Zimmermannella* are synonymic designations for a single genus. The taxonomic position of *Pseudoclavibacter* remained uncertain for a long time. Rainey et al. (1994) showed that strain DSM 20419^T, previously known as "*Brevibacterium helvolum*" (Zimmermann 1890) Lochhead (1955), formed a separate subline of descent within the family *Microbacteriaceae*. Based on cell-wall peptidoglycan type and menaquinones profile, Sasaki et al. (1998) argued that "*Brevibacterium helvolum*" 20419^T could be placed in the species *Clavibacter michiganensis*, whereas results from 16S rRNA gene sequence analysis does not support this affiliation (Sasaki et al., 1998).

The name *Pseudoclavibacter* was proposed by Manaia et al. (2004) based on a further characterization of "*Brevibacterium helvolum*" DSM 20419, and *Pseudoclavibacter helvolus* was proposed as the type species of the genus. A few months later, the genus *Zimmermannella*, with four distinct species and the type species *Zimmermannella helvola* (formerly "*Brevibacterium helvolum*" DSM 20419), was proposed by Lin et al. (2004). The description of *Zimmermannella alba* was based on the characterization of one strain (IAM 14724) which was isolated from human urine in France. The description of *Zimmermannella bifida* was based on three strains that were isolated from soil (Thailand; IAM 14848), from human blood (IAM 15028), and from a human wound (France; IAM 15029). *Zimmermannella faecalis* was described based on re-examination of *Corynebacterium bovis* ATCC 13722 (= IAM 15030). The latter species was listed as an addendum in the first edition of *Bergey's Manual of Systematic Bacteriology* (Collins and Cummins, 1986). In fact, the cell wall of *Corynebacterium bovis* ATCC 13722 contains DAB instead of the *meso*-diaminopimelic acid characteristic of corynebacteria and exhibits a higher mol% G+C content. Moreover, strain ATCC 13722 presents low $T_{m(e)}$ values of DNA-rRNA heteroduplexes with other members of *Corynebacterium* (Döpfer et al., 1982). Based on these features, Collins and Cummins (1986) suggested that *Corynebacterium bovis* ATCC 13722 should constitute the nucleus of a new taxon. Watts et al. (2000, 2001) supported Döpfer et al. (1982), reporting that *Corynebacterium bovis* ATCC 13722 shows highest 16S rRNA gene sequence similarity to "*Brevibacterium helvolum*" (95%) and a rep-PCR pattern different from all the other strains of *Corynebacterium bovis* tested.

Pseudoclavibacter soli Kim and Jung (2009) was described recently, based on the characterization of strain KCTC 19255^T which was isolated from soil in South Korea.

According to the *Bacteriological Code* (1990 Revision), Rule 51b, the genus name *Zimmermannella* Lin et al. 2004 and the species name *Zimmermannella helvola* Lin et al. 2004 are illegitimate. The name *Zimmermannella* is a later homotypic synonym of *Pseudoclavibacter* (Euzéby, 2005) and *Zimmermannella helvola* a later homotypic synonym of the name *Pseudoclavibacter helvolus* (Rule 24a). After formal proposal for combining these two taxa into *Pseudoclavibacter* according to Rule 37a, the species named as *Zimmermannella alba* Lin et al. 2004, *Zimmermannella bifida* Lin et al. 2004, and *Zimmermannella faecalis* Lin et al. 2004 cannot be maintained in the genus *Zimmermannella* because of lack of a type species.

List of species of the genus *Pseudoclavibacter*

1. **Pseudoclavibacter helvolus** Manaia, Nogales, Weiss and Nunes 2004, 787[VP]

hel′vo.lus. L. masc. adj. *helvolus* pale yellow, yellowish.

In addition to the characteristics described for the genus and listed in Table 153, Table 168, and Table 169, cells are 0.3–0.5 × 0.8–1.1 μm, and usually occur in pairs. Oxidase reaction is weakly positive. Maximal growth rate is observed in the presence of 1% (w/v) NaCl; 8% NaCl inhibits growth. The diamino acids of the cell-wall peptidoglycan are L- and D-DAB. The major respiratory quinone is MK-9. Major polyamines are cadaverine and 1,3-diaminopropane.

Source: butter.

DNA G+C content (mol%): 67 (HPLC).

Type strain: ATCC 13715, CCUG 43303, DSM 20419, IAM 14726, JCM 9491, NBRC 15775, TISTR 1509.

Sequence accession no. (16S rRNA gene): X77440.

2. **Pseudoclavibacter soli** Kim and Jung 2009, 838[VP]

so′li. L. neut. gen. n. *soli* of soil, the source of the organism.

In addition to the characteristics described for the genus and listed in Tables (Table 153, Table 168, and Table 169), cells are 0.3–0.3 × 0.3–1.5 μm. Oxidase reaction is negative. Maximal growth rate is observed at 30°C and pH 7. The diamino acid of the cell-wall peptidoglycan is DAB. The major respiratory quinones are MK-9 and MK-8.

Source: soil.

DNA G+C content (mol%): 64 (HPLC).

Type strain: KP02, JCM 15058, KCTC 19255.

Sequence accession no. (16S rRNA gene): AB329630.

Genus XXII. **Rathayibacter** Zgurskaya, Evtushenko, Akimov and Kalakoutskii 1993, 147[VP]

Lyudmila I. Evtushenko and Lubov V. Dorofeeva

Ra.thay.i.bac′ter. N.L. n. *Rathaya* Rathay, referring to E. Rathay, Australian plant pathologist who first isolated strains of the genus; N.L. masc. n. *bacter* rod; N.L. masc. n. *Rathayibacter* a rod isolated by Rathay.

Young cells are **irregular, straight to slightly curved rods**, most of which are 0.5–0.7 µm in diameter and ~1.1–2.0 µm in length, **with bluntly rounded ends**. **Cells are often disposed at an angle to each other, giving V-forms** or sometimes more complex angular arrangements. **In older cultures, coccobacillaric forms usually predominant**. Nonmotile. Nonsporeforming. Capsule is produced. Stains Gram-**positive** but not acid-fast. **Lysozyme resistant. Chemo-organotrophs. Obligately aerobic**, having a **respiratory type of metabolism** with oxygen as the terminal electron acceptor. Catalase-positive. **Oxidase reaction is usually negative** or weakly positive. **Nutritionally exacting**, most strains require vitamins and amino acids for growth. Growth moderate

to good on standard laboratory media based on peptone, yeast extract, and glucose at near neutral pH. Colonies are yellow or rose-orange to pink. Acids are produced oxidatively and rather weakly from carbohydrates. **Nitrate is not reduced to nitrite**; nitrite is not reduced. Mesophilic. Optimum temperature ~24–27°C; no growth at 7°C or 37°C.

The cell-wall peptidoglycan is a group B type containing L-**diaminobutyric acid** as the diamino acid. Characteristic cell-wall sugars are rhamnose, glucose, and mannose. Menaquinones are the sole respiratory quinones; the major component is an **unsaturated menaquinone with ten isoprene units (MK-10)**. Saturated anteiso- and iso-methyl-branched fatty acids predominate; 12-methyl-tetradecanoic ($C_{15:0}$ anteiso), 14-methylhexadecanoic ($C_{17:0}$ anteiso), and 14-methylpentadecanoic ($C_{16:0}$ iso) are the major fatty acids. Straight chain saturated acids are present in minor amounts. Mycolic acids absent. Principal polar lipids comprise phosphatidylglycerol, diphosphatidylglycerol, and some characteristic glycosyldiacylglycerols. Polyamine patterns include spermidine and spermine as the predominant compounds.

Most bacteria of the genus *Rathayibacter* so far isolated are plant pathogens causing gummosis in grasses and cereals that are transmitted by nematodes of the genus *Anguinina*.

DNA G+C (mol%): 60–69.

Type species: **Rathayibacter rathayi** (Smith 1913) Zgurskaya, Evtushenko, Akimov and Kalakoutskii 1993, 146[VP] ("*Aplanobacter rathayi*" Smith 1913, 926; "*Phytomonas rathayi*" Bergey, Harrison, Breed, Hammer and Hunton 1923, 192; *Corynebacterium rathayi* Dowson 1942, 313; "*Pseudobacterium rathayi*" Krasil'nikov 1949, 225; "*Corynebacterium michiganense* pv. *rathayi*" Dye and Kemp 1977, 578; *Clavibacter rathayi* Davis, Gillespie, Vidaver and Harris 1984, 113).

Further descriptive information

The genus *Rathayibacter* belongs to the family *Microbacteriaceae*, order *Micrococales*, and, at the time of writing, includes six species: *Rathayibacter rathayi*, *Rathayibacter caricis*, *Rathayibacter festucae*, *Rathayibacter iranicus*, *Rathayibacter tritici*, and *Rathayibacter toxicus*. Based on the 16S rRNA gene sequence analysis, *Rathayibacter* species form a common phylogenetic cluster in which *Rathayibacter toxicus* is the deepest branching species and also possesses the lowest 16S rRNA gene sequence similarities (approx. 96.5–97.5% sequence similarity) with other species of the genus. Comparison of less conserved gene sequences encoding DNA gyrase subunit B (*gyrB*), RNA polymerase subunit B (*rpoB*), recombinase A (*recA*), and polyphosphate kinase (*ppk*) in *Rathayibacter festucae*, *Rathayibacter iranicus*, and *Rathayibacter tritici* support the close relatedness of these species (Stackebrandt et al., 2007). The DNA–DNA similarity values for *Rathayibacter* species range from 15–19% to 50–59% for the pairs of *Rathayibacter rathay*–*Rathayibacter toxicus* and *Rathayibacter rathayi*–*Rathayibacter tritici*, respectively (Sasaki et al., 1998) as determined by the method of Ezaki et al. (1989). A somewhat lower DNA–DNA similarity value was obtained for *Rathayibacter rathayi* and *Rathayibacter tritici* (43%) using the membrane filter method (Zgurskaya et al., 1993).

Cells in young cultures (2–3 d) are straight to slightly curved rods or may be wedge-shaped (Figure 195, top); occurred singly, in pairs, or sometimes in palisade aggregates. The cells range from 0.4–0.8 μm in diameter but most are ~0.5–0.7 μm.

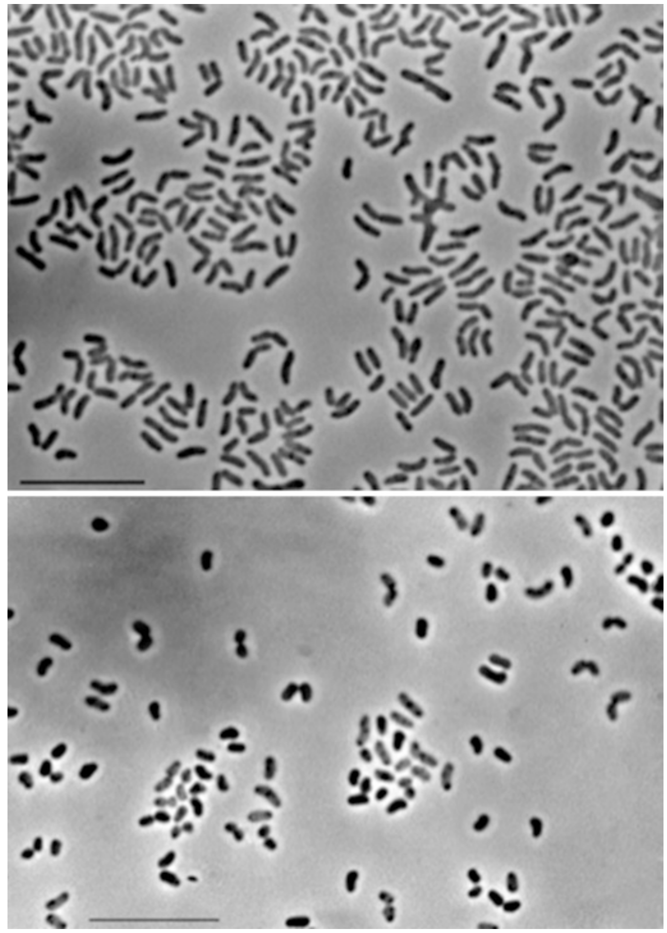

FIGURE 195. Cellular morphology of *Rathayibacter rathayi*, 3-d-old culture (top) and of *Rathayibacter tritici*, 6-d-old culture (bottom), on CB agar. Phase-contrast microscopy. Bars = 10 μm. (Courtesy of Dr N.E. Suzina).

Cells grown for 1 week or more are usually composed of shorter rods to coccoid cells (0.6–0.8 × 0.7–1.2 μm.) which are single or arranged in pairs with angular dispositions (Figure 195, bottom), sometimes forming short chains or clumps. On fresh agar medium, outgrowth of cells occurs by elongation from one or sometimes two (polar, subpolar, or lateral) parts of the cell (Figure 196 A-E). Reproduction is by fission with the formation of a transverse septum. Divided cells often fail to separate after septum formation. Thus, cells may appear quite variable in length and shape under the light microscope and sometimes resemble primary branching cells or hyphae (Figure 195, top; Figure 196 E, F). Larger globose or oval cells may occur occasionally, some of them 2–2.5-fold larger in diameter than the remainder. A distinct rod–coccoid cycle resembling that of *Arthrobacter* species may be observed in some strains during growth on complex agar media, especially in synchronized culture. Cells are surrounded by a capsule (Bird and Stynes, 1977; Bird, 1981, 1985; Ophel et al., 1993; Figure 197) approximately 0.1–0.2 μm or even more thick. Capsular material is usually structured and exhibits radial bundles (Figure 197a) or distinct extracellular outer layers (Figure 197b, arrows).

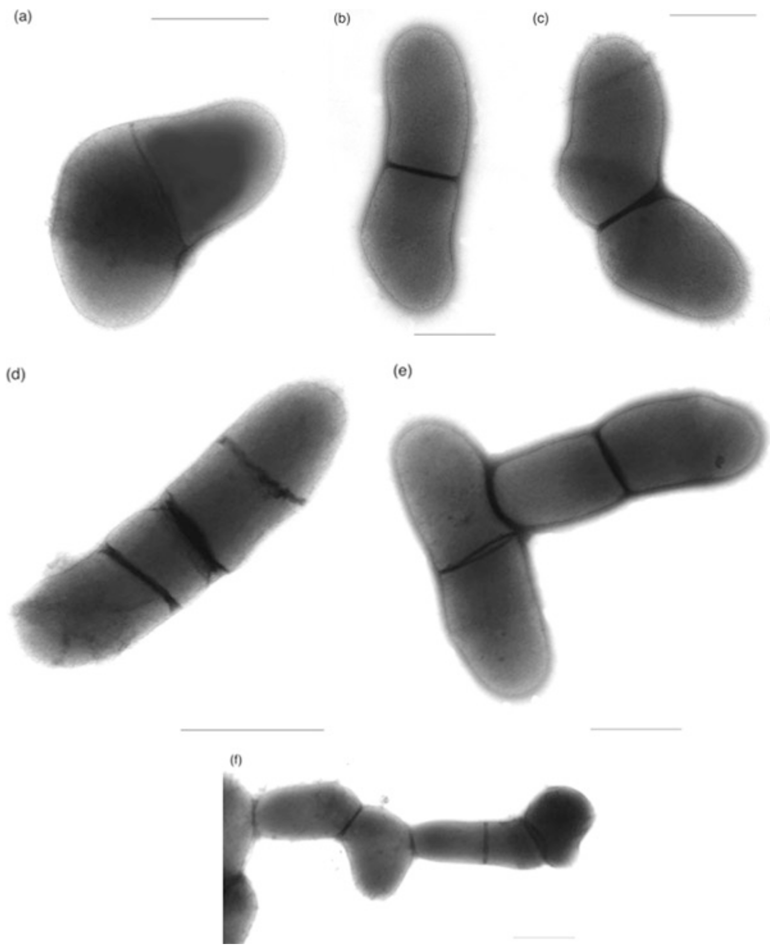

FIGURE 196. Various cell shapes of *Rathayibacter rathayi* (a–f), 1–3-d-old cultures on CB agar. Negative strained; transmission electron microscopy. The cell sizes are most likely smaller than in a living bacterium as the samples were dried during the fixation process. Bar = 0.5 µm. (Courtesy of Dr N.E. Suzina.)

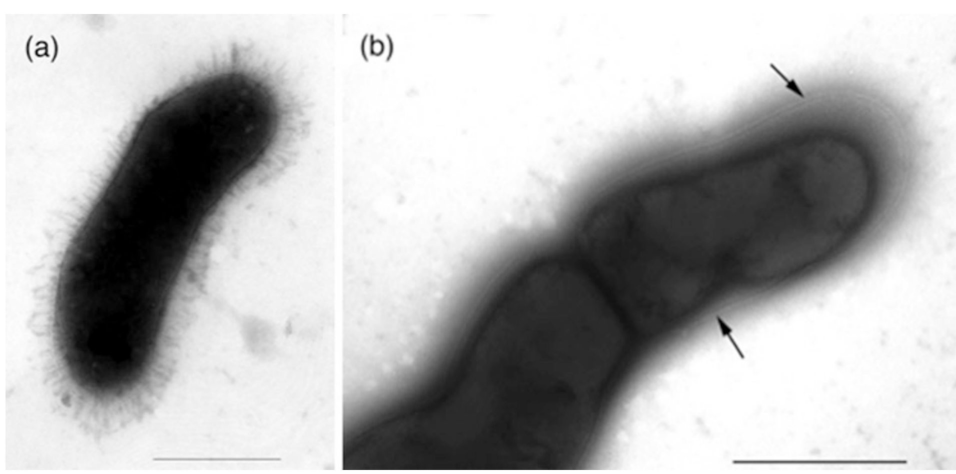

FIGURE 197. Cells of *Rathayibacter rathayi* with structured capsular material, radial bundles (a) and extracellular outer layers (b, *arrows*). 5-d-old culture on CB agar. Negatively stained; transmission electron microscopy. The sizes are most likely smaller than in a living bacterium as the sample was dried during the fixation process. Bar = 0.5 µm. (Courtesy of N.E. Suzina.)

TABLE 170. Characteristics differentiating species of the genus *Rathayibacter*[a,b]

[a]Symbols: +, positive reaction/characteristic; −, negative reaction/characteristic; d, different results either between strains, test methods, or when repeated; w, weak reaction; Y, yellow; O, orange; RO, rose-orange; P, pink.

[b]Data compiled from: Sabet (1954); Gupta and Swarup (1972); Dye and Kemp (1977); Gross et al. (1979); Price (1979); Bradbury (1986); Riley and McKay (1990); Henningson and Cugmestad (1991); Riley and Ophel (1992); Zgurskaya et al. (1993); Sasaki et al. (1998); Behrendt et al. (2002); and Dorofeeva et al. (2002).

[c]Minor or trace amounts of galactose were additionally detected in some strains of *Rathayibacter rathayi* and *Rathayibacter tritici*.

[d]Data from Zgurskaya et al. (1993) for *Rathayibacter toxicus* ICMP 6307 (= WSM 188 = CS 28 = FH-138) originating from Western Australia (Agarkova et al., 2006; Riley and Ophel, 1992; Riley et al., 1988) and for strains ICMP 6306 (= WSM 163), ICMP 6308 (= WSM 189), ICMP 6309 (= WSM 195 = VKM Ac-1600), ICMP 6310 (= WSM 194), and ICMP 6311 (= WSM 190) (see *Taxonomic comments* section for details); no data are available for the type strain of *Rathayibacter toxicus*.

[e]Basal medium: ISP 9 (Shirling and Gottlieb, 1966) supplemented with yeast extract (0.1%) and Casamino acids (Difco) (0.1%).

[f]Method 1 of Dye and Kemp (1977).

[g]Data for type strain according to Behrendt et al. (2002).

[h]CNS agar medium (Gross and Vidaver, 1979b).

[i]Method of Gross and Vidaver (1979a).

[j]Data for type strain.

[k]According to Sasaki et al. (1998). Somewhat higher values were obtained by other authors using different methods (Riley and Ophel, 1992; Starr et al., 1975; Zgurskaya et al., 1993).

[l]Different plant sources (usually occurring in the sites with *Lolium rigidum* infested with *Anguina funesta*) and different nematode vectors were also reported; see the text for more information and references.

[m]Sedge species are host plants for the nematode *Heteroanguina caricis* (Krall, 1991).

Colonies are often variable in size, probably because of adhesive properties of the capsule (Riley and Ophel, 1992) and the presence of clumps of cells in the inoculum, which is especially pronounced with cells from agar media. Colony color is usually yellow to rose-orange or pink (Table 170); the color intensity and shade vary depending on the species, growth medium, culture age, and incubation temperature. The pigments are C_{40}-carotenoids, as seen both from the characteristic three absorption peaks in the spectrum and by mass spectroscopy (Trutko et al., 2005). Pigmentation (but not growth) is inhibited by fosmidomycin at concentrations of 0.1–0.5 mg/ml (Trutko et al., 2005), which suggests the non-mevalonate pathway of pigment biosynthesis (Kuzuyama, 2002; Lichtenthaler, 2000).

The cell-wall peptidoglycan of *Rathayibacter* species contains 2,4-diaminobutyric (DAB), glycine, glutamic acid, and alanine in the molar ratio close to 2:1:1:1 (Dorofeeva et al., 2002; Sasaki et al., 1998; Zgurskaya et al., 1993). When studied in more detail, the peptidoglycans of *Rathayibacter rathayi*, *Rathayibacter*

iranicus, *Rathayibacter tritici*, and *Rathayibacter toxicus* were found to contain predominantly the L-isomer of DAB (Perkins and Cummins, 1964; Sasaki et al., 1998). About a half of the L-DAB in *Rathayibacter tritici* has a free γ-amino group (Perkins, 1965). The peptidoglycan type is supposedly [L-DAB] D-Glu–L-DAB, in which L-DAB is located in the tetrapeptide, like that in many other DAB-containing bacteria (DSMZ, 2001; Schleifer and Kandler, 1972) and also in the interpeptide bridge. The polymer structure differs from that in some other DAB-containing genera (e.g. *Clavibacter*, *Leifsonia*, *Pseudoclavibacter*), which have the peptidoglycan type [L-DAB] D-Glu–D-DAB, variation B2γ, in accordance with the classification of Schleifer and Kandler (1972). Cell-wall mono-sugars of the *Rathayibacter* strains studied so far are glucose, rhamnose, and mannose; some species additionally contain galactose, fucose, or xylose, or their combinations (Davis et al., 1984; Dorofeeva et al., 2002; Zgurskaya et al., 1993). The cell walls of *Rathaybacter* species are resistant to lysozyme (Gross et al., 1979; Zgurskaya et al., 1993).

The major respiratory menaquinone is MK-10 (up to 73–83% of the peak area) (Sasaki et al., 1998); other menaquinones (MK-7, MK-8, MK-9, and MK-11) may be present in minor or trace amounts (Collins and Jones, 1980; Dorofeeva et al., 2002; Sasaki et al., 1998; Zgurskaya et al., 1993). The respiratory chain usually contains three oxidases in different proportions depending on the species, growth phase, and growth conditions: the bb_3- and aa_3- type cytochrome oxidases and non-heme cyanide-resistant oxidase. Under oxygen deficiency, *bd*-oxidase is also produced (Trutko et al., 2003). Oxidase reaction in the tetramethyl-*p*-phenylenediamine test is usually negative, however, some strains exhibit positive reaction (Dorofeeva et al., 2002). Saturated anteiso- and iso-methyl branched fatty acids dominate among cellular fatty acids, with anteiso-methyl branched fatty acids reaching 75–80% or more of the total; the major iso-branched acid is $C_{16:0}$ iso (up to ~40% in *Rathayibacter tritici*) (Collins and Jones, 1980; Dorofeeva et al., 2002; Henningson and Gudmestad, 1991; Zgurskaya et al., 1993). Principal polar lipids are phosphatidylglycerol, diphosphatidylglycerol, and 1–3 characteristic glycolipids, glycosyldiacylglycerols (Collins and Bradbury, 1986; Collins and Jones, 1980).

Polyamines were determined for strains of *Rathayibacter rathayi*, *Rathayibacter tritici*, and *Rathayibacter iranicus*. The overall polyamine content is 4.8–18.2 µmol/g, with spermine (56–71%) and spermidine (13–40%) as predominant components. Other compounds, such as 1,3-diaminopropane, putrescine, and cadaverine are present in minor quantities. Tyramine, *sym*-homospermidine, and *sym*-norspermidine may occur in minor or trace amounts in some species (Altenburger et al., 1997).

The data on minimal nutritional requirements of *Rathayibacter* species are incomplete. Strains grow well on salt mineral media with glucose or sucrose, supplemented with yeast extract (Riley and Ophel, 1992; Zgurskaya et al., 1993). Biotin alone is required for the growth of some *Rathayibacter rathayi* and *Rathayibacter tritici* strains including the type strains. For growth, the type strain of *Rathayibacter iranicus* requires a medium supplemented with biotin, calcium pantothenate, and nicotinic acid; the same vitamins do not satisfy the growth requirements of *Rathayibacter toxicus* (Riley and Ophel, 1992). Many strains grow in the presence of biotin, thiamine, and methionine (Zgurskaya et al., 1993). Glucose metabolism has been shown to take place in a strain of *Rathayibacter tritici*, primarily via the Embden–Meyerhof–Parnas pathway and, to a lesser extent, via the pentose-phosphate pathway (Collins and Bradbury, 1986; Zagallo and Wang, 1967). *Rathayibacter* strains utilize a wide range of carbohydrates and other compounds as carbon and energy sources on appropriate growth media (Carlson and Vidaver, 1982; Davis et al., 1984; Dorofeeva et al., 2002; Dye and Kemp, 1977; Jones, 1975; Locci et al., 1989; Riley and Ophel, 1992; Zgurskaya et al., 1993).

Acid production from various carbon sources is rather weak; test results may vary with the method used, with strains, or when repeated. Tests for acidification of the media supplemented with melibiose, raffinose, L-rhamnose, ribose, sorbose, adonitol, dulcitol, and inositol are negative both when tested with the conventional methods as well as with the API (bioMerieux) test systems (Behrendt et al., 2002). Methionine and phenylalanine can be used as sole sources of nitrogen (Zgurskaya et al., 1993). Most of the strains tested so far do not decompose casein, starch, elastin, hypoxanthine, xanthine, testosterone, Tween 65, urea, and hippurate. H_2S is typically produced from peptone (except for *Rathayibacter toxicus*) and cysteine. Growth is susceptible to 7% NaCl and 0.03% potassium tellurite (Carlson and Vidaver, 1982; Davis et al., 1984; Dorofeeva et al., 2002; Dye and Kemp, 1977; Locci et al., 1989; Zgurskaya et al., 1993). The numerical analysis of 85 strains, including 19 strains of *Rathayibacter* and other bacteria with DAB in the cell wall such as members of the genera *Clavibacter* and *Agromyces*, show that *Rathayibacter* strains form well-defined phenetic clusters in accordance with their species affiliation (Zgurskaya, 1992; Zgurskaya et al., 1993).

The genomes of toxigenic strains described in the literature under the species name *Rathayibacter toxicus* consist of a single linear chromosome (Agarkova et al., 2006). The genome sizes of strain FH-99 (belonging to the same genetic cluster as the type strain of *Rathayibacter toxicus*), strain FH-138 (= CS 28 = ICMP 6307), and FH-100 (= SE3) from two other genomic groups were estimated to be 2.21, 2.25, and 2.30 Mb, respectively (Agarkova et al., 2006).

Plasmids were found in all tested strains of *Rathayibacter rathayi* and *Rathayibacter tritici* except for *Rathayibacter tritici* ICMP 2628 (Gross et al., 1979; Zgurskaya, 1992; Zgurskaya et al., 1993). The sizes of plasmids, as determined by agarose gel electrophoresis, were ~50 kb in *Rathayibacter tritici* strains and 83 kb in *Rathayibacter rathay* strains, including the type strains. Two strains of *Rathayibacter rathayi* also contain a second plasmid of 37 kb. No plasmids were found in the type strain of *Rathayibacter iranicus* and in all tested toxigenic strains assigned to *Rathayibacter toxicus* (Agarkova et al., 2006; Gross et al., 1979; Zgurskaya et al., 1993).

Bacteriophages were isolated for several *Rathayibacter* strains (for early publications, see Collins and Bradbury, 1986). Later, bacteriophages lytic for *Rathayibacter toxicus* and related toxigenic strains but not for *Rathayibacter rathayi*, *Rathayibacter iranicus*, and *Rathayibacter tritici* have been described (McKay et al., 1993; Riley and Gooden, 1991). The phages associated with toxigenic rathayibacters are thought (McKay and Ophel, 1993; Ophel et al., 1993) to be involved in regulation of biosynthesis of the glycolipid toxins (tunicaminyluracil antibiotics) known as corynetoxins (Chatel et al., 1979; Finnie, 2006). However, Kowalski et al. (2007) analyzed bacterially infected galls from toxic grain of *Lolium rigidum* and demonstrated a positive correlation between the presence of the bacterium and corynetoxins

but not with the presence of the bacteriophage isolate NCPPB 3778 (Ophel et al., 1993; Riley and Gooden, 1991).

Out of 18 tested strains of *Rathayibacter rathayi*, *Rathayibacter tritici*, *Rathayibacter iranicus*, and *Rathayibacter toxicus*, production of certain antibacterial substances active against closely related taxa (termed originally bacteriocins) was revealed in the type strains of *Rathayibacter iranicus* and *Rathayibacter tritici* as well as *Rathayibacter tritici* ICMP 2624 (Gross and Vidaver, 1979a; Zgurskaya, 1992; Zgurskaya et al., 1993). An antibiotic with a wide activity spectrum produced by *Rathayibacter iranicus* was identified as a glycolipid (Gross et al., 1979; Gross and Vidaver, 1979a).

Earlier serological studies of plant-pathogenic bacteria, including *Rathayibacter tritici* and *Rathayibacter rathayi*, have been reviewed by Collins and Bradbury (1986) and Riley (1987). Immunodiffusion and enzyme-linked immunosorbent assays (ELISA) and polyclonal ELISA tests showed a close serological similarity among strains of the *Rathayibacter toxicus* group and differences from *Rathayibacter rathayi*, *Rathayibacter iranicus*, and *Rathayibacter tritici* (Riley, 1987). The immunodiffusion technique with antisera raised against *Rathayibacter rathayi*, *Rathayibacter iranicus*, and *Rathayibacter tritici* showed some cross-reactions, however, clear differences were found in the band patterns (Riley, 1987).

The main habitats of recognized *Rathayibacter* species, most of which are plant pathogens causing a gumming disease, are thought to be plants and related sources. *Rathayibacter iranicus* and *Rathayibacter tritici* usually occur in wheat (*Triticum aestivum*), and *Rathayibacter rathayi* is found in cocksfoot grass (*Dactylis glomerata*) (Bradbury, 1973a, 1973b; Collins and Bradbury, 1986, 1991; Gupta and Swarup, 1972; Postnikova et al., 2004; Sabet, 1954; Vidaver, 1982). Strains assigned to *Rathayibacter toxicus* are most commonly found in annual ryegrass (*Lolium rigidum*) and some related grasses (Chatel et al., 1979; McKay and Ophel, 1993; Riley and Ophel, 1992; Riley and Reardon, 1995). The type strains of *Rathayibacter festucae* and *Rathayibacter caricis* have been isolated from *Festuca rubra* and *Carex* species; their plant pathogenic properties are unknown (Dorofeeva et al., 2002). There are also reports of rathayibacters being found in some other sources, e.g. symptomless poplar (Ulrich et al., 2008), tomato leaf, barnyard dust, surface soil of short-grass steppe, cow rumen, a bark beetle (from the database entries of the 16S rRNA gene sequences AB242783, AM237343, AY150910, AY244990, EU379250, EU476035, and AY167853), as well as in ancient Siberian permafrost (Vishnivetskaya et al., 2006) and an ancient salt mine deposit (DQ358658). Representatives of *Rathayibacter* have also been isolated from airliner cabin air (Osman et al., 2008a) and detected among the human skin microbiota (Grice et al., 2009).

In nature, the plant pathogenic rathayibacters are carried into the grass by gall-forming plant parasitic nematodes of the genus *Anguina* (Krall, 1991; Subbotin et al., 2004), where they colonize the inflorescence and can inhabit specific galls induced by the nematodes in various organs of the plant host (Bird, 1981; Bradbury, 1986; Gupta and Swarup, 1972; McKay and Ophel, 1993; Pathak and Swarup, 1984; Postnikova et al., 2004; Price et al., 1979; Riley, 1992, 1995; Riley and McKay, 1991a; Riley and Reardon, 1995; Sabet, 1954). The bacteria show specific adhesion to the cuticle of *Anguina* species and are apparently carried to plants on the nematode surface (Bird, 1981; McClure and Spiegel, 1991; Riley and McKay, 1990). Under natural environmental conditions, the strains of each plant pathogenic *Rathayibacter* species are most commonly found in association with the normal vector nematode (Table 171). Different nematodes have also been shown to act as vectors for some *Rathayibacter* species under experimental conditions (Bradbury, 1973b; Riley, 1995; Sabet, 1954). It is suggested that the bacterial infection of a plant is largely influenced by the host specificity of the vector nematode, the receptiveness of nematodes to bacterial adhesion, and availability of a suitable vector nematode (Agarkova et al., 2006; Riley, 1992; Riley and McKay, 1990, 1991a; Riley and Reardon, 1995; Riley et al., 2001). The bacterial infection of a plant that is not a host of any known vector nematode is most probably related to non-specific invasion by the nematode of grasses, in which it is unable to reproduce (Agarkova et al., 2006; Riley and McKay, 1991b). On documented occasions, such plants were found in the sites with *Lolium rigidum* heavily infested with *Anguina funesta* (Chatel et al., 1979; Riley, 1987; Riley and McKay, 1991b). Some other toxigenic rathayibacters which differ from *Rathayibacter toxicus* at the genomic level can be associated with other vector nematodes (see the Taxonomic comments section).

The typical symptoms of gumming disease caused by plant pathogenic rathayibacters are yellow bacterial slime on developing seed heads, stems, and leaves of a plant and some distortion of these organs (Bradbury, 1986; Gupta and Swarup,

TABLE 171. Characteristics differentiating the genera *Rathayibacter* and *Plantibacter*[a,b]

Characteristic	*Rathayibacter*	*Plantibacter*
Colony color	Yellow, rose-orange, pink	Yellow
Cell diameter, μm	0.4–0.8	0.3–0.6
Cells in a week-old culture, CB agar	Cocco-bacillary	Polymorphic
Acid production from L-rhamnose	–	+
DNase	–/+	+
Resistance to lysozyme	+	–
Sensitivity to fosmidomycin (1 mg/ml)	+	–
Menaquinone composition:[c]		
MK-8	tr	0–12
MK-9	8–18	9–24
MK-10	73–83	55–60
MK-11	tr-18	8–16
Cytochrome oxidase	bb_3 or bb_3, aa_3	aa_3
Quinole oxidase	none	bo_3/bb_3/none
Polyamine, total amount (μmol/g dry wt)[d]	4.8–18.2	1.3–1.43
Predominant polyamines (%):[d]		
Spermine	55.5–71.1	60.8–86.9
Spermidine	13–40	3.5–4.6
1,3-Diaminopropane	0.4–6.4	tr–25.9
DNA G+C content (mol%)	60.4–69	67–70

[a]Symbols: +, positive reaction; –, negative reaction; tr, trace amounts.

[b]Data from Riley and Ophel (1992); Altenburger et al. (1997); Sasaki et al. (1998); Behrendt et al. (2002); Dorofeeva et al. (2002); Trutko et al. (2003, 2005); Evtushenko and Takeuchi (2006); Lin and Yokota (2006); and recent observations.

[c]Peak area.

[d]Data for *Plantibacter* are based on analyses of two strains, VKM Ac-1787 and VKM Ac-1789, supposedly belonging to two novel species.

1972; Riley and Ophel, 1992; Sabet, 1954; Scharif, 1961; Vidaver, 1982). The biochemical mechanisms of distortion have not been strictly elucidated but most likely involve glycolipids, enzymes, and other metabolites (Collins and Bradbury, 1986). *Rathayibacter toxicus* and related bacteria producing corynetoxins (tunicaminyluracil antibiotics) are responsible for toxicity of infected plants, which often results in fatal poisoning of grazing animals (Finnie, 2006; McKay et al., 1993; Riley et al., 2003, 2004b). Corynetoxins induce neurological disorder and are among the most lethal natural toxins (Cheeke, 1995; Finnie, 2006). The ability of rathayibacters to produce corynetoxins rapidly declines following isolation and subculturing (Riley and Ophel, 1992).

The bacteria within desiccated mature plant galls are highly resistant to environmental perturbations and are recoverable after several years from such sources (Bird, 1981; Bradbury, 1973a, 1973b). Strains of "*Corynebacterium agropyri*" have been isolated from 30- to 40-year-old herbarium specimens (Murray, 1986), however, there is no clear evidence for their affiliation with the genus *Rathayibacter*. The presence of a capsule with protective properties and finding of *Rathayibacter* species in some ancient samples suggests that rathayibacters are also able to withstand the hot and arid conditions characteristic of summer (Bird and Stynes, 1977) and some extreme environments in the absence of a host plant or residual plant materials.

Enrichment and isolation procedures

The parts of plants colonized by bacteria (visible bacterial slime or infected plant galls) are the preferable source of isolation of plant pathogenic rathayibacters. If the bacteria are isolated in the earlier phase of bacterial (nematode) infection, the developing seed heads and leaves are selected. Certain common rules of isolation of plant-pathogenic bacteria outlined by Collins and Bradbury (1986) should be followed to reduce contamination with saprophytic bacteria. A number of media based on glucose, peptone, yeast extract, and Casamino acids, e.g. the sterling or tenth-diluted CB* agar medium, NBY† agar, R2A agar (Difco), and some others, can be used for isolation and subculturing of the rathayibacters so far described. CNS‡ agar medium (Vidaver, 1967) enhances the chance of selective recovery of *Rathayibacter tritici*. *Rathayibacter toxicus* and closely related toxic species grow well on 523M agar medium§ (Riley and Ophel, 1992), R agar** (Sasaki et al., 1998), and CB agar.

Maintenance procedures

Rathayibacter strains can be maintained on CB agar, R2A agar, or other suitable growth media for up to 3 months at 4°C or 10°C. For long-term maintenance, strains may be lyophilized by standard procedures. The agar media outlined above are suitable for subculturing before lyophilization.

Differentiation of the genus *Rathayibacter* from other genera

Phenotypic characteristics that delineate *Rathayibacter* from other genera comprising the family *Microbacteriaceae* are listed in Table 170. The genus *Rathayibacter* is phenotypically distinguishable from most genera in the family *Microbacteriaceae* primarily due to the presence of both L-DAB in the cell wall and MK-10 as the predominant menaquinone. Chemotaxonomically, *Rathayibacter* species are similar to *Plantibacter* in the above characteristics. Like *Rathayibacter*, members of the genus *Plantibacter* also often occur in plants and related sources (Behrendt et al., 2002; Evtushenko and Takeuchi, 2006). Distinct gummosis symptoms of a specific plant host and the information on the associated vector nematode (Table 170) are generally indicative of the known plant pathogenic members of genus *Rathayibacter*. Rathayibacters are also distinguished from *Plantibacter* by cell morphology, especially in older (6–8 d) cultures; *Rathayibacter* cells appear cocco-bacillary (Figure 195, bottom), which are usually of similar density (CB agar), whereas cells of *Plantibacter* are markedly polymorphic (heterogeneous in size and density). Other characteristics useful to delineate these genera are listed in Table 171. In addition, Fourier-transform infrared (FT-IR) spectroscopy (Oberreuter et al., 2002) is helpful to differentiate the yellow-pigmented species of *Rathayibacter* and *Plantibacter* (Behrendt et al., 2002). Strains of these two genera can be readily delineated by restriction analysis of amplified 16S rRNA gene as described by Lee et al. (1997). Clear differentiation of *Rathayibacter* strains from *Plantibacter* and other genera is achieved by the 16S rRNA gene sequence analysis.

Taxonomic comments

The organisms of the genus *Rathayibacter*, originally described as "*Aplanobacter rathayi*" (Smith, 1913) and "*Pseudomonas tritici*" (Hutchinson, 1917), are among the oldest distinctly documented representatives of the family *Microbacteriaceae*. After several reclassifications, the above species were assigned to *Corynebacterium* (Burkholder, 1948; Cummins et al., 1974; Dowson, 1942). "*Corynebacterium iranicum*" was described in 1961 (Scharif, 1961). However, only *Corynebacterium rathayi* was included in the Approved Lists (Skerman et al., 1980). Carlson and Vidaver (1982) further supported the separate species status of *Corynebacterium iranicum* and *Corynebacterium tritici* based on analyses of the cellular proteins and previously performed phenotypic studies (Collins and Jones, 1980; Dye and Kemp, 1977; Gross and Vidaver, 1979b). Though the above plant pathogenic species significantly differed from *Corynebacterium sensu stricto* in many properties including cell chemistry (Collins and Jones, 1980; Goodfellow et al., 1976; Keddie and Cure, 1977, 1978; Minnikin et al., 1978; Schleifer and Kandler, 1972), the species were retained within the genus *Corynebacterium* pleading convenience and practicality (Carlson and Vidaver, 1982). In the first

*Corynebacterium medium, CB (DSMZ medium 53): casein peptone, tryptic digest, 10 g; yeast extract, 5.0 g; glucose, 5 g; NaCl, 5 g; agar, 15 g; distilled water, 1 liter (pH 7.2–7.4).

†NBY agar (Vidaver, 1967): nutrient broth, 8 g; yeast extract, 2 g; K_2HPO_4, 2 g; KH_2PO_4, 0.5 g; agar, 15 g, water, 1 liter (pH 7.2).

‡CNS agar medium (Gross and Vidaver, 1979b): the CNS medium is based on NBY medium which is supplemented with 1% lithium chloride and the following antibiotics: nalidixic acid, 25 mg (2.5 ml freshly made 1% solution in 0.1 M NaOH); polymyxin B sulfate, 32 mg (3.2 ml of 1% aqueous solution of 8,000 USP units/mg, or a total of 256,000 units); cycloheximide, 40 mg (4 ml of 1% aqueous solution); and tetrachloro-isophthalonitrile, 0.66 mg (0.625 ml of Bravo 6F diluted 1:50).

§523M agar (Riley and Ophel, 1992): sucrose, 10 g; Casamino acids, 2 g; yeast extract, 2 g; K_2HPO_4, 2 g; $MgSO_4 \cdot 7\,H_2O$, 0.3 g; agar, 15 g, water, 1 liter (pH 7.2).

**R agar (Yamada and Komagata, 1972b): Bacto peptone, 10 g; yeast extract, 5 g; malt extract, 5 g; Casamino acids, 5 g; beef extract 2 g; glycerol 2 g; Tween 80, 50 mg; $MgSO_4 \cdot 7H_2O$, 1 g; agar, 15 g; water, 1 liter (pH 7.2).

edition of *Bergey's Manual of Systematic Bacteriology*, these and other plant pathogenic species characterized by DAB in the cell wall were described as the separate group "Plant pathogenic species of *Corynebacterium*", while stressing that none of them is an authentic *Corynebacterium* species (Collins and Bradbury, 1986). Almost at the same time, Davis et al. (1984) reclassified these species into the newly established genus *Clavibacter*.

The genus *Rathayibacter*, with the three species *Rathayibacter rathay*, *Rathayibacter tritici*, and *Rathayibacter iranicus*, was proposed by Zgurskaya et al. (1993) based on DNA–DNA hybridization, chemotaxonomic studies, and extensive phenotypic studies followed by numerical analysis as well as the relevant information about the group published by that time. This information included, in particular, the data on chemotaxonomy (Collins, 1983; Collins and Jones, 1980), serology (Riley, 1987), multilocus enzyme electrophoresis (Riley et al., 1988), and protein patterns (Carlson and Vidaver, 1982). The proposed generic affiliation of the strains was also consistent with associated diseases, host plants, and transfer by vector nematodes (Bradbury, 1986; Collins and Bradbury, 1991; Vidaver, 1982). The separate generic status of *Rathayibacter* species and their differences from *Clavibacter* was subsequently supported by the analyses of 16S rRNA gene sequences (Rainey et al., 1994; Takeuchi and Yokota, 1994). A little later, Sasaki et al. (1998) reclassified *Clavibacter toxicus* (Riley and Ophel, 1992) as *Rathayibacter toxicus*. The species *Rathayibacter festucae* and *Rathayibacter caricis* were added to the genus more recently (Dorofeeva et al., 2002).

Although many strains of the genus *Rathayibacter* have been isolated and studied due to their practical importance, a relatively small number of 16S rRNA gene sequences of *Rathayibacter* strains or uncultured clones are available in public databases. As is suggested by particular 16S rRNA gene sequence comparisons, some of these organisms may represent novel species. On the other hand, some recognized *Rathayibacter* species are not genetically homogeneous (Agarkova et al., 2006; Johnston et al., 1996; Riley and Ophel, 1992; Riley and Reardon, 1995; Riley et al., 1988). Further study may justify specific or subspecific status of the strains representing separate genomic groups. A few examples regarding *Rathayibacter toxicus* and related toxigenic bacteria are considered below.

The *Rathayibacter toxicus* strains colonizing *Lolium rigidum* grasses in Australia are clustered by multilocus enzyme electrophoresis patterns in two main groups reflecting their origin from the two regions in Western or South Australia (the South Australian group includes the type strain) (Riley et al., 1988). The grouping correlates well with the clusters generated from AFLP and PFGE patterns of whole genomes of a larger set of strains (Agarkova et al., 2006), including strains isolated from different grasses (*Phalaris* sp., *Austrodanthonia caespitosa*, *Avena sativa*, and *Avena caespitosa*) found among infected *Lolium rigidum* plants (Agarkova et al., 2006). Recent data (L.N. Anan'ina and L.I. Evtushenko, unpublished) have shown that strain VKM Ac-1600 (= ICMP 6309 = WSM 195) from *Phalaris minor*, which is most probably a representative of the Western Australian group [like the strain ICMP 6307 (= CS 28 = WSM 188) (Agarkova et al., 2006; Riley and Ophel, 1992)], exhibits 99.4% 16S rRNA gene sequence similarity to the type strain of *Rathayibacter toxicus*. Such a value, although high, is similar to those reported for many closely related species of the family *Microbacteriaceae* whose validity was supported by the DNA–DNA hybridization experiments. Representatives of the two groups, however, exhibited very similar physiological and biochemical characteristic traditionally used to differentiate species (Riley and Ophel, 1992), which is not unusual for bacteria occupying a similar ecological niche and adapted to similar nutritional conditions (Behrendt et al., 2001, 2002; Forst and Nealson, 1996; Pukall et al., 1999). Strains from the South Australian and Western Australian groups, on the other hand, showed clear differences in the specificity of their adhesion to the cuticle of nematodes representing different *Anguina* species (Riley and McKay, 1990). This result suggests that the groups may differ in the cell surface chemistry, perhaps targeting specific nematode receptors and yet-unknown molecular mechanisms responsible for interactions.

The toxigenic *Rathayibacter* strains from *Polypogon monspeliensis* and *Lachnagrostis filiformis* (syn. *Agrostis avenacea*) associated with closely related unnamed nematodes of the genus *Anguina* (Powers et al., 2001) differ by multilocus enzyme electrophoresis patterns from each other and from the type strain and all other strains assigned to *Rathayibacter toxicus* (Johnston et al., 1996; McKay et al., 1993). Strain FH-100 (= SE 3) from *Polypogon monspeliensis* was further shown to form a separate cluster by AFLP and PFGE analyses of whole genomes (Agarkova et al., 2006). It is worth noting that the regions of isolation of these strains are geographically separated from the area of the *Lolium rigidum* distribution and *Anguina funesta* infestation, and *Lachnagrostis filiformis* is an Australian native, in contrast to *Lolium rigidum* and *Polypogon monspeliensis* which are of Mediterranean origin (Agarkova et al., 2006; McKay et al., 1993; Riley et al., 2004b; Riley and Ophel, 1992).

The recently described toxigenic bacteria associated with *Anguina woodi*, a leaf gall nematode of dune grass *Ehrharta villosa* var. *villosa* in South Africa, possess some phenotypic characteristics consistent with those of *Rathayibacter* (Riley et al., 2004a). They also adhere to the juveniles of *Anguina woodi* but not *Anguina funesta*, and display distinct AFLP patterns, which are indicative of a novel species (Riley et al., 2004a).

The toxigenic bacteria associated with old nematode seed-galls in *Festuca nigrescens* from New Zealand (NZ) and New Jersey, USA, may represent another novel species or geographical variants (subspecies) of *Rathayibacter toxicus* (Riley et al., 2003, 2004b). The corynetoxin-like tunicaminyluracil-glycolipids detected in the NZ and USA galls differed from similar toxins produced by *Rathayibacter toxicus* (Anderton et al., 2004; Riley et al., 2004b). The NZ galls also gave a positive response to a *Rathayibacter toxicus*-specific monoclonal antibody assay, although a considerably weaker response than that seen with Australian *Rathayibacter toxicus* galls; the older USA galls were negative, probably due to deterioration of the antigen (Riley et al., 2003, 2004b). These bacteria may belong to a species thought to be responsible for the toxicity of *Festuca nigrescens* (syn. *Festuca rubra* subsp. *commutata*) on sites infested with *Anguina* species (*Anguina agrostis*) in Oregon, USA, in the 1940s to 1960s (Bird, 1981; Galloway, 1961). In this connection, it should be noted that in some earlier studies there is uncertainty

related to synonymy of names used for some nematodes and thereafter inadequate identification of associated bacteria. In particular, in the past the nematodes *Anguina graminis*, *Anguina funesta*, and the unnamed nematode infesting *Dactylis glomerata* have been synonymized with *Anguina agrostis* by some authors, and several grasses, including *Festuca*, *Lolium*, *Phalaris*, *Dactylis*, etc., have been listed as hosts for *Anguina agrostis* (see Southey et al., 1990, and Subbotin et al., 2004, for details). Accordingly, *Rathayibacter toxicus* and related toxigenic strains have been described under the name *Corynebactrium rathayi* in some of the earlier works (e.g. Bird and Stynes, 1977; Stynes et al., 1979; Bird, 1981; Vidaver, 1982).

Further study is required to determine the taxonomic position of strains assigned to the species "*Corynebacterium agropyri*" (O'Gara, 1915), which cause the gumming disease of *Agropyron smithii*. This species was not included in the *Approved Lists of Bacterial Names* because extant cultures were not available, and "*Corynebacterium agropyri*" and *Corynebacterium rathayi* (*Rathayibacter rathayi*) could not be clearly distinguished on the basis of their descriptions (Cummins et al., 1974; Murray, 1986; Young et al., 1978). The strains identified as "*Corynebacterium agropyri*" were afterwards isolated from old herbarium specimens of wheat grasses that were naturally infected at the time of collection (Murray, 1986). Strain "*Corynebacterium agropyri*" CS 35 (= T.D. Murray, CA-1) from *Agropyron smithii* exhibited rod-shaped cells (0.36–0.60 × 0.73–1.23 µm) and positive Gram-stain reaction, contained DAB in the cell wall, did not reduce nitrates (Murray, 1986), possessed specific adhesion to some *Anguina* species, and differed significantly from *Rathayibacter* species (*Rathayibacter rathayi*, *Rathayibacter iranicus*, *Rathayibacter tritici*, and *Rathayibacter toxicus*) in the multilocus enzyme electrophoresis patterns (Johnston et al., 1996; McKay et al., 1993; Riley et al., 1988). Attempts to determine the pathogenicity of cultured "*Corynebacterium agropyri*" in the absence of nematode vector were unsuccessful (Murray, 1986).

Differentiation of the species of the genus *Rathayibacter*

A familiar plant host and distinct symptoms of the gumming disease, along with information on the vector nematode and production of corynetoxins (tunicaminyluracil antibiotics) have a predictive value in identification of plant pathogenic *Rathayibacter* species. Some characteristics useful in distinguishing six species of the genus *Rathayibacter* are listed in Table 170. In addition, multilocus enzyme electrophoresis successfully differentiates strains of *Rathayibacter rathayi*, *Rathayibacter tritici*, *Rathayibacter iranicus*, and *Rathayibacter toxicus* (Riley et al., 1988). Strains of *Rathayibacter toxicus* are also distinguishable from other plant pathogenic *Rathayibacter* species by serology (Riley, 1987) and bacteriophage sensitivity (Riley and Gooden, 1991). PCR-based assays for identification of *Rathayibacter toxicus* and the bacteriophage isolate NCPPB 3778 have been described (Kowalski et al., 2007). The data on *gyrB*, *rpoB*, *recA*, and *ppk* gene sequences (Stackebrandt et al., 2007) for three species (*Rathayibacter festucae*, *Rathayibacter iranicus*, and *Rathayibacter tritici*) show that the analysis of housekeeping genes can be useful to differentiate *Rathayibacter* species. The AFLP and PFGE analyses of whole genomes (Agarkova et al., 2006) also seem applicable for this purpose, especially upon consideration of further improvement of taxomic structure of the genus. The 16S rRNA gene sequence similarity 98–99% (and more) between the organism in question and the type strains of phylogenetically neighboring species is generally predictive of a novel species. The DNA–DNA hybridization studies are expedient to support delineation.

List of species of the genus *Rathayibacter*

1. **Rathayibacter rathayi** (Smith 1913) Zgurskaya, Evtushenko, Akimov and Kalakoutskii 1993, 146^{VP} ("*Aplanobacter rathayi*" Smith 1913, 926; "*Phytomonas rathayi*" Bergey, Harrison, Breed, Hammer and Hunton 1923, 192; *Corynebacterium rathayi* Dowson 1942, 313; "*Pseudobacterium rathayi*" Krasil'nikov 1949, 225; "*Corynebacterium michiganense* pv. *rathayi*" Dye and Kemp, 1977, 578; *Clavibacter rathayi* Davis, Gillespie, Vidaver and Harris 1984, 113)

   rath′ay.i. N.L. masc. gen. n. *rathayi* of Rathay, named for E. Rathay, Australian plant pathologist, who first isolated the organism.

   The characteristics are as described for the genus and given in Table 170 and Table 171 with the following additional information compiled from: Sabet (1954), Bradbury (1973a), Jones (1975), Dye and Kemp (1977), Gross et al. (1979b), Gross and Vidaver (1979a), Carlson and Vidaver (1982), Davis et al. (1984), Henningson and Gugmestad (1991), Riley and Ophel (1992), Zgurskaya et al. (1993), Altenburger et al. (1997), Sasaki et al. (1998), Behrendt et al. (2002), and Dorofeeva et al. (2002).

   The colonies on corynebacterium agar are bright yellow. D-Glucose, L-arabinose, cellobiose, fructose, galactose, lactose, maltose, mannose, melezitose, raffinose, sucrose, trehalose, turanose, D-xylose, and glycerol are used as a carbon sources for growth on mineral base medium ISP 9 (Shirling and Gottlieb, 1966) supplemented with 0.1% (w/v) yeast extract and 0.1% (w/v) Casamino acids. Adonitol, dulcitol, lyxose, L-rhamnose, and tagatose are typically not used for growth on the same basal medium. Growth with sorbitol is weak and strain-dependent. Acids are produced oxidatively from xylose and glycerol. Strains are able to produce acids from glucose, cellobiose, trehalose, maltose, mannitol, fructose, galactose, lactose, sucrose, and sorbitol, but the test results may vary either with the method used or the strain examined and are often not reproducible. Acid production

by the type strain from melezitose was not detected by conventional methods and the API (bioMerieux) test system. Citrate, fumarate, malate, and succinate are utilized; results with malonate vary dependent on strain examined or the test method. Glutamate, DL-ornithine, and DL-valine are utilized as sole nitrogen source. Arbutin, Tween 21, 40, and 85 are hydrolyzed; some strains hydrolyze starch. Strains of this species decompose arbutin, gelatin, and Tween 60, but the test results may vary either with the strain examined or the test method. Tween 80 is not lipolyzed. Typically sensitive to tobramycin (10 μg per disk). Some strains, including the type strain, are also sensitive to the following antibiotics (μg/disk): streptomycin (10), chloramphenicol (10), kanamycin (30), novobiocin (5), oleandomycin (15), gentamicin (10), tetracycline (10), bacitracin, and penicillin (both 10 IU per disk). Some strains produce antibacterial substances active against closely related taxa.

The cell-wall sugars are rhamnose, glucose, mannose, and xylose; galactose may be a minor component in some strains. Polyamine pattern includes spermine (56–65%) and spermidine (30–40%) as predominant components, along with minor amounts of 1,3-diaminopropane, putrescine, cadaverine, tyramine, and trace amounts of *sym*-homospermidine and *sym*-norspermidine.

Causes a gumming disease of seed heads of cocksfoot grass (*Dactylis glomerata* Gaud.) and probably some related grasses. Artificial infection of wheat, using the nematode vector *Anguina tritici*, was reported. The normal vector nematode is an unnamed *Anguina* species parasitizing *Dactylis glomerata*.

Type strain: CFBP 2406, CIP 104036, DSM 7485, ICMP 2574, JCM 9307, LMG 7288, NCPPB 2980, VKM Ac-1601.

Sequence accession no. (16S rRNA gene): D45062, X77439.

2. **Rathayibacter caricis** Dorofeeva, Evtushenko, Krausova, Karpov, Subbotin and Tiedje 2002, 1921[VP]

ca′ri.cis. L. n. *carex* sedge; L. gen. n. *caricis* of sedge where the type strain of this species was found.

The characteristics are as described for the genus and given in Table 170 and Table 171 with the following additional information reported by Dorofeeva et al. (2002).

Colonies on corynebacterium agar are bright yellow. D-Glucose, D-galactose, L-arabinose, cellobiose, D-fructose, D-lactose, maltose, mannose, mannitol, melezitose, melibiose, raffinose, L-rhamnose, sorbitol, trehalose, turanose, and D-xylose are used for growth as a carbon source on ISP 9 medium (Shirling and Gottlieb, 1966) supplemented with yeast extract (0.1%, w/v) and Casamino acids (0.1%, w/v). Dextran, fucose, lyxose, and ribose are not utilized on the same basal medium. Alkaline reaction is positive with fumarate, malate, maleinate, and succinate but negative with acetate, citrate, glutamate, formate, lactate, oxalate, propionate, stearate, and tartrate. Asparagine, glycine, leucine, proline, tyrosine are used as nitrogen sources for growth. Tween 40 is hydrolyzed; starch, Tween 60, and Tween 80 are not decomposed. Resistant to ampicillin, gentamicin, and rubomicin (10 μg/ml). Susceptible to karbonicillin, levomicetin, metacycline, rifampin, and streptomycin at the same concentration.

Predominant cell-wall sugars are rhamnose and mannose, with a lower content of fucose, glucose, and xylose.

Plant pathogenicity is unknown.

Type strain: UCM Ac-618, CIP 108056, DSM 15933, JCM 13576, VKM Ac-1799.

Sequence accession no. (16S rRNA gene): AF159364.

3. **Rathayibacter festucae** Dorofeeva, Evtushenko, Krausova, Karpov, Subbotin and Tiedje 2002, 1921[VP]

fes.tu′ca.e. N.L. gen. n. *festucae* from *Festuca*, generic name of fescue, a host plant of this species.

The characteristics are as described for the genus and given in Table 170 and Table 171 with the following additional information taken from Dorofeeva et al. (2002).

Colonies are orange to rose-orange or pink. Oxidase test with tetramethyl-*p*-phenylenediamine is positive. D-Glucose, D-galactose, L-arabinose, cellobiose, fructose, maltose, mannose, raffinose, L-rhamnose, trehalose, turanose, D-xylose, and mannitol are used for growth as a carbon source on ISP 9 medium (Shirling and Gottlieb, 1966) supplemented with yeast extract (0.1%, w/v) and Casamino acids (0.1%, w/v). Dextran, lyxose, ribose, and sorbose are not used on the same basal medium. Acetate, citrate, fumarate, gluconate, α-keto-glutarate, malate, malonate, succinate, and tartrate are utilized but formate and propionate are not. Asparagine, glycine, proline, and tyrosine are used as nitrogen sources for growth. Starch, Tween 40, Tween 60, and Tween 80 are hydrolyzed. Resistant to the following antibiotics (10 μg/ml): ampicillin, gentamicin, oxacillin, and rubomicin. Susceptible to doxycycline, levomicetin, metacycline, rifampin, and streptomycin at the same concentration.

Cell-wall sugars are mannose, rhamnose, glucose, and xylose.

Plant pathogenicity *per se*, if any, is unknown.

4. **Rathayibacter iranicus** (Carlson and Vidaver 1982) Zgurskaya, Evtushenko, Akimov and Kalakoutskii 1993, 146[VP] ("*Corynebacterium iranicum*" Scharif 1961, 21; "*Corynebacterium michiganense* pv. *iranicum*" Dye and Kemp 1977, 578; *Corynebacterium iranicum* (*ex* Scharif 1961) Carlson and Vidaver 1982, 322; *Clavibacter iranicus* Davis, Gillespie, Vidaver and Harris 1984, 113)

i.ran′i.cus. N.L. masc. adj. *iranicus* of or pertaining to Iran.

The characteristics are as described for the genus and given in Table 170 and Table 171 with the following additional information compiled from: Dye and Kemp (1977), Gross and Vidaver (1979a), Carlson and Vidaver (1982), Davis et al. (1984), Collins and Bradbury (1986), Riley and Ophel (1992), Zgurskaya et al. (1993), Altenburger et al.

(1997), Sasaki et al. (1998), Behrendt et al. (2002), and Dorofeeva et al. (2002).

Colonies on corynebacterium agar are bright yellow. D-Glucose, L-arabinose, cellobiose, fructose, galactose, lactose, maltose, mannose, melezitose, raffinose, salicin, sucrose, trehalose, turanose, D-xylose, glycerol, and sorbitol are used for growth as a carbon source on ISP 9 medium (Shirling and Gottlieb, 1966) supplemented with 0.1% (w/v) yeast extract and 0.1% (w/v) Casamino acids. Adonitol, dulcitol, lyxose, L-rhamnose, and tagatose are not used for growth on the same basal medium. Acid is produced from xylose, galactose, fructose, glycerol, and sorbitol (weakly). The type strain produces acid from cellobiose, lactose, maltose, mannose, mannitol, melezitose, trehalose, and inulin, but test reactions vary with the methods used. Acid is not produced from tagatose, erythritol, and salicin. Citrate, fumarate, malate, and succinate are utilized but lactate is not. Malonate is utilized, but the test results may vary with the method used and is often not reproducible. Asparagine, glutamic acid, and DL-ornithine are used as a nitrogen source. Tween 21, Tween 40, and Tween 85 are hydrolyzed. Some strains decompose Tween 60 and Tween 80, but the test results may vary with the method. Arbutin, gelatin, and starch are not hydrolyzed. *Rathayibacter iranicus* NCPPB 2253 produces a glycolipid with antibacterial activity against strains of some *Rathayibacter* species and all tested strains of *Clavibacter*.

The cell-wall sugars are rhamnose, glucose, and mannose. Polyamine pattern of the type strain includes spermine (71%) and spermidine (19%) as the predominant components, with a lesser amount of putrescine (8%) and minor quantities of 1,3-diaminopropane and cadaverine.

Causes a gumming disease of seed heads of wheat (*Triticum aestivum*) and probably some related plants. Normal vector nematode is *Anguina tritici*.

Source: Triticum aestivum, Iran.

DNA G+C content (mol%): 66 (HPLC).

Type strain: CCUG 23897, CFBP 807, CIP 104037, DSM 7484, ICMP 3496, JCM 9308, LMG 3677, NCPPB 2253, VKM Ac-1602.

Sequence accession no. (16S rRNA gene): AM410684.

5. **Rathayibacter toxicus** (Riley and Ophel 1992) Sasaki, Chijimatsu and Suzuki 1998, 409[VP]
(*Clavibacter toxicus* Riley and Ophel 1992, 67)

tox′i.cus. L. m. *toxicus* (*sic*) poison.

The characteristics are as described for the genus and given in Table 170 and Table 171 with the following additional information compiled from: Riley and Ophel (1992), Sasaki et al. (1998), and Behrendt et al. (2002), unless indicated.

Colonies on R agar are flat, smooth, and pale yellow in a 5-d culture at 30°C. Cells are irregular rods, generally 0.6–0.75 × 1.5 μm. Oxidase-negative. Acid is produced from galactose, mannose, and xylose; the test reactions with inulin may vary with the method used. Acid is not produced from lactose, D-maltose, and D-melezitose and many other sugars and polyols. Acetate, glutamate, malonate, succinate, and some other organic acids are typically not utilized, but some strains may show positive reaction with acetate. Does not hydrolyze gelatin, Tween 80, and cotton seed oil. Tyrosinase and acetoin are not produced. The maximum concentration of NaCl tolerated is 1% (w/v).

Strains are lysed by the bacteriophage NCPPB 3778 (Ophel et al., 1993; Riley and Gooden, 1991). Causes gumming disease of ryegrass (*Lolium rigidum* Gaud.) and, occasionally, some related grasses. Produces corynetoxins (tunicaminyluracil antibiotics) in colonized plant hosts. The most common nematode vector is *Anguina funesta*. Under experimental conditions, the bacterium has been shown to be transmitted by other *Anguina* species such as *Anguina tritici* and *Anguina australis* (Riley, 1992; Riley et al., 2001).

Source: Lolium rigidum Gaud., from a site in Murray Bridge, South Australia, where toxicity to grazing animals and infestation with the nematode *Anguina funesta* had been observed.

DNA G+C content (mol%): 60.4 (HPLC); 67 (T_m).

Type strain: CS14, ATCC 49908, CIP 104617, DSM 7488, ICMP 9525, JCM 9669, NCPPB 3552.

Sequence accession no. (16S rRNA gene): D84127.

Additional comments: there are at least two distinct genetic groups among strains of this species originating from the two regions in Western and South Australia (Agarkova et al., 2006; Riley and Ophel, 1992; Riley et al., 1988). On compiling additional genotypic and phenotypic data, the group from Western Australia may eventually be classified as a separate species or subspecies of *Rathayibacter toxicus* (see the Taxonomic comments section for details).

6. **Rathayibacter tritici** (Carlson and Vidaver 1982) Zgurskaya, Evtushenko, Akimov and Kalakoutskii 1993, 146[VP] ["*Pseudomonas tritici*" Hutchinson 1917, 174; "*Corynebacterium michiganense* pv. *tritici*" Dye and Kemp 1977, 578; *Corynebacterium tritici* (*ex* Hutchinson 1917) Carlson and Vidaver 1982, 324; *Clavibacter tritici* Davis, Gillespie, Vidaver and Harris 1984, 113]

tri′ti.ci. L. n. *triticum* wheat, and also the generic name of wheat (*Triticum*); L. gen. n. *tritici*, of wheat, of *Triticum*.

The characteristics are as described for the genus and given in Table 170 and Table 171 with the following additional information compiled from: Bradbury (1973b), Dye and Kemp (1977), Gross et al. (1979), Gross and Vidaver (1979a), Carlson and Vidaver (1982), Henningson and Gugmestad (1991), Riley and Ophel (1992), Zgurskaya et al. (1993), Altenburger et al. (1997), Sasaki et al. (1998), Behrendt et al. (2002), and Dorofeeva et al. (2002).

Colonies on corynebacterium agar are bright yellow. D-Glucose, L-arabinose, cellobiose, fructose, galactose, maltose, mannose, raffinose, salicin, sucrose, trehalose, turanose, D-xylose, mannitol, and glycerol are used for growth as a carbon sources on salt medium supplemented with 0.1% of yeast extract (w/v) and 0.1% of Casamino acids (w/v). Growth with lactose and sorbitol is variable. Adonitol, dulcitol, erythritol, inositol, lyxose, melibiose, L-rhamnose, and tagatose are not used for growth on the same basal medium. Acid is produced from glucose, fructose, xylose, and glycerol. Strains are able to produce acid from cellobiose, galactose, lactose, maltose, mannose, sucrose, trehalose, mannitol and sorbitol, but the test reactions vary with the strain examined and the test method and are often not reproducible. Acid is not produced from melezitose and salicin. Utilizes citrate, fumarate, and succinate; the test results with acetate, malate, and malonate vary with the method and are often not reproducible. Glutamic acid and ornithine are used as a sole nitrogen source.

Tweens 21, 40, 60, and 85 are hydrolyzed; some strains are able to decompose arbutin and Tween 80, but the test results vary either with the strains or the test conditions.

The cell-wall sugars are rhamnose, glucose, mannose, and xylose; galactose is a minor component in some strains. Polyamine pattern includes spermine (64–67%) and spermidine (13–28%) as predominant components, along with minor amounts of 1,3-diaminopropane, putrescine, cadaverine, and *sym*-homospermidine.

Causes a gumming disease of wheat (*Triticum aestivum*) and some related plants. Artificial infection of *Triticum dicoccum*, *Triticum durum*, and *Triticum pyramidale* using the nematode vector *Anguina tritici* has been reported. *Dactylis glomerata* and *Secale cereale* can also be infected under experimental conditions. Normal vector nematode is *Anguina tritici*.

Genus XXIII. **Rhodoglobus** Sheridan, Loveland-Curtze, Miteva and Brenchley 2003, 992[VP]

Peter P. Sheridan

Rho.do.glo′bus. Gr. n. *rhodon* the rose; L. masc. n. *globus* ball; N.L. masc. n. *rhodoglobus* red ball.

Slender thin rods (0.15–0.2 × 1–1.2 µm) **with bulbous protuberances are seen at all stages of growth**. The protuberances are of a mean diameter of 0.8 µm. **Cells are** aerobic, **Gram-stain-positive**, easily decolorized, **motile, nonsporeforming, and grow aerobically between −2 and 21°C, with optimal growth at 18°C.** They do not exhibit a marked rod–coccus cycle. Colonies are smooth, round, convex, non-slimy, **translucent red**, and small in size (2–3 mm in diameter). Positive enzymic activity is shown for alkaline phosphatase (weak), catalase, β-galactosidase (weak), α- and β-glucosidase, pyrazimidase, and pyrrolidonylarylamidase, but are negative for β-glucuronidase, *N*-acetyl-β- glucosidase, nitrate reductase, and urease. Gelatin is not hydrolyzed, nor is acid formed from glucose, glycogen, lactose, maltose, mannitol, ribose, sucrose, or xylose. **Cell walls contain ornithine as the diagnostic amino acid. The major menaquinones are MK-11 and MK-12. The predominant fatty acids are $C_{15:1}$ anteiso, $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso.** Phylogenetic analysis of the 16S rRNA gene sequence indicates that the genus *Rhodoglobus* is a member of the family *Microbacteriaceae* and related to, but distinct from, organisms belonging to the genera *Agreia*, *Leifsonia*, and *Subtercola*. **Alignments of the 16S rRNA gene sequences contain a 13 base pair insertion in the *Rhodoglobus* sequence** that is found only in the gene sequences of a few related organisms (*Leifsonia aurea*, *Leifsonia rubra*, and *Subtercola frigoramans*).

DNA G+C content (mol%): 62.

Type species: **Rhodoglobus vestalii** Sheridan, Loveland-Curtze, Miteva and Brenchley 2003, 992[VP].

Further descriptive information

The 16S rRNA gene sequence amplified from *Rhodoglobus vestalii* was analyzed using maximum- parsimony, maximum-likelihood, and distance methods. The alignments were based on 1,549 nucleotide positions and the results of all three analyses were congruent. The distance analysis results found using the Jukes–Cantor model with equal rates for variable sites (Figure 198) show that *Rhodoglobus vestalii* is related to, but phylogenetically distinct from, organisms belonging to the *Agreia*, *Leifsonia*, and *Subtercola* genera. The grouping of *Rhodoglobus vestalii* with *Leifsonia aurea* and *Leifsonia rubra* was supported by high bootstrap values (Figure 198). A distance matrix table

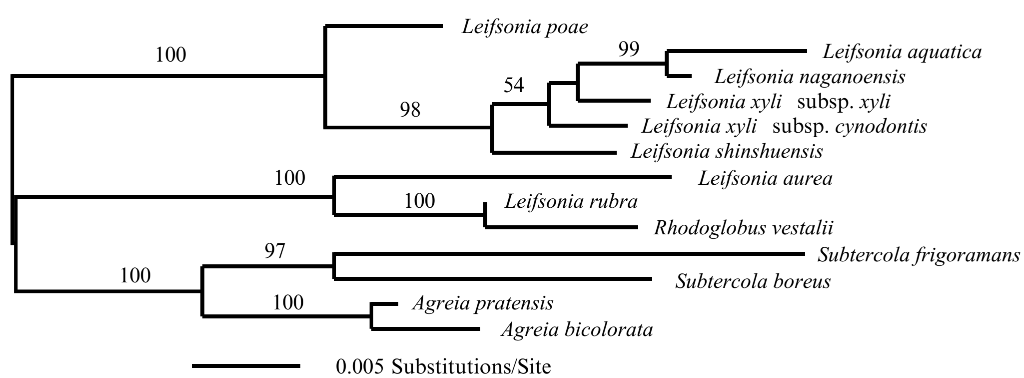

FIGURE 198. Phylogenetic tree based on an alignment of 1549 nucleotides from the 16S rRNA gene sequences of *Rhodoglobus vestalii* and closely related taxa. Phylogenetic analysis was performed using the distance method with Jukes–Cantor correction (equal rates for variable sites). Bootstrap values are based on 10,000 replicates, with only values >50 reported.

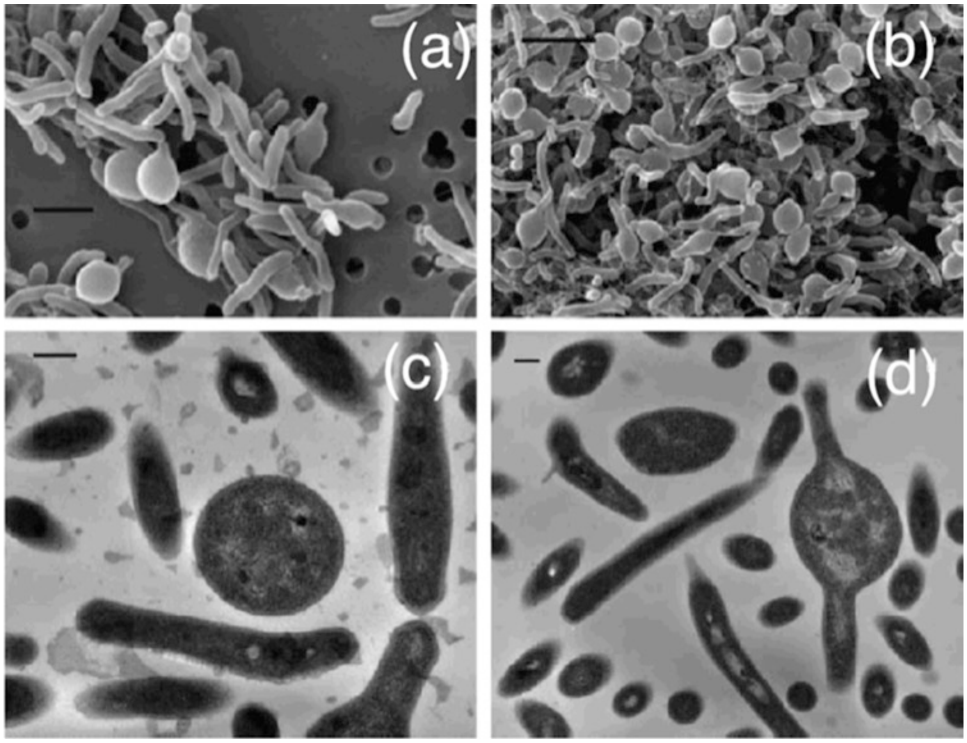

FIGURE 199. Scanning electron (a and b; bars = 1 μm) and transmission electron (c and d; bars = 200 nm) micrographs of *Rhodoglobus vestalii*. generated using the Jukes-Cantor model showed that the evolutionary distances between the *Rhodoglobus vestalii* 16S rRNA gene sequence and the sequences of the closest type strains (*Agreia bicolorata*, *Agreia pratensis*, *Leifsonia aquatica*, *Leifsonia aurea*, *Leifsonia naganoensis*, *Leifsonia poae*, *Leifsonia rubra*, *Leifsonia shinshuensis*, *Leifsonia xyli* subspecies *cynodontis*, *Leifsonia xyli* subspecies *xyli*, *Subtercola boreus*, and *Subtercola frigoramans*) are 5.07, 4.84, 5.90, 2.79, 5.36, 5.21, 0.71, 6.35, 6.05, 5.75, 5.42, and 6.31% percentage different, respectively. These values are either borderline or exceed the accepted values for a genus, with the exception of the distances for *Leifsonia aurea* and *Leifsonia rubra*. Both *Leifsonia aurea* and *Leifsonia rubra* were isolated from a pond in the Wright Valley, Antarctica, which is within 100 miles of the lake from which the sample containing *Rhodoglobus vestalii* was collected.

The 16S rRNA gene sequence of *Rhodoglobus vestalii* contains a 13 base pair insert that is only present in a few related 16S rRNA genes. Inserts with almost the exact same sequence are found in *Leifsonia aurea* and *Leifsonia rubra*, although *Subtercola boreus* and *Subtercola frigoramans* have smaller inserts (4 and 10 base pairs, respectively) of dissimilar sequence. Based on the evolutionary distances between *Rhodoglobus vestalii*, *Leifsonia aurea*, and *Leifsonia rubra* and other members of the genus *Leifsonia*, as well as the presence of the 13 base pair insertion in the 16 rRNA gene sequences of these three organisms which is distinct from the other members of the genus *Leifsonia*, it is possible that *Leifsonia aurea* and *Leifsonia rubra* may need to be reclassified as members of the genus *Rhodoglobus*.

Cells of *Rhodoglobus* are pleomorphic short, slender rods about 0.15–0.2 × 1.0–1.2 μm (Figure 199). There is no marked rod–coccus cycle as occurs in organisms classified in the genera *Arthrobacter*, *Frigoribacterium*, and *Leifsonia*. Cells from freshly inoculated cultures are longer than those from older cultures, however, no true rod–coccus cycle is observed. Clumps of cells often form in broth cultures. In addition, cells frequently appear swollen at the ends or in the middle. Scanning electron micrographs show extremely slender cells with enlarged, bulbous protuberances approximately 0.8 μm in diameter (Figure 199 A and B). Some cells are slightly curved but lack the typical fragmented shapes often seen with members of the genus *Arthrobacter*. Most protuberances appear to be in the central part of the cells and occur at all growth stages and under all culture conditions.

The amino acids present in *Rhodoglobus* cell walls contain ornithine as the diamino acid in the peptidoglycan. Significant amounts of alanine, glycine, and glutamic acid are also found, although only small amounts of lysine are detected. The molar ratio of glutamic acid to glycine to alanine to ornithine is 1:1.5:1.1:1.4. The predominant fatty acids in *Rhodoglobus* cells cultured at 18°C are branched-chain saturated fatty acids, $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. When *Rhodoglobus* is cultured at −2°C, the amount of $C_{15:0}$ anteiso decreases by 1.5 fold and the unsaturated fatty acid $C_{15:1}$ anteiso increases tenfold. These results are consistent with changes in the unsaturated and saturated fatty acid ratios found in other Gram-stain-positive nonsporeforming rods grown at different temperatures.

Rhodoglobus forms smooth, round, convex, non-slimy, reddish, small (2–3 mm in diameter) colonies on solid media. The organism grows aerobically on most agar media, with the exception of Nutrient Agar (na), at temperatures of 2, 10, and 18°C, but does not grow at 25°C or higher. Cells reach a higher density when grown in Tryptic Soy Broth (TSB) or Luria Broth (LB) than when grown in R2 broth. The generation time in TSB is estimated to be 10 h at 18°C, 20 h at 10°C, and 29 h at 5°C. Cells grow more slowly at 21°C than they do at 18°C, indicating that 18°C is the optimal temperature for growth. The upper temperature limit of growth is 22°C. Cells of *Rhodoglobus* will grow at −2°C even though there is an extended lag phase independent of the growth temperature of the inoculum. Formation of the reddish intracellular pigment appears soon after the beginning of the exponential phase in all cultures. Cells also reach a high cell density and remain viable after prolonged incubation, with over 10^{10} colony forming units per milliliter (c.f.u./ml) remaining after 4 months in TSB at −2 and 10°C.

Rhodoglobus shows positive enzymic activity for alkaline phosphatase (weak), catalase, β-galactosidase (weak), α- and β-glucosidase, pyrazimidase, and pyrrolidonylarylamidase. Enzyme activity is not shown for *N*-acetyl-β-glucosidase, β-glucuronidase, nitrate reductase, and urease. *Rhodoglobus* does not hydrolyze gelatin nor does it form acid from glucose, glycogen, lactose, maltose, mannitol, ribose, sucrose, or xylose. It does not grow anaerobically or in the presence of 2.5, 5.0 or 10.0% NaCl, and does not form spores. The G+C mol% of *Rhodoglobus* is calculated to be 62 mol% based on the melting temperature of *Rhodoglobus* DNA. A plasmid of approximately 900 base pairs has been found in *Rhodoglobus vestalii*, although its function has not been determined.

Rhodoglobus vestalii was isolated from a cyanobacterial mat sample from a meromictic pond (informally called "Lake Vestal" in honor of the late J. Robie Vestal) located south of the Miers and Adams glaciers near Bratina Island, on the McMurdo Ice Shelf, Antarctica. Organisms determined to be closely related to *Rhodoglobus vestalii* by 16S rRNA gene sequence identity (*Leifsonia aurea* and *Leifsonia rubra*) were isolated from an Antarctic Dry Valley pond in the Wright Valley, Antarctica, approximately 100 miles from "Lake Vestal."

Enrichment and isolation procedures

A cyanobacterial mat sample was collected in January 1993 from a meromictic pond (informally called "Lake Vestal") located South of the Miers and Adams glaciers near Bratina Island, on the McMurdo Ice Shelf, Antarctica. The sample was kept frozen at −80°C until an approximately 2 g sample was inoculated into 5 ml of Instant Ocean broth (Loveland-Curtze et al., 1999) and incubated at 10°C until the culture became turbid. Organisms were isolated on Instant Ocean agar using streak plating techniques, and colonies were passed at least three times to ensure purity.

Maintenance procedures

Growth of *Rhodoglobus vestalii* has been tested on a variety of media. The organism grows aerobically on most agar media, except na, at temperatures of 2, 10, and 18°C, but does not grow at 25°C or higher. Cells reach a higher density when grown in LB or TSB than when grown in R2 broth. The generation time in TSB was estimated to be 10 h at 18°C, 20 h at 10°C, and 29 h at 5°C. Cells grow more slowly at 21°C than they do at 18°C. The upper temperature limit of growth is 22°C. Cells grow at −2°C even though there is an extended lag phase independent of the growth temperature of the inoculum. Formation of the reddish intracellular pigment appears soon after the beginning of the exponential phase in all cultures. Cells reach a high cell density and remain viable after prolonged incubation with over 10^{10} c.f.u./ml remaining after 4 months in TSB at −2 and 10°C. Cells can be stored via either lyophilization or as 20% glycerol stocks at either −20°C or −80°C.

Procedures for testing special characteristics

The 16S rRNA gene sequence was amplified from a genomic DNA preparation with the Bacterial Domain-specific primer 8 Forward and the Universal primer 1492 Reverse (Pace et al., 1986; Weisburg et al., 1991) using the following conditions: 10′ at 95°C, followed by 30 cycles of (1′ at 94°C, 1′ at 53°C, 2′30″ at 72°C), followed by 7′ at 72°C, followed by a 4°C "hold."

Differentiation of the genus *Rhodoglobus* from other genera

Based on 16S rRNA gene sequence analysis, as well as the presence of a similar 13 base pair insert in their 16S rRNA gene sequences, the taxa most closely related to *Rhodoglobus vestalii* are *Leifsonia aurea* and *Leifsonia rubra*. *Rhodoglobus vestalii* can be distinguished from these organisms not only by sequencing of the 16S rRNA gene, but also through the presence of $C_{15:1}$ anteiso fatty acids in *Rhodoglobus vestalii*; these are not found in *Leifsonia aurea* and *Leifsonia rubra* (Table 172). Moreover, *Rhodoglobus vestalii* is motile, while *Leifsonia aurea* and *Leifsonia rubra* are not. In addition, the major menaquinones are MK-11 and MK-12 in *Rhodoglobus vestalii*, while the major menaquinone is MK-11 in *Leifsonia aurea* and *Leifsonia rubra*. The cell walls of *Rhodoglobus vestalii* contain ornithine as the diamino acid, while DL-diaminobutyric acid is the diamino acid in the cell walls of *Leifsonia aurea* and *Leifsonia rubra*. Cells of *Rhodoglobus vestalii* exhibit bulbous protuberances at all stages of growth, but these structures have not been reported for either *Leifsonia aurea* or *Leifsonia rubra*. Less significantly, the minimum growth temperature for *Rhodoglobus vestalii* is −2°C, but is 0°C for *Leifsonia aurea* and *Leifsonia rubra*, and *Rhodoglobus vestalii* is unable to grow in NaCl concentrations above 2.5%, although the upper limit of NaCl tolerated by *Leifsonia aurea* and *Leifsonia rubra* is 3%.

Taxonomic comments

The genus *Rhodoglobus* was first described in 2003 by Sheridan and co-authors (Sheridan et al., 2003). The type strain, *Rhodoglobus vestalii*, was isolated from a cyanobacterial mat sample collected from a pond near the Miers and Adams glaciers in the Dry Valleys of Antarctica. Amplification and sequencing of the isolate's 16S rRNA gene sequence indicates that the organism is a member of the family *Microbacteriaceae* and related to, but distinct from, organisms belonging to the genera *Agreia* (Evtushenko et al., 2001; Schumann et al., 2003), *Leifsonia* (Evtushenko et al., 2000; Suzuki et al., 1999), and *Subtercola* (Behrendt et al., 2002; Männistö et al., 2000). Analysis of the 16S rRNA gene sequences of the validly published organisms within the family *Microbacteriaceae* indicate that *Rhodoglobus vestalii* contains a 13 base pair insertion that is only found in a few related organisms (*Leifsonia rubra*, *Leifsonia aurea*, and *Subtercola frigoramans*). Electron micrographs of *Rhodoglobus vestalii* show the presence of

large, bulbous protuberances that are present at all stages of growth. Detailed inspection of the protuberances indicate that they are contiguous with the portions of the cell that were rods. The evolutionary distances from described taxa, along with the 16S rRNA gene insertion and the presence of ornithine as the diamino acid in the cell wall and of MK-11 and MK-12 as the major menaquinones are deemed sufficient to warrant the creation of the novel genus *Rhodoglobus*.

The organisms *Leifsonia aurea* and *Leifsonia rubra* were being described at the same time in 2003, and the phylogenetic analyses of the 16S rRNA gene sequence data indicate a close relationship to the proposed novel organism *Rhodoglobus vestalii* (evolutionary distances of 2.79 and 0.71, respectively). It was proposed by Sheridan (2003) that perhaps *Leifsonia aurea* and *Leifsonia rubra* should be included within the novel genus *Rhodoglobus*, as they had not been validly published as members of the genus *Leifsonia*. However, a number of significant differences between *Rhodoglobus vestalii* and *Leifsonia aurea* and *Leifsonia rubra* argue for their exclusion from the genus *Rhodoglobus*. *Rhodoglobus vestalii* is distinct from the two *Leifsonia* species in that it has $C_{15:1}$ anteiso fatty acids. Furthermore, *Rhodoglobus vestalii* is motile, while *Leifsonia aurea* and *Leifsonia rubra* are not. Additionally, the major menaquinones in *Rhodoglobus vestalii* are MK-11 and MK-12, while the major menaquinone is MK-11 in *Leifsonia aurea* and *Leifsonia rubra*. The cell walls of *Rhodoglobus vestalii* contain ornithine as the diamino acid, while DL-diaminobutyric acid is the diamino acid in the cell walls of *Leifsonia aurea* and *Leifsonia rubra*. Finally, cells of *Rhodoglobus vestalii* exhibit bulbous protuberances at all stages of growth; these structures have not been reported for either *Leifsonia aurea* or *Leifsonia rubra*. Therefore, inclusion of *Leifsonia aurea* and *Leifsonia rubra* in the genus *Rhodoglobus* is not warranted, although the significant differences between *Leifsonia aurea* and *Leifsonia rubra* and other members of the genus *Leifsonia* indicate that these organisms should be placed within their own genus distinct from both *Leifsonia* and *Rhodoglobus*.

Acknowledgements

I wish to thank my colleagues Jean Brenchley, Jennifer Loveland-Curtze, and Vanya Miteva for their work in the original characterization and description of the genus *Rhodoglobus* and the organism *Rhodoglobus vestalii*. Additional thanks to Vanya Miteva and Rosemary Walsh for the preparation of the electron micrographs.

List of species of the genus *Rhodoglobus*

1. **Rhodoglobus vestalii** Sheridan, Loveland-Curtze, Miteva and Brenchley 2003, 992[VP]

ves.ta′.li.i. N.L. gen. masc. n. *vestalii* of Vestal, in honor of J. Robie Vestal, who studied the ecology and physiology of Antarctic microorganisms.

Colonies are smooth, round, convex, non-slimy, translucent red, and small in size (2–3 mm in diameter). Cells are slender thin rods (0.15–0.2 × 1–1.2 µm) with bulbous protuberances seen at all stages of growth. The protuberances are of a mean diameter of 0.8 µm. Cells are Gram-stain-positive, easily decolorized, nonsporeforming, and motile. They grow aerobically between −2 and 21°C, with optimal growth rate at 18°C, but do not exhibit a marked rod–coccus cycle. Cell walls contain ornithine as the diagnostic amino acid. The major menaquinones are MK-11 and MK-12. The predominant fatty acids are $C_{15:1}$ anteiso, $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. Cells do not hydrolyze gelatin and do not form acid from glucose, glycogen, lactose, maltose, mannitol, ribose, xylose, or sucrose, but show positive enzymic activity for alkaline phosphatase (weak), catalase, β-galactosidase (weak), α-and β-glucosidase, pyrazimidase, and pyrrolidonylarylamidase but are negative for β-glucuronidase, *N*-acetyl-β- glucosidase, nitrate reductase, and urease.

Source: an Antarctic Dry Valley lake located south of the Miers and Adams glaciers near Bratina Island, on the McMurdo Ice Shelf, Antarctica.

DNA G+C content (mol%): 62 (T_m).

Type strain: LV3, ATCC BAA-534, CIP 107482, JCM 12695, NBRC 103084.

Sequence accession no. (16S rRNA gene): AJ45910.

Genus XXIV. **Salinibacterium** Han, Nedashkovskaya, Mikhailov, Kim and Bae 2003, 2064[VP]

Seung Bum Kim and Olga I. Nedashkovskaya

Sa.li.ni.bac.te′ri.um. L. n. *salinum* salt-cellar; L. neut. n. *bacterium* a small rod and, in biology, a bacterium (so called because the first ones observed were rod-shaped); N.L. neut. n. *Salinibacterium* a saline bacterium.

Gram-stain-positive, **nonmotile, aerobic, nonsporeforming, irregular rods**. Mycolic acid is absent. Metabolism is respiratory, but acids can also be formed from some sugars. Arginine dihydrolase, oxidase, and urease-negative, but catalase-positive. **Grows in the presence of NaCl**. Grows at mesophilic temperatures and around neutral pH. **Cell-wall peptidoglycan is type B; lysine and ornithine are the diagnostic diamino acids**. **Muramic acid contains acetyl residues**. Principal phospholipids are phosphatidylglycerol and diphosphatidylglycerol (**phospholipid type I**). Cellular fatty acids consist of branched, saturated species; major components are 12-methyltetradecanoic acid ($C_{15:0}$ anteiso) and 14-methylpentadecanoic acid ($C_{16:0}$ iso). **Predominant menaquinone is MK-11**, and a smaller amount of MK-10 is also present.

DNA G+C content (mol%): 61.0–63.5.

Type species: **Salinibacterium amurskyense** Han, Nedashkovskaya, Mikhailov, Kim and Bae 2003, 2065[VP].

Further descriptive information

Salinibacterium is one of the 26 genera belonging to the family *Microbacteriaceae* and currently contains two species, *Salinibacterium amurskyense* (Han et al., 2003) and *Salinibacterium xinjiangense* (Zhang et al., 2008). The level of DNA–DNA relatedness between *Salinibacterium amurskyense* and *Salinibacterium xinjiangense* is reported to be 46.7%, and the 16S rRNA gene sequence similarity is 97.4% (Zhang et al., 2008). The differential phenotypic and chemotaxonomic properties between the two species are listed in Table 173. *Rhodoglobus* is the closest neighbor of *Salinibacterium*, and two species of *Leifsonia*, namely *Leifsonia aurea* and *Leifsonia rubra*, are also closely related to the genus (Figure 200). The relationship among *Salinibacterium*, *Rhodoglobus*, and two *Leifsonia* species is discussed in the Taxonomic Comments section.

The genus has common morphological features shared by the members of *Microbacteriaceae*, such as irregular cell shapes (Figure 201), aerobic respiratory metabolism, unsaturated menaquinones, type I phospholipids (major amount of phosphatidylglycerol), and branched/saturated fatty acids as the major components. The colonies of *Salinibacterium* are yellow-colored and smooth-surfaced. Good growth occurs on marine agar plates at mesophilic temperatures and neutral pH. All strains of *Salinibacterium* are halophilic, although salt is not required for growth.

Cell-wall hydrolysates contain major amounts of lysine and ornithine as diagnostic cell-wall diamino acids, and the molar ratio of alanine: glycine: glutamic acid: lysine: ornithine of *Salinibacterium amurskyense* was reported as 1.0:1.0:0.4:0.25:1.0. The membrane fatty acids consist of 12-methyltetradecanoic acid ($C_{15:0}$ anteiso, 40.4–58.4% of the total), 14-methylpentadecanoic acid ($C_{16:0}$ iso, 21.1–34.7%), 12-methyltridecanoic acid ($C_{14:0}$ iso, 10.3–14.7%), 13-methyltetradecanoic acid ($C_{15:0}$ iso, 0.5–6.6%) and 14-methylhexadecanoic acid ($C_{17:0}$ anteiso, 2.8–7.2%). A considerable degree of difference can be observed between

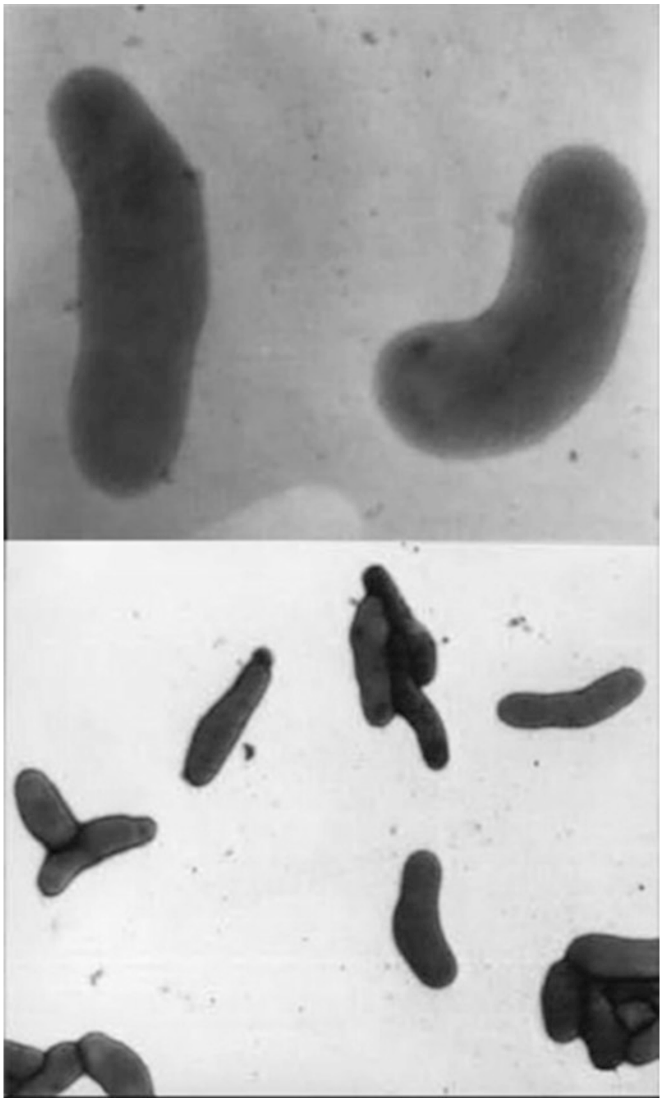

FIGURE 201. Transmission electron photomicrographs of cells of *Salinibacterium xinjiangense* 0543^T grown on PYG medium. (Reproduced with permission from Zhang et al., 2008. Int. J. Syst. Evol. Microbiol. *58*: 2739–2742.)

the two species in the proportion of each major constituent (Zhang et al., 2008). MK-11 is the major menaquinone and smaller amount of MK-10 is present in *Salinibacterium amurskyense* (Han et al., 2003), but MK-10 (54.4%) is the major component and smaller amounts of MK-11 (28.9%), MK-9 (6.8%), MK-12 (5.4%), and MK-8 (4.3%) are present in *Salinibacterium xinjiangense* (Zhang et al., 2008). The major chemotaxonomic profiles of *Salinibacterium* are consistent with their classification in the family *Microbacteriaceae*.

Salinibacterium amurskyense was the first species of *Microbacteriaceae* reported from a marine environment. A marine environment is not a common habitat for the members of *Microbacteriaceae*, and only a few cases of taxa isolated from a marine environment are known - *Labedella gwakjiensis* and *Phycicola gilvus* isolated from seaweed (Lee et al., 2008; Lee, 2007) and some species of *Microbacterium* isolated from seawater and marine sediment (Kageyama et al., 2007b; Lee et al., 2006; Shivaji et al., 2007). There are currently 22 entries of *Salinibacterium* sequences available in the GenBank database, and 12 out of 19 entries for which the sources are known originated from the marine environment. The sources include seawater, the Antarctic Ocean, estuary, marine bacterioneuston, marine sediment, permafrost ice wedge, glacier soil, and soils contaminated by chlorinated pesticides.

Enrichment and isolation procedures

The strains of *Salinibacterium* can be isolated using marine agar or PYG medium (Han et al., 2003; Zhang et al., 2008). For the enrichment of *Salinibacterium xinjiangense*, the glacier soil samples were resuspended in PYG broth, incubated at 4°C, and then spread on PYG agar plates for isolation. Since the organisms are halophilic, addition of NaCl or seawater to the isolation medium would enhance their growth. Growth temperature may vary depending on the nature of the sample. For the isolation of *Salinibacterium amurskyense*, 28°C was used, whereas *Salinibacterium xinjiangense* was isolated at 18°C. The optimal pH range is between 7.0 and 7.5.

Maintenance procedures

Strains can be cultivated on marine agar 2216 (Difco) or PYG medium (0.5% Bacto peptone, 0.02% yeast extract, 0.5% glucose, 0.3% beef extract, 0.05% NaCl, and 0.15% $MgSO_4 \cdot 7H_2O$). The cultures can be maintained at 25–28°C for mesophilic strains, and at 18–19°C for psychrophilic strains. For long-term preservation, storage of the cell suspensions in 20–30% (v/v) glycerol at −20 to −80°C, or lyophilization is recommended.

Differentiation of the genus *Salinibacterium* from other genera

Salinibacterium can be differentiated from the related genera of the family *Microbacteriaceae* based on the chemotaxonomic properties, including cell-wall diamino acids, isoprenoid quinones, acyl type, fatty acid profiles, and DNA G+C content (Table 140 for *Microbacteriaceae*). *Salinibacterium* contains lysine and ornithine as the diagnostic diamino acid of the cell wall, which separates the genus from other genera containing diaminobutyric acid including *Agreia*, *Agrococcus*, *Agromyces*, *Clavibacter*, *Cryobacterium*, *Leifsonia*, *Leucobacter*, *Microterricola*, *Plantibacter*, *Pseudoclavibacter*, *Rathayibacter*, *Rhodoglobus*, *Subtercola*, *Yonghaparkia*, and *Zimmermannella* (Lin et al., 2004; Matsumoto et al., 2008; Zhang et al., 2007c). The major menaquinone of *Salinibacterium* is either MK-10 or MK-11, which is different from those of *Clavibacter* (MK-9), *Curtobacterium* (MK-9), *Frigoribacterium* (MK-9), *Frondihabitans* (MK-8), *Gulosibacter* (MK-9), *Microcella* (MK-12 and 13), *Microterricola* (MK-12), *Pseudoclavibacter* (MK-9), *Rhodoglobus* (MK-12 and MK-11); *Subtercola* (MK-9 and 10), *Yonghaparkia* (MK-12), and *Zimmermannella* (MK-8, 9 and 10) (Lin et al., 2004; Matsumoto et al., 2008; Zhang et al., 2007c). *Salinibacterium* has acetyl type peptidoglycan (Han et al., 2003) which separates the genus from *Microbacterium* and *Okibacterium*, both having glycolyl type (Evtushenko et al., 2002).

Taxonomic comments

Salinibacterium was described in 2003 (Han et al., 2003) when the description of *Rhodoglobus*, the mostly related genus to the former, was also published (Sheridan et al., 2003). The 16S

rRNA gene sequence similarity clearly indicates close relationship between the two genera, as the similarity values are 95.8–97.1% based on the BLAST results (http://blast.ncbi.nlm.nih.gov/blast.cgi). *Rhodoglobus vestalii*, isolated from a lake in Antarctica, shows many properties similar to the species of *Salinibacterium*; growth between 2 and 21°C with an optimal temperature of 18°C, 62 mol% molar G+C content of the genomic DNA, and $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso as the major fatty acids. In contrast, red-pigmented colonies, small rods with unusual bulbous protuberances during all phases of growth, MK-12 as the major menaquinone with smaller amount of MK-11, absence of lysine in the cell wall, and lack of growth in the presence of 2.5% and higher concentration of NaCl, are obvious differences between *Rhodoglobus* and *Salinibacterium*. Considering the high level of 16S rRNA gene sequence similarity, the taxonomic status of the two genera will have to be further examined.

The two species of *Leifsonia*, *Leifsonia rubra* and *Leifsonia aurea* have also been constantly clustered with *Salinibacterium* (Lee et al., 2008; Lee, 2007; Zhang et al., 2008). The level of 16S rRNA gene sequence similarities between the *Salinibacterium* species and two *Leifsonia* species range from 95.1–97.6%. Coincidentally, the two *Leifsonia* species were also described in 2003 (Reddy et al., 2003b), and thus proper comparison between *Salinibacterium amurskyense* and *Leifsonia* species could not be performed then. Zhang et al. (2008) pointed out such problems regarding the taxonomic positions of five taxa, namely the two species of *Salinibacterium*, *Rhodoglobus vestalii*, and the two *Leifsonia* species. Since the level of 16S rRNA gene sequence similarity ranges between 95.1– 99.4% based on the BLAST results, it is likely that the five taxa form a single genus. Further investigation will be able to clarify their taxonomic status.

List of species of the genus *Salinibacterium*

1. **Salinibacterium amurskyense** Han, Nedashkovskaya, Mikhailov, Kim and Bae 2003, 2065[VP]

a.mur.sky.en′se. N.L. neut. adj. *amurskyense* of or belonging to Amursky Bay, the geographical location where the organism was first isolated.

General morphological and chemotaxonomic properties are as given in the genus description. Grows between 4 and 37°C (with optimal growth at 25–28°C), between pH 4.5 and 11.0 (with optimal growth around pH 7.2–7.5), and in the presence of 0–10% NaCl (with optimal growth at 1–3%). Gelatin and DNA are degraded, but agar, casein, starch, cellulose, alginate, chitin, and Tweens 20 and 40 are not. Acid is produced from rhamnose and glycerol. Acid is not produced from acetate, *N*-acetylglucosamine, adonitol, cellobiose, dulcitol, fumarate, galactose, glucose, inositol, lactose, malate, maltose, melibiose, raffinose, sorbitol, sorbose, sucrose, or xylose. Susceptible to ampicillin (10 μg per disc), carbenicillin (100 μg), and streptomycin (10 μg), but resistant to gentamicin (10 μg), kanamycin (30 μg), neomycin (30 μg), polymyxin B (300 U), and tetracycline (30 μg).

Source: sea water.

DNA G+C content (mol%): 61.0 (T_m).

Type strain: JCM 12362, KCTC 9931, KMM 3673, NBRC 100448.

Sequence accession no. (16S rRNA gene): AF539697.

2. **Salinibacterium xinjiangense** Zhang, Liu, Xin, Yu, Zhou and Zhou 2008, 2741[VP]

xin.jiang.en′se. N.L. neut. adj. *xinjiangense* of or pertaining to Xinjiang, where the type strain was isolated.

Psychrophilic, nonsporeforming, nonflagellated, and nongliding irregular rods. Cells are 1.4–2.3 μm long and 0.5–0.8 μm wide. Colonies are yellow, smooth, circular, and convex with entire margins. Grows at 4–23°C (optimal temperature 18–19°C) and also at pH 5.0–9.0 (approximate optimal pH 6.0–8.0). Grows in the presence of 0–14% (w/v) NaCl. Catalase-positive but oxidase-negative. Starch and Tweens 20, 60, and 80 are hydrolyzed, but gelatin or casein are not. Nitrate is reduced. Tests for naphthol-AS-BI-phosphohydrolase, amannosidase, esterase (C4), esterase lipase (C8), cystine arylamidase, leucine arylamidase, and valine arylamidase are positive. Tests for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, alkaline phosphatase, acid phosphatase, indole production, α-chymotrypsin, trypsin, urease, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, α-glucosidase, and α-fucosidase are negative. Arabinose, cellobiose, fructose, galactose, glucose, maltose, D-mannose, melibiose, and sucrose can be utilized as sole carbon sources. Acids are produced from glucose, fructose, D-mannose, and galactose. Erythritol, fumarate, hippurate, melezitose, pyruvate, L-rhamnose, D-sorbitol, sorbose, succinate, tartrate, and uric acid are not utilized as sole carbon sources. The major menaquinone is MK-10, and a smaller amount of MK-11 is also present. The polar lipids are diphosphatidylglycerol and phosphatidylglycerol. The peptidoglycan contains ornithine and lysine as major diamino acids, and alanine, glycine, and glutamic acid are also present. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{14:0}$ iso, and $C_{17:0}$ anteiso.

Source: glacier soil.

DNA G+C content (mol%): 63.5 (T_m).

Type strain: 0543, CGMCC 1.5381, JCM 13926.

Sequence accession no. (16S rRNA gene): DQ515964.

Genus XXV. **Subtercola** Männistö, Schumann, Rainey, Kämpfer, Tsitko, Tiirola and Salkinoja-Salonen 2000, 1737[VP]

Peter Kämpfer

Sub.ter'co.la. L. prep. *subter* below, underneath; L. masc. suff. *-cola* inhabitant; N.L. masc. n. *subtercola* the one who lives underneath.

Short irregular rods, 0.2–0.4 × 0.6–1.6 μm, often occurring singly or in v-forms. **Gram-stain-positive**. Nonencapsulated. Nonmotile. Nonsporeforming. Aerobic. The colonies are circular, convex, smooth, and pale to bright yellow, depending on the medium. **Growth occurs best at 15–17°C, but is also observed in the temperature range 2–28°C.** The cell-wall diamino acid is **diamino butyric acid (DAB)**. **The main cell-wall amino acids are alanine, glycine**, ***threo*-3-hydroxy-glutamic acid, and DAB**. The peptidoglycan type is B2γ. The polar lipids are phosphatidylglycerol, diphosphatidylglycerol, one unknown phospholipid, and two glycolipids. The main cellular fatty acids are 12-methyltetradecanoic acid ($C_{15:0}$ anteiso), 14-methylpentadecanoic acid ($C_{16:0}$ iso), and 14-methylhexadecanoic acid ($C_{17:0}$ anteiso). **The whole-cell methanolysates of *Subtercola* species contain 1,1-dimethoxy-anteiso-pentadecane ($C_{15:0}$ anteiso DMA) and 1,1-dimethoxy-iso-hexadecane ($C_{16:0}$ iso DMA) as major components in amounts comparable to those of fatty acids.** No mycolic acids are present. The major isoprenoic quinones are MK-9 and MK-10.

DNA G+C content (mol%): 64–68.

Type species: **Subtercola boreus** Männistö, Schumann, Rainey, Kämpfer, Tsitko, Tiirola and Salkinoja-Salonen 2000, 1737[VP].

Further descriptive information

Isolated from Finnish groundwater (Männistö et al., 2000). Belong to the few psychrophilic or pychrotolerant actinobacteria of the family *Microbacteriaceae*. Two species have been described so far, *Subtercola boreus* and *Subtercola frigoramans* (Männistö et al., 2000). An additional species, *Subtercola pratensis*, was proposed by Behrendt et al. (2002), however, after the description of the genus *Agreia* (Evtushenko et al., 2001), *Subtercola pratensis* was transferred to the genus *Agreia* (Schumann et al., 2003).

Phylogenetic analyses based on a dataset comprising 1330 unambiguous nucleotides between positions 38 and 1478 (but excluding positions 97–193 due to the absence of this region in the reference sequence of *Leucoacter komagatae* D17751, *Escherichia coli* positions; Brosius et al., 1978) showed that the new isolates cluster together as distinct lineages within the radiation of the actinomycete genera with group-B-peptidoglycan that comprises the family *Microbacteriaceae* (Stackebrandt et al., 1997). Both species show the highest levels of 16S rRNA gene sequence similarity with species of the genera *Clavibacter* (95.1–97.1%), *Frigoribacterium* (95.5–96.7%), and *Rathayibacter* (94.3–96.7%). The 16S rRNA gene sequences (1465 bp) of the type strains of both species show a similarity of 96.4%.

The two established species share major chemotaxonomic characteristics including peptidoglycan type B2γ (Schleifer and Kandler, 1972), murein type, quinone system with MK-9 and MK-10 (in almost equal proportions), a similar polar lipid profile with phosphatidylglycerol, diphosphatidylglycerol, one unknown phospholipid and two glycolipids, and a fatty acid profile with almost exclusively branched acids and the predominant $C_{15:0}$ anteiso. Significant quantitative differences in the presence of certain fatty acids and several physiological traits (Table 174 and Table 175) are found.

TABLE 174. Characteristics differentiating *Subtercola boreus* from *Subtercola frigoramans*[a,b]

Characteristic	*S. frigoramans* K265[T]	*S. boreus* K300[T]
Assimilation of:		
p-Arbutin, salicin	+	−
L-Rhamnose, D-ribose, i-inositol, citrate, 3-hydroxybenzoate, acetate, propionate, *cis*-aconitate	−	+
Hydrolysis of:		
*p*NP-β-D-Glucuronide, Bis-*p*NP-phosphate	−	+
*p*NP-β-D-Xylopyranoside	+	−

[a]Symbols: +, >85% positive; d, different strains give different reactions (16–84% positive); −, 0–15% positive; D, different reactions occur in different taxa (species of a genus or genera of a family); w, weak reaction; nd, not determined; nr, not reported. *p*NP, para-nitrophenyl.

[b]Data from Männistö et al. (2000).

The principal phospholipids of *Subtercola boreus* and *Subtercola frigoramans* are similar to those of *Clavibacter* (Collins and Jones, 1980), *Rathayibacter* (Zgurskaya et al., 1993), *Cryobacterium* (Suzuki et al., 1997), and *Frigoribacterium* (Kämpfer et al., 2000). The whole-cell methanolysates of both species contain predominantly iso- and anteisobranched fatty acids and 1,1-dimethyl acetals. The whole-cell methanolysates of *Subtercola* species are quite similar to that of *Frigoribacterium faeni* (Table 175), but the peptidoglycan type of *Frigoribacterium* is B2β, whereas that of *Subtercola* is B2γ. The amino acid ratio in the peptidoglycan of *Subtercola* is different from that of other DAB containing genera (Table 175) in the low levels of glutamic acid. In both *Subtercola* species, nearly all of the glutamic acid residues at position 2 of the peptide subunit were replaced by hydroxyglutamic acid. The optimal growth temperatures of both species are 15–17°C. These temperatures are approximately 10 degrees, down to −2°C for *Subtercola frigoramans*, lower than those in the genera *Clavibacter* (Davis et al., 1984) and *Rathayibacter* (Zgurskaya et al., 1993). The new genus *Frigoribacterium* (Kämpfer et al., 2000), recently described and isolated from a Finnish farming environment, showed a similar growth-temperature range, whereas *Cryobacterium* (Suzuki et al., 1997) showed no growth above 18°C. A strong influence of temperature decrease was observed both for the fatty acid and dimethyl acetal compositions of *Subtercola boreus* and *Subtercola frigoramans* (Table 175).

The production of 1,1-dimethyl acetals has been observed by the methanolysis of alk-1′-enyl glyceryl ethers (plasmalogens) (Jantzen and Hofstad, 1981). These plasmalogens are known

[b]Data from Männistö et al. (2000).

[c]Data from Groth et al. (1996).

[e]Data from Kämpfer et al. (2000).

[d]Data from Suzuki et al. (1997).

[f]Data from Zgurskaya et al. (1993).

to occur as significant components of animal cell membranes and in many obligately anaerobic bacteria such as *Fusobacterium* species (Jantzen and Hofstad, 1981), clostridia (Johnston and Goldfine, 1994), *Megasphaera elsdenii* (Kaufman et al., 1990), and *Eubacterium lentum* (Verhulst et al., 1987). They are also present in the anaerobic actinobacterial species *Propionibacterium freudenreichii* and *Propionibacterium jensenii* and also in *Frigoribacterium faeni* (Kämpfer et al., 2000).

The biological function of plasmalogens is not known, but Kaufman et al. (1990) showed that membranes of *Megasphaera elsdenii* (with high plasmalogen content) were more ordered than membranes devoid of plasmalogens. This may indicate that the changes in the plasmalogen derived 1,1-dimethyl acetal composition may reflect a role in membrane liquidity.

Enrichment and isolation procedures

No specific isolation medium has been described so far. Good growth occurs on R2A agar and also PYGV agar (Staley, 1968) as well as on TS agar at 15–17°C. Growth is observed at −2°C–25°C.

Maintenance procedures

Subtercola cultures may be lyophilized by common procedures used for many bacteria. In addition, cultures can be maintained by serial transfers on solid complex media. Growth on agar slants in screw-capped tubes can be kept at 4°C for about 2–4 weeks. Long-term preservation of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

Differentiation of the genus *Subtercola* from other genera

Subtercola may be distinguished from other genera in the family *Microbacteriaceae* by cell-wall peptidoglycan, the menaquinone type, the colony pigmentation, presence of DMA, the G+C content, and the growth at low temperatures (Table 175).

List of species of the genus *Subtercola*

1. **Subtercola boreus** Männistö, Schumann, Rainey, Kämpfer, Tsitko, Tiirola and Salkinoja-Salonen 2000, 1737[VP]

bo.re′us. L. masc. adj. *boreus* Northern, referring to the boreal groundwater aquifer in Finland, from which the organism was isolated.

Cells are short, irregular rods 0.2–0.3 × 0.6–1.0 µm. Colonies are yellow pigmented, circular, convex, and smooth. Growth occurs at 2–28°C. The major cellular fatty acids are 12-methyltetradecanoic acid ($C_{15:0}$ anteiso), 14-methylpentadecanoic acid ($C_{16:0}$ iso), 14-methylhexadecanoic ($C_{17:0}$ anteiso) acid, and 13-methyltetradecanoic acid ($C_{15:0}$ iso). 1,1-Dimethoxy-iso-pentadecane ($C_{15:0}$ iso DMA), 1,1-dimethoxy-anteiso-heptadecane ($C_{17:0}$ anteiso DMA), and 1,1-dimethoxy-hexadecane ($C_{16:0}$ DMA) are found in whole-cell methanolysates. The cell wall contains glucose, rhamnose, and xylose. Other chemotaxonomic characteristics are as described for the genus. The following carbon sources are utilized: L-arabinose, D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-mannose, D-maltose, L-rhamnose, D-ribose, sucrose, D-trehalose, D-xylose, adonitol, *i*-inositol, D-mannitol, acetate, propionate, *cis*-aconitate, citrate, fumarate, DL-3-hydroxybutyrate, 3-hydroxybenzoate, and 4-hydroxybenzoate. Amino acids are mostly not utilized.

Source: groundwater.

DNA G+C content (mol%): 68 (HPLC).

Type strain: K300, ATCC BAA-168, CCUG 43135, CIP 106947, DSM 13056, JCM 11267, NBRC 103085.

Sequence accession no. (16S rRNA gene): AF224722, AM410674.

2. **Subtercola frigoramans** Männistö, Schumann, Rainey, Kämpfer, Tsitko, Tiirola and Salkinoja-Salonen 2000, 1737[VP]

fri.gor.a′mans. L. neut. n. *frigus -oris* the cold; L. part. pres. *amans* loving; N.L. part. adj. *frigoramans* loving the cold.

Cells are pleomorphic, irregular rods 0.3–0.4 × 0.9–1.5 µm. In liquid culture, the cells may show v- or y-forms. Colonies appear pale yellow to bright yellow depending on the culture medium. Large, mucoid colonies are formed on glucose-containing media. Growth occurs at −2°C to 28°C. The major cellular fatty acids are 12-methyltetradecanoic acid ($C_{15:0}$ anteiso), 14-methylpentadecanoic acid ($C_{16:0}$ iso), 14-methylhexadecanoic acid ($C_{17:0}$ iso), and 12-methyltridecanoic acid ($C_{14:0}$ iso). 1,1-Dimethoxy-anteiso-heptadecane ($C_{17:0}$ anteiso DMA) is found in whole-cell methanolysates. The cell wall contains rhamnose, ribose, xylose, and mannose. The main isoprenoid quinones are MK-10 and MK-9.

Other chemotaxonomical characteristics are the same as described for the genus. The following carbon sources are utilized: L-arabinose, *p*-arbutin, D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-mannose, D-maltose, sucrose, salicin, D-trehalose, D-xylose, adonitol, and D-mannitol. Acetate, propionate, aconitate, and most amino acids are not utilized as sole source of carbon. Fumarate, but not citrate, is assimilated.

Source: groundwater.

DNA G+C content (mol%): 64 (HPLC).

Type strain: K265, ATCC BAA-169, CCUG 43136, CIP 106948, DSM 13057, JCM 11268, NBRC 103086.

Sequence accession no. (16S rRNA gene): AF224723, AM410673.

Genus XXVI. **Yonghaparkia** Yoon, Kang, Schumann and Oh 2006b, 2418[VP]

Jung-Hoon Yoon

Yong.ha.park′i.a. N.L. fem. n. *Yonghaparkia* named after Yong-Ha Park, a Korean microbiologist who proposed the family *Microbacteriaceae* and has contributed significantly to bacterial systematics.

Cells are short rods or rods, 0.2–0.4 × 0.6–1.4 mm under optimal growth conditions. Gram-stain-positive. Nonsporeforming. Nonmotile. Strictly aerobic. The cell-wall peptidoglycan type is B2γ and contains the dipeptide D-Glu–D-2,4-diaminobutyrate (D-DAB) with Gly in position 1 and L-DAB in position 3. The predominant menaquinone is MK-12. A significant amount of MK-11 is also present. The fatty acid profile consists of branched and straight-chain fatty acids; predominant fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso.

DNA G+C content (mol%): 71.1–71.6.

Type species: **Yonghaparkia alkaliphila** Yoon, Kang, Schumann and Oh 2006b, 2418[VP].

Further descriptive information

Growth is alkaliphilic and moderately oligotrophic. The optimal pH for growth is 9.0. Growth does not occur at pH 7.0. Good growth occurs on half strength nutrient agar with the pH adjusted to 9.0, with Na_2CO_3 but growth is poor on nutrient agar and does not occur on trypticase soy agar. Growth occurs in the absence of additional NaCl. Phylogenetically, the genus *Yonghaparkia* belongs to the family *Microbacteriaceae* of the order *Micrococcales* and is phylogenetically most closely related to the genus *Microcella*.

Enrichment and isolation procedures

The type of the genus *Yonghaparkia*, *Yonghaparkia alkaliphila*, was isolated from an alkaline serpentinite soil (approximate pH 10.0) from Kwangkchun, Korea. It is not known whether members of this genus can be enriched from similar samples from other natural habitats. However, two potential species of the genus with 99.1 and 99.6% 16S rRNA gene similarity to *Yonghaparkia alkaliphila* KSL-133[T], were isolated from another alkaline soil on Luria–Bertani (LB) agar (pH 9.0) under an atmosphere of 5% CO_2 (Ueda et al., 2008). This observation supports the

view that this genus is comprised of alkalophiles. When present, *Yonghaparkia* may be isolated by standard dilution plating techniques using 2–10× diluted nutrient agar, pH 9.0–10.0.

Maintenance procedures

For short-term preservation, serial transfer on agar slants (e.g. half-strength nutrient agar, pH 9.0) is recommended. Agar slants can be stored at 4°C for at least 2 months. For long-term preservation, lyophilization, storage in liquid nitrogen, and frozen glycerol suspensions are suitable. For lyophilization, the cells are collected by centrifugation, and the cells are suspended in 20% (w/v) skim milk prior to lyophilization. For storage in liquid nitrogen, cells are harvested from agar plates by suspending in 1 ml sterile water and transferred to cryo-tubes containing 1 ml of 20% (w/v) glycerol solution. The tube is stored at −20°C or −70°C.

Differentiation of the genus *Yonghaparkia* from other genera

The genus *Yonghaparkia* is distinguished from members of the family *Microbacteriaceae* by differences in chemotaxonomic properties such as predominant menaquinone(s) and the diamino acids in their cell walls. It is distinguishable from the genera *Microcella*, *Frigoribacterium*, *Frondihabitans*, and *Mycetocola*, the closest phylogenetic neighbors, by differences of the predominant menaquinone, the fatty acid profile, and the cell-wall composition. The genus *Yonghaparkia* contains MK-12 as the predominant menaquinone, whereas the genera *Microcella*, *Frigoribacterium*, *Frondihabitans*, and *Mycetocola* contain MK-12 and MK-13, MK-9, MK-7 and MK-8, or MK-10, respectively (Table 176). Likewise, while the fatty acids abundant in the genus *Yonghaparkia* are found in other closely related genera, the profile is readily distinguishable from that of the genera *Microcella*, *Frigoribacterium*, *Frondihabitans*, and *Mycetocola* (Table 176). The genus *Yonghaparkia* is further distinguished by cell walls containing 2,4-diaminobutyric acid (DAB) as the diamino acid in position 3 of the peptidoglycan. In contrast, cell walls of the genera *Microcella*, *Frigoribacterium*, and *Mycetocola* and the genus *Frondihabitans* contain lysine and D-ornithine, respectively (Table 176). The genus *Yonghaparkia* is further differentiated from the above-mentioned genera by some other phenotypic characteristics which are listed in Table 176. Although the genus *Yonghaparkia* is similar to the genus *Agromyces* in the chemotaxonomic properties, it forms an independent lineage in the phylogenetic tree based on 16S rRNA gene sequences.

TABLE 176. Phenotypic characteristics differentiating *Yonghaparkia* and some phylogenetically related genera of the family *Microbacteriaceae*[a]

[a]Symbols: +, positive; –, negative; v, variable (results for the type strain of the type species are in parentheses); nd, not determined. All genera are positive for Gram stain and catalase activity.

[b]Data from Yoon et al. (2006b).

[c]Data from Dastager et al. (2008a); Suzuki et al. (1997); and Zhang et al. (2007b).

[d]Data from Dastager et al. (2008d) and Kämpfer et al. (2000).

[e]Data from Greene et al. (2009) and Zhang et al. (2007c).

[f]Data from Lee (2007).

[g]Data from Tiago et al. (2006, 2005b).

[h]Data from Bora et al. (2008) and Tsukamoto et al. (2001).

[i]$C_{15:0}$ anteiso DMA, 1,1-dimethyl-anteiso-pentadecane.

[j]Though reported in the original description to be present along with $C_{14:0}$ 2-OH (Zhang et al., 2007c), it is most likely that the fatty acid data were not obtained from the same bacterium which was also subjected to the other examinations for characterization and then described as *Frondihabitans australicus.* The fatty acid profile suggests no affiliation of the corresponding bacterium with the *Microbacteriaceae* but with the Gram-negative family *Sphingomonadaceae* within the *Alphaproteobacteriaceae.* So far, all taxa of the *Microbacteriaceae* were reported to contain predominantly iso- and anteiso-methylbranched fatty acids and most of them contain $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso fatty acids as the major compounds. No other taxon except *Frondihabitans* was reported to contain $C_{18:1}$ ω7*c*.

List of species of the genus *Yonghaparkia*

1. **Yonghaparkia alkaliphila** Yoon, Kang, Schumann and Oh 2006b, 2418[VP]

al.ka.li′phi.la. N.L. n. *alkali* alkali; N.L. fem. adj. *phila* (from Gr. fem. adj. *philê*) loving; N.L. fem. adj. *alkaliphila* loving alkaline conditions.

Cells are short rods or rods, 0.2–0.4 × 0.6–1.4 mm, under optimal growth conditions. Gram-stain-positive. Nonspore-forming. Nonmotile. Strictly aerobic. Colonies are circular, slightly convex, smooth, glistening, yellow in color, and 1.5–2.0 mm in diameter after incubation for 10 d at 30°C on one-half strength nutrient agar, pH 9.0. Growth occurs at 10 and 37°C, but not at 4 and 38°C. Optimal pH for growth is 9.0. Growth occurs at 0–2% (w/v) NaCl, with an optimum at 1% but not at 3% NaCl. Growth does not occur under anaerobic conditions on half-strength nutrient agar (pH 9.0) in the absence or presence of 0.1% nitrate (w/v). Urease-negative. Starch and Tween 40 are hydrolyzed. Hypoxanthine, xanthine, L-tyrosine, Tween 20, Tween 60, and Tween 80 are not hydrolyzed. Nitrate is not reduced to nitrite. In assays with the API ZYM system, esterase (C 4), esterase lipase (C 8), leucine arylamidase, β-glucuronidase, and α-glucosidase are present, but alkaline phosphatase, lipase (C 14), valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase α-galactosidase, β-galactosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are absent. Acetate, succinate, benzoate, L-malate, formate, and L-glutamate are not utilized as sole carbon and energy sources. Utilization of salicin is variable (positive for type strain). Susceptible to polymyxin B, streptomycin, chloramphenicol, gentamicin, novobiocin, lincomycin, oleandomycin, neomycin, and carbenicillin, but not to penicillin G, ampicillin, tetracycline, and kanamycin. The major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. The major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, unidentified phospholipids, and unidentified glycolipids.

Source: an alkaline soil.

DNA G+C content (mol%): 71.1–71.6 (HPLC).

Type strain: KSL-113, CIP 108920, JCM 15138, KCTC 19126.

Sequence accession no. (16S rRNA gene): DQ256087.

Family XII. **Promicromonosporaceae** Rainey, Ward-Rainey and Stackebrandt 1997, 484[VP] emend. Zhi, Li and Stackebrandt 2009, 598

Peter Schumann and Erko Stackebrandt

Pro.mi.cro.mo.no.spo.ra.ce′a.e. N.L. fem. n. *Promicromonospora* type genus of the family; L. suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Promicromonosporaceae* the *Promicromonospora* family.

The pattern of 16S rRNA gene sequence signatures consists of nucleotides at positions: 120 (A), 131:231 (A–G), 196 (U), 342:347 (C–G), 444:490 (A–U), 580:761 (C–G), 602:636 (G–U), 670:736 (A–U), 822:878 (G–C), 823:877 (G–C), 826:874 (C–G), 827 (U), 843 (U), 950:1231 (U–A), 1047:1210 (G–C), 1109 (C), 1145 (G), 1309:1328 (G–C), 1361 (G), and 1383 (C). Chemotaxonomically, the family is defined by peptidoglycan type A4α, MK-9(H_4) as predominant menaquinone and iso- and anteiso-branched cellular fatty acids. The family *Promicromonosporaceae* belongs to the order *Micrococcales* (formerly suborder *Micrococcineae* Rainey, Ward-Rainey and Stackebrandt (1997) of the class *Actinobacteria* Stackebrandt, Rainey and Ward-Rainey (1997).

Type genus: **Promicromonospora** Krasil'nikov, Kalakoutskii and Kirillova 1961, 107[AL].

Taxonomic comments

The family *Promicromonosporaceae* Rainey, Ward-Rainey and Stackebrandt (1997) was established to accommodate *Promicromonospora* as the only genus because of its distinct phylogenetic position within the suborder *Micrococcineae* and the presence of a taxon-specific set of 16S rRNA signature nucleotides (Stackebrandt et al., 1997). This pattern has been revised in view of novel members added to the family (Zhi et al., 2009). Taxonomic investigations of cellulolytic and xylanolytic isolates and reclassifications of validly named species have resulted in the proposals of six additional genera of this family: *Cellulosimicrobium* (Schumann et al., (2001), emend. Brown et al., 2006), *Isoptericola* (Stackebrandt et al., 2004), *Myceligenerans* (Cui et al., 2004), *Xylanibacterium* (Rivas et al., 2004), *Xylanimicrobium* (Stackebrandt and Schumann, 2004), and *Xylanimonas* (Rivas et al., 2003). The chemotaxonomic properties characterizing these genera are indicated in Table 177. Many of the representatives of the family can degrade polysaccharides such as cellulose or xylan. A phylogenetic dendrogram of members of the family *Promicromonosporaceae* is shown in Figure 202.

Genus I. **Promicromonospora** Krasil'nikov, Kalakoutskii and Kirillova 1961, 107[AL]

Peter Schumann and Erko Stackebrandt

Pro.mi.cro.mo.no.spo′ra. Gr. pref. *pro* before, primitive; Gr. adj. *mikros* small; Gr. adj. *monos* single, solitary; Gr. fem. n. *spora* a seed, and in microbiology a spore; N.L. fem. n. *Promicromonospora* the genus name was coined to reflect the combination of traits then thought to be characteristic of the actinomycete form-genera "*Proactinomyces*" (the tendency of the mycelium to fragment) and *Micromonospora* (the formation of single spores on the substrate mycelium).

Branching septate **hyphae** (0.5–1.0 µm in diameter) growing on the surface of and penetrating into the agar, which **break up into fragments** of various size and shape. Fragmentation results in **nonmotile**, Y- or V-shaped, rodlike, coccoid, chlamydospore-like, and other spore-shaped elements. All of them may give rise to new mycelia. **Growth pasty to leathery**. Aerial hyphae in different strains may vary in abundance (sometimes discernible only microscopically). These are straight to curved, sometimes sparsely branched, usually fragmented into rodlike or elongated coccoid elements. **Gram-stain-positive, non-acid-fast, catalase-positive. Aerobic.** Chemo-organotrophic. Glucose metabolized oxidatively, rarely also fermentatively. **Mesophilic. Peptidoglycan type A4α, variation L-Lys←L-Ala←D-Glu**. Mycolic acids and wall teichoic acids are lacking. Branching fatty acids of the iso- and anteiso- types ($C_{15:0}$ iso and $C_{15:0}$ anteiso) predominate. Diagnostic phospholipids are represented by phosphatidylglycerol and an unidentified glucosamine-containing phospholipid. Major **menaquinone** is **MK-9(H_4)**. Mainly found in soils. The genus *Promicromonospora* is the type genus of the family *Promicromonosporaceae* of the order *Micrococcales*, class *Actinobacteria*.

DNA G+C content (mol%): 70–75 (T_m).

Type species: **Promicromonospora citrea** Krasil'nikov, Kalakoutskii and Kirillova 1961, 107[AL].

Further descriptive information

The genus *Promicromonospora* was established by Krasil'nikov et al. (1961) to harbor at that time the only species *Promicromonospora citrea* which embraced approximately 30 soil isolates. Six additional species were described later, *Promicromonospora enterophila* (Jáger et al., 1983), *Promicromonospora sukumoe* (Takahashi et al., 1987), *Promicromonospora pachnodae* (Cazemier et al., 2003), *Promicromonospora aerolata* (Busse et al., 2003), *Promicromonospora vindobonensis* (Busse et al., 2003), and *Promicromonospora kroppenstedtii* (Alonso-Vega et al., 2008). Two of them (*Promicromonospora enterophila* and *Promicromonospora pachnodae*) have been reclassified as species of other genera (see *Taxonomic comments*). Members of the genus *Promicromonospora* are characterized by the development of mycelia which fragment into nonmotile, coccoid, Y- or V-shaped, rod-like, diphtheroid or chlamydospore-like elements. Aerial

TABLE 177. Differential characteristics of members of the family *Promicromonosporaceae*[a,b]

Characteristic	*Promicromonospora* species	*Xylanimicrobium pachnodae* DSM 12657^T	*Xylanibacterium ulmi* XIL08^T	*Xylanimonas cellulosilytica* XIL07^T	*Isoptericola* species	*Myceligenerans* species	*Cellulosimicrobium* species

[a]Abbreviations and symbols: Ara, arabinose; Gal, galactose; Rha, rhamnose; Fuc, fucose; Man, mannose; Glc, glucose; Xyl, xylose; PG, phosphatidylglycerol; DPG, diphosphatidylglycerol; PI, phosphatidylinositol; PIM, phosphatidylinositol mannosides; PL, unknown phospholipid; PGL, unknown phosphoglycolipid; GL, unknown glycolipid; –, negative; w, weak; +, positive; nd, not determined.

[b]Data from Rivas et al. (2003), Rivas et al. (2004), Busse et al. (2003), Stackebrandt and Schumann (2004), Cui et al. (2004), Stackebrandt et al. (2004), Zhang et al. (2005), Groth et al. (2005), Groth et al. (2006) and Yoon et al. (2006).

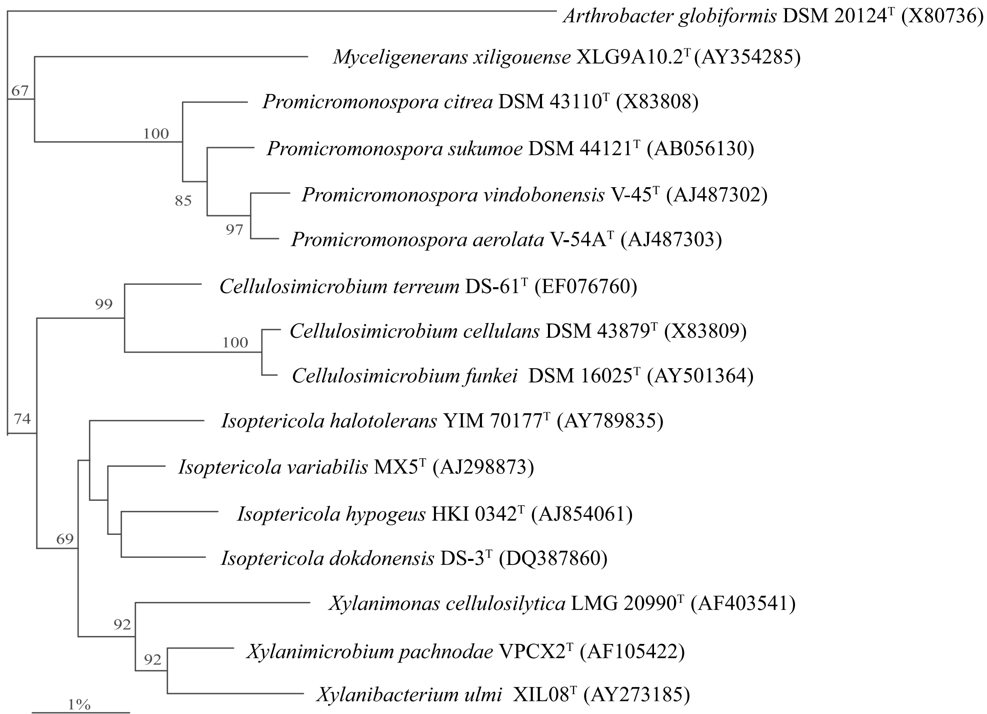

FIGURE 202. Distance matrix dendrogram of 16S rRNA gene sequence relationship (DeSoete, 1983), displaying the relatedness of members of the family *Promicromonosporaceae*. Bar = 1 inferred nucleotide change per 100 substitutions. Numbers at branch points are bootstrap values (500 resamplings) (Felsenstein, 1985). The sequence of *Arthrobacter globiformis* served as the root for the dendrogram.

hyphae are produced after 2–4 d and are straight to curved and only sparsely branched or not branched at all. The length of hyphae, the extent of branching, and the tendency to fragmentation depend on the media and cultivation conditions but are also strain-specific. The aerial hyphae are usually sparse and short, and only a few strains produce distinct aerial mycelium.

Fragmentation may begin after 8 h of cultivation and occurs preferably in shaken liquid cultures of complex media but to a lesser extent on mineral salt agar media. Spore-shaped elements, observed for *Promicromonospora citrea* in solid surface cultures, were often located at the end of short side branches (Krasil'nikov et al., 1961). Chlamydospore-like forms were observed for *Promicromonospora kroppenstedtii* (Alonso-Vega et al., 2008). The formation of monospores by *Promicromonospora citrea* could not be confirmed by Lechevalier and Lechevalier (1981) and spores were not reported for *Promicromonospora aerolata*, *Promicromonospora sukumoe*, and *Promicromonospora vindobonensis* (Busse et al., 2003; Takahashi et al., 1987).

Ambiguous data about the peptidoglycan structure of members of the genus *Promicromonospora* have been reported in the literature. Evtushenko et al. (1984) reported the peptidoglycan type A4α Lys←Ala←Glu, whereas Stackebrandt et al. (1983) found a molar ratio of amino acids which suggested the type A3α Lys←Ala←Ala for *Promicromonospora citrea*. Busse et al. (2003) proposed the peptidoglycan type A3α Lys←Gly←Ala for *Promicromonospora aerolata* and *Promicromonospora vindobonensis*, and only the occurrence of lysine and the absence of glycine and aspartic acid were reported for *Promicromonospora sukumoe* (Takahashi et al., 1987). The reinvestigation of the peptidoglycan structure of all present members of the family *Promicromonosporaceae* by supplementing the methods of Schleifer (1985) with gas-chromatographic and mass spectrometric techniques (MacKenzie, 1984, 1987) revealed that all members display the peptidoglycan type A4α and that the type strains of *Promicromonospora citrea*, *Promicromonospora aerolata*, *Promicromonospora sukumoe*, and *Promicromonospora vindobonensis* all display the peptidoglycan type A4α L-Lys←L-Ala←D-Glu (Schumann et al., 2004). Analytical data reported for *Promicromonospora kroppenstedtii* (Alonso-Vega et al., 2008) suggest the occurrence of the same peptidoglycan structure.

Colonies vary from yellow to white in color and are usually concave to wrinkled, but some strains may also have smooth and pasty colonies.

Strains of the genus *Promicromonospora* grow under aerobic conditions at 28–30°C on organic medium 79 (Prauser and Falta, 1968; 10 g of glucose, 10 g of Bacto peptone, 2 g of Casamino acids, 2 g of yeast extract, 6 g of NaCl, 15 g of agar, and 1000 ml of tap water, pH 7.5), Czapek peptone agar (30.00 g of sucrose, 3.00 g of $NaNO_3$, 1.00 g of K_2HPO_4, 0.50 g of $MgSO_4 \cdot 7H_2O$, 0.50 g of KCl, 0.01 g of $FeSO_4 \cdot 7H_2O$, 2.00 g of yeast extract, 5.00 g of peptone, 15.00 g of agar, and 1000 ml of distilled water, pH 7.3), trypticase soy yeast extract medium (30.0 g of trypticase soy broth, 3.0 g of yeast extract, 15.0 g of agar, and 1000 ml of distilled water pH 7.0–7.2), or yeast starch agar (15.0 g of soluble starch, 4.0 g of yeast extract, 0.5 g of K_2HPO_4, 0.5 g of $MgSO_4 \cdot 7H_2O$, 15.0 g of agar, and 1000 ml of distilled water, pH 7.4).

Four phages are available which cause true lysis and/or clearing effects on strains of *Promicromonospora citrea* and *Promicromonospora sukumoe* (Stackebrandt and Prauser, 1991): P1 (=DSM 49141), P2 (=DSM 49106), P3 (=DSM 49107), and P4 (=DSM 49108). *Promicromonospora citrea* strains are not susceptible to any other phages, including those specific for *Oerskovia* species, nocardioforms, and sporoactinomycetes. None of the *Promicromonospora* phages were effective against strains of other taxa investigated at that time (Prauser, 1984; Prauser and Falta, 1968). The phage susceptibility of *Promicromonospora* species other than *Promicromonospora citrea* and *Promicromonospora sukumoe* have not been examined yet.

Members of the genus *Promicromonospora* were mainly isolated from soils or from air and were considered nonpathogenic. The susceptibility of *Promicromonospora citrea* and *Promicromonospora sukumoe* to antimicrobial agents was reported by Takahashi et al. (1987).

Promicromonospora citrea, *Promicromonospora aerolata*, *Promicromonospora sukumoe*, *Promicromonospora vindobonensis*, and *Promicromonospora kroppenstedtii* share approximately 99% 16S rRNA gene sequence similarity (Alonso-Vega et al., 2008; Busse et al., 2003). The ranges of DNA–DNA similarity values between *Promicromonospora vindobonensis* and *Promicromonospora citrea*, *Promicromonospora aerolata*, and *Promicromonospora sukumoe* are below 55%, while those between *Promicromonospora aerolata* and *Promicromonospora citrea*, *Promicromonospora vindobonensis*, and *Promicromonospora sukumoe* are below 48% (Busse et al., 2003). Species of the genus *Promicromonospora* cannot be differentiated unambiguously by chemotaxonomic characteristics such as major menaquinone, cellular fatty acid profile, polar lipids (Busse et al., 2003), and peptidoglycan structure (Schumann et al., 2004). *Promicromonospora sukumoe* differed from the other species in having a lower concentration of major polyamines (Busse et al., 2003). *Promicromonospora sukumoe* is the only member of the genus for which the production of an antibiotic (7-hydro-8-methylpteroylglutamylglutamic acid; Murata et al., 1987) was reported. The type strains of all five *Promicromonospora* species can clearly be differentiated by their metabolic profiles (Alonso-Vega, et al., 2008; Busse et al., 2003; see Table 178). Owing to the application of different test methods and non-standardized criteria for evaluation of results, some of the reported physiological data differ between laboratories (Alonso-Vega et al., 2008; Busse et al., 2003; Kalakoutskii et al., 1986; Takahashi et al., 1987).

Enrichment and isolation procedures

The strains of *Promicromonospora citrea*, *Promicromonospora sukumoe*, and *Promicromonospora kroppenstedtii* were isolated from soils or aluminum hydroxide gel antacid (Alonso-Vega et al., 2008; Lechevalier, 1972; Takahashi et al., 1987). Among the various isolation media were several kinds of soil extract agar, oatmeal agar, and peptone-corn extract agar (Kalakoutskii et al., 1986). The growth of contaminating bacilli and hyphal fungi can be successfully suppressed by supplementing the isolation media with nalidixic acid (20–50 mg/l) and cycloheximide (50 mg/l) since promicromonosporae are not susceptible to these compounds. The use of double-layer agar plates is recommended for isolation (Stackebrandt and Prauser, 1991). *Promicromonospora aerolata* and *Promicromonospora vindobonensis* were isolated as airborne bacteria using an air-sampler and subcultivation on PYES agar (Zlamala et al., 2002).

Maintenance procedures

For preservation, cells are serially transferred at 3-month intervals, maintained at 4°C, and stored as 20% (w/v) glycerol suspensions at −20°C and at −80°C. Long-term preservation methods are freeze drying in skim milk and maintenance in liquid nitrogen at −196°C.

Procedures for testing special characters

Since the application of other methods for determination of the peptidoglycan structure of members of the genus *Promicromonospora* lead in some cases to unambiguous results, the procedure of Schleifer (1985) in combination with methods for quantitative amino-acid analysis (e.g. the method of MacKenzie (1987) is recommended.

Differentiation of the genus *Promicromonospora* from other genera

Authentic members of the genus *Promicromonospora* represent a distinct cluster within the phylogenetic tree of the family *Promicromonosporaceae* (Figure 203). The genus *Promicromonospora* can be differentiated from all other genera of its family except *Xylanibacterium* by the occurrence of the peptidoglycan type A4α, variation A4α L-Lys←L-Ala←D-Glu (see the family *Promicromonosporaceae*, above). *Promicromonospora* strains show a nocardioform life cycle and differ from the type strain of *Xylanibacterium* by occurring invariably as small rods that have catalase activity and lack phosphatidylinositol mannosides.

Taxonomic comments

The family affiliation of the nocardioform actinomycete genus *Promicromonospora* has caused problems during the pre-molecular era of bacterial systematics, and the genus has been regarded as "in search of a family" (Lechevalier and Lechevalier, 1981). The genus *Promicromonospora* was considered a relative of the genera *Cellulomonas* and *Oerskovia* because of common chemotaxonomic characteristics such as menaquinone MK-9(H_4), iso/anteiso branched chain fatty acids, and similarity with *Oerskovia* spp. in the occurrence of lysine in the peptidoglycan and a nocardioform life cycle (Prauser, 1986). As a consequence of a phylogenetic study (Stackebrandt et al., 1983), the genus *Promicromonospora* was united with these two genera and the genus *Jonesia* in the family *Cellulomonadaceae* (Stackebrandt and Prauser, 1991). Later, the genus *Jonesia* was excluded from the family *Cellulomonadaceae* on the basis of obvious differences in chemotaxonomic characteristics and 16S rRNA gene sequence data (Rainey et al., 1995), and in the present volume it is classified in its own family, *Jonesiaceae*. The occurrence of a characteristic set of 16S rRNA signature nucleotides revealed that the genus *Promicromonospora* represents a family of its own, the family *Promicromonosporaceae* (Stackebrandt et al., 1997). Whereas the species *Promicromonospora citrea*, *Promicromonospora aerolata*, *Promicromonospora kroppenstedtii*, *Promicromonospora sukumoe*, and *Promicromonospora vindobonensis* form a well distinguished cluster within the phylogenetic tree of the family *Promicromonosporaceae* (Figure 203), the species *Promicromonospora enterophila* and

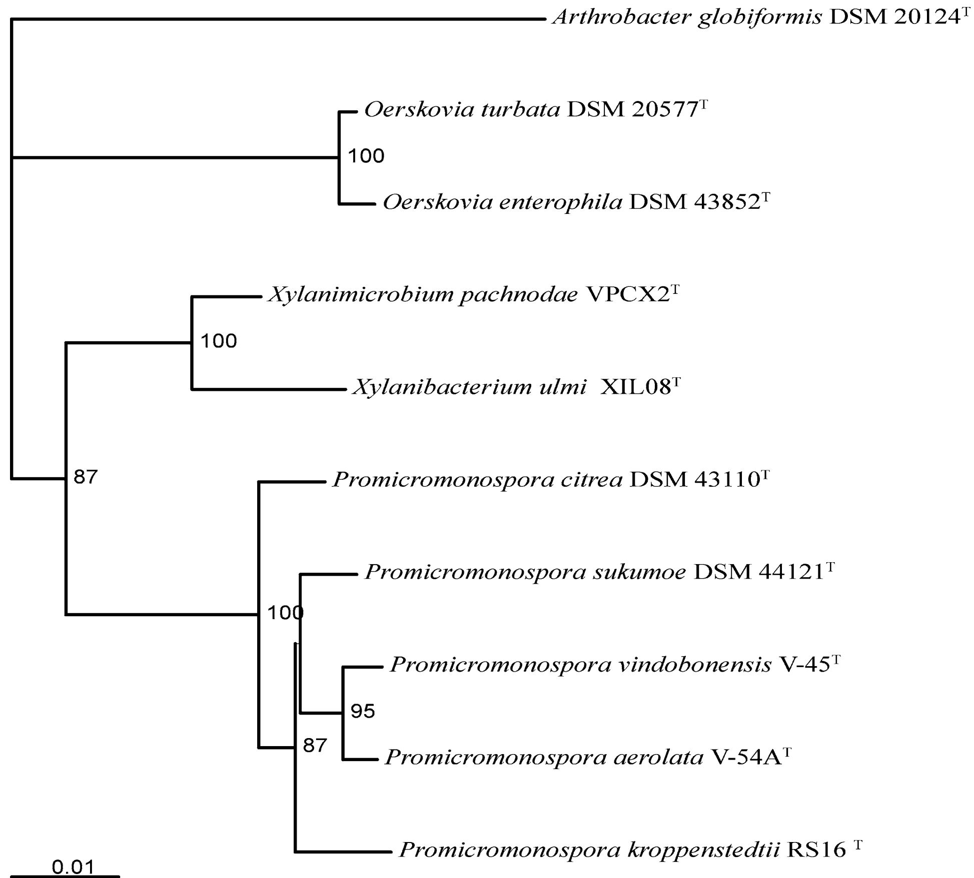

FIGURE 203. 16S rRNA gene sequence neighbor joining tree (Felsenstein, 1993) of *Promicromonospora citrea*, *Promicromonospora aerolata*, *Promicromonospora kroppenstedtii*, *Promicromonospora sukumoe*, *Promicromonospora vindobonensis*, *Oerskovia* (*Promicromonospora*) *enterophila*, *Xylanimicrobium* (*Promicromonospora*) *pachnodae*, and related species, represented by their type strains. Bootstrap values (>80%) of 1000 resamplings (Felsenstein, 1985) are indicated at nodes. *Arthrobacter globiformis* served as the root. Bar = 1 nt substitution per 100 nt.

Promicromonospora pachnodae (shown as *Oerskovia enterophila* and *Xylanimicrobium pachnodae*, respectively) represent separate phylogenetic lineages (Figure 203). The species *Promicromonospora enterophila* (Jáger et al., 1983) was already considered a species *incertae sedis* by Kalakoutskii et al. (1986) because of its susceptibility to *Oerskovia*- rather than to *Promicromonospora*-specific phages, occurrence of threonine in the peptidoglycan, lack of aerial mycelium, motility of two strains, and colony appearance (Prauser, 1986). On the basis of phylogenetic and chemotaxonomic evidence, *Promicromonospora enterophila* was reclassified as member of the emended genus *Oerskovia*, as *Oerskovia enterophila* (Stackebrandt et al., 2002).

The species *Promicromonospora pachnodae* (Cazemier et al., 2003) did not develop aerial hyphae, showed only 95.8–96.7% 16S rRNA gene sequence similarity (calculated by using the EzTaxon server; Chun et al., 2007) to authentic species of the genus *Promicromonospora*, and differed from them in its peptidoglycan type A4α, variation L-Lys←L-Ser←D-Glu. Since *Promicromonospora pachnodae* differed from its closest phylogenetic neighbor *Xylanibacterium ulmi* (98.5% 16S rRNA gene sequence similarity) in the composition of the peptidoglycan and in additional chemotaxonomic characteristics as well as in morphology, the new genus *Xylanimicrobium* was established and *Promicromonospora pachnodae* was reclassified as *Xylanimicrobium pachnodae* (Stackebrandt and Schumann, 2004).

Stackebrandt, E., P. Schumann and H. Prauser. 2006. The family *Cellulomonadaceae*. *In* The Prokaryotes: a Handbook on the Biology of Bacteria, 3rd edn, vol. 3, *Archaea*, *Bacteria*, *Firmicutes*, Actinomycetes (edited by Dworkin, Falkow, Rosenberg, Schleifer and Stackebrandt). Springer, New York, pp. 983–1001.

List of species of the genus *Promicromonospora*

1. **Promicromonospora citrea** Krasil'nikov, Kalakoutskii and Kirillova 1961, 107[AL]

ci'tre.a. L. fem. adj. *citrea* of or pertaining to the citron-tree; intended to mean lemon-yellow.

In addition to the properties given in the genus description and in Table 178, this species has the following characteristics. Life cycle nocardioform; primary and aerial hyphae fragmenting. Colors of colonies on oatmeal agar and inorganic salts-starch agar citron-yellow or white to whitish; on peptone-corn extract agar citron-yellow or cream; on the latter media in exceptional cases brown to orange-brown.

Aerial hyphae are only microscopically visible in some strains, but well developed in others; in the latter case these are thin, white, and chalky.

Optimal temperature 28°C; growth occurs between 6°C and 42°C. The following features were found to be of value in presumptive differentiation of *Promicromonospora citrea* from related strains: utilization of malate, malonate, and succinate; production of acid from rhamnose and raffinose, and absence of clearing zones on yeast-peptone agar with $CaCO_3$.

Susceptible to taxon-specific phages.

Source: mainly from soil, also found on aluminum hydroxide gel antacid.

DNA G+C content (mol%): >70 (T_m; strain VKM Ac 665^T); 73.6 (Evtushenko et al., 1984).

Type strain: ATCC 15908, DSM 43110, NBRC 12397, INMI 18, JCM 3051, KCC A 0051, LMG 4076, NRRL B-3485, RIA 562, VKM Ac-665.

Sequence accession no. (16S rRNA gene): X83808.

2. **Promicromonospora aerolata** Busse, Zlamala, Buczolits, Lubitz, Kämpfer and Takeuchi 2003, 1505[VP]

a.e.ro.la'ta. Gr. n. *aer aeros* air; L. part. adj. *latus, -a, -um* carried; N.L. part. fem. adj. *aerolata* airborne.

In addition to the properties given in the genus description and in Table 178, this species has the following characteristics. Cells show branching hyphae that are 0.3–0.5 µm in diameter after 18 h of growth on PY agar. After 3 d of growth, the mycelium fragments into nonmotile, Y- or V-shaped, rod-like, coccoid elements, 0.3–0.5 × 0.6–1.5 µm. No sessile, oval spores, chlamydospore-like or other spore-like elements are observed. Colonies are light yellow, translucent, and reach approx. 1 mm in diameter. Cell-wall sugars are glucose, galactose, and rhamnose. Diphosphatidylglycerol, phosphatidylglycerol, two unknown glycolipids, two unknown phosphoglycolipids, and one unknown phospholipid are present in the polar lipid profile. $C_{16:0}$ and $C_{17:0}$ anteiso are present in moderate amounts. Spermidine is the predominant cellular polyamine and spermine is present in moderate amounts.

Source: air in the "Virgilkapelle" chapel in Vienna.

DNA G+C content (mol%): 70 (HPLC).

Type strain: V54A, NBRC 16526, CCM 7043, DSM 15943, JCM 14119.

Sequence accession no. (16S rRNA gene): AJ487303.

3. **Promicromonospora kroppenstedtii** Alonso-Vega, Santamaría, Martínez-Molina and Trujillo 2008, 1480[VP]

krop.pen.stedt'i.i. N.L. gen. masc. n. *kroppenstedtii* of Kroppenstedt, named in honor of Reiner M. Kroppenstedt for his valuable contribution to the chemotaxonomy and systematics of actinobacteria.

Gram-stain-positive, aerobic, chemo-organotrophic actinobacterium. Colonies are cream to yellow in ISP 2, Bennett's, and nutrient agar. Well developed branched septate hyphae that break into nonmotile, V and Y forms. Chlamydospores observed in ISP 2 broth. Aerial mycelium or diffusible pigments are not observed. Temperature growth range 12–37°C with an optimum at 28°C. Oxidase- and catalase-positive. NaCl tolerance up to 8%. Other physiological characteristics are described in Table 178. The peptidoglycan contains alanine, glutamic acid, and lysine. Cell-wall sugars galactose and rhamnose are present. The main menaquinone component is MK-9(H_4), in addition RS16^T also contains MK-8(H_4). The polar lipid pattern includes phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol. Major fatty acids are $C_{15:0}$, $C_{15:0}$ iso, and $C_{16:0}$ iso.

Source: sandy soil.

DNA G+C content (mol%): 70.8 (HPLC).

Type strain: RS16, DSM 19349, LMG 24382.

Sequence accession no. (16S rRNA gene): AM709608.

4. **Promicromonospora sukumoe** Takahashi, Tanaka, Iwai and Ōmura 1988, 449[VP] (Effective publication: Takahashi, Tanaka, Iwai and Ōmura 1987, 512.)

su.ku'mo.e. N.L. fem. adj. *sukumoe* (*sic*) of or belonging to Sukumo City, Kochi Prefecture in Japan, where the soil sample was collected from which strain SK-2049^T was isolated.

In addition to the properties given in the genus description and in Table 177, this species has the following characteristics. Grows well on synthetic and organic agar media under aerobic conditions. Filamentous. The substrate mycelia fragment into bacillary and coccoid elements. Poor aerial mycelia without spores are produced on a few agar media. In general, the colonies are yellow in color; leathery on synthetic media, but bacteroid on organic ones. No growth occurs under anaerobic conditions.

The characteristic whole cell sugars are glucose, ribose, and rhamnose. Phospholipids are of the P I or P IV type. Mycolic acids are absent. The *N*-acylmuramic acid in the cell wall is of the acetyl type.

Soluble pigments and melanins are not produced. Nitrate reduction is positive. The range of growth temperature is 10–35°C.

Source: soil.

DNA G+C content (mol%): not available.

Type strain: SK-2049, JCM 6845, NBRC 14650, DSM 44121, JCM 6845, VKM Ac-1966.

Sequence accession no. (16S rRNA gene): AB023375.

4. **Promicromonospora vindobonensis** Busse, Zlamala, Buczolits, Lubitz, Kämpfer and Takeuchi 2003, 1505[VP]

vin.do.bo.nen'sis, L. fem. adj. *vindobonensis* of Vindobona, the Roman name for Vienna, where the type strain was isolated.

In addition to the properties given in the genus description and in Table 177, this species has the following characteristics. Cells show branching hyphae that are 0.3–0.5 µm in diameter after 18 h of growth on PY agar. After 3 d of growth,

the mycelium fragments into nonmotile, Y- or V -shaped, rod-like, coccoid elements, 0.3–0.5 × 0.6–1.5 μm. No sessile spores, oval spores, chlamydospore-like elements, or other spore-like elements are observed. On PY agar, colonies are whitish, translucent, convex, glistening, and approx. 1 mm in diameter with an entire edge. Cell-wall sugars are glucose, galactose, and rhamnose. Diphosphatidylglycerol, phosphatidylglycerol, two unknown glycolipids, three unknown phosphoglycolipids, one unknown phospholipid, and one unknown polar lipid are present in the polar lipid profile. $C_{16:0}$ and $C_{17:0}$ anteiso are present in moderate amounts. Spermidine is the predominant cellular polyamine and spermine is present in moderate amounts.

Source: air in the "Virgilkapelle" chapel in Vienna.

DNA G+C content (mol%): 70 (HPLC).

Type strain: V45, NBRC 16525, CCM 7044, DSM 15942, JCM 14120.

Sequence accession no. (16S rRNA gene): AJ487302.

Genus II. **Cellulosimicrobium** Schumann, Weiss and Stackebrandt 2001, 1009[VP] (emend. Brown, Steigerwalt, Morey, Daneshvar, Romero and McNeil 2006, emend. Yoon, Kang, Schumann and Oh 2007)

Peter Schumann and Erko Stackebrandt

Cel.lu.lo.si.mi.cro′bi.um. N.L. n. *cellulosum* cellulose; N.L. neut. n. *microbium*, microbe; N.L. neut. n. *Cellulosimicrobium* cellulose microbe.

Gram-stain-positive, but cells are very readily decolorized. In young cultures, a substrate mycelium is produced which fragments later into irregular, curved, and club-shaped rods which may be arranged in V forms. After exhaustion of the medium, the rods are transformed into shorter rods or even spherical cells. Do not form endospores. Not acid-fast. Motile or nonmotile. Chemo-organotrophic; metabolism respiratory and facultatively anaerobic. Acid produced from several carbohydrates. Catalase positive. Nitrate reduction is positive or negative. **Cellulolytic**. **Peptidoglycan contains L-lysine; the interpeptide bridge consists of D-Ser–D-Asp or L-Thr–D-Asp, type A4α. Major menaquinone is MK-9(H_4), and predominating fatty acids are $C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso.** Whole-cell sugars are galactose, rhamnose, glucose, fucose, and mannose or galactose and ribose; one type strain contains only galactose. Phylogenetically, a member of the family *Promicromonosporaceae.*

DNA G+C content (mol%): 72.9–76.5 (T_m).

Type species: **Cellulomicrobium cellulans** (Metcalfe and Brown 1957) Schumann, Weiss and Stackebrandt, 2001, 1009[VP] (*Nocardia cellulans* Metcalfe and Brown 1957).

The description is based on the description of the species *Nocardia cellulans* DSM 43879[T] (Schumann et al., 2001; Stackebrandt et al., 1980), *Cellulomonas cartae* (Stackebrandt and Kandler, 1980), considered a subjective synonym of *Cellulomonas cellulans* (Stackebrandt and Keddie, 1986), basonym *Nocardia cellulans* and on the descriptions of *Cellulosimicrobium funkei* (Brown et al., 2006) and *Cellulosimicrobium terreum* (Yoon et al., 2007). The fatty acid composition has been determined by Funke et al. (1995) for *Oerskovia xanthineolytica* CIP 81.28.

Further descriptive information

The observation that *Cellulomonas cellulans* clustered outside the genus *Cellulomonas* as revealed by phylogenetic comparison of 16S rRNA gene sequences of the current members of the order *Micrococcales* and the detection of its peptidoglycan type A4α (instead of type A4β as in *Cellulomonas* species), led to the proposal of the new genus *Cellulosimicrobium* and reclassification of *Cellulomonas cellulans* as *Cellulosimicrobium cellulans* (Schumann et al., 2001). The closest phylogenetic neighbors of *Cellulosimicrobium cellulans* are strains of *Cellulosimicrobium funkei* (Brown et al., 2006) sharing 99.5–99.8% 16S rRNA gene sequence similarities. The intraspecies relatedness of strains of *Cellulosimicrobium funkei*, determined by the hydroxyapatite method of DNA–DNA reassociation, ranges between 76% and 79%; the gene sequence similarities of these strains range between 99.9% and 100%. The type strains of *Cellulosimicrobium cellulans* and *Cellulosimicrobium funkei* share 47% DNA–DNA similarity (Brown et al., 2006).

Phylogenetic neighbors of *Cellulosimicrobium* are the genera *Isoptericola*, *Xylanimonas*, *Xylanimicrobium*, and *Xylanibacterium* of the family *Promicromonosporaceae* (see Figure 202 in the chapter on *Xylanimicrobium*). Members of the genus *Cellulosimicrobium* form a primary mycelium which fragments into irregular, curved, and club-shaped rods. Rods are transformed into shorter rods or even spherical cells after exhaustion of the medium. Cells of *Cellulosimicrobium funkei* are motile by one to five polar and/or lateral flagella (Sottnek et al., 1977), whereas *Cellulosimicrobium cellulans* is nonmotile (Schumann et al., 2001). The peptidoglycan of members of the genus *Cellulosimicrobium* is of the type A4α, variation L-Lys←D-Ser←D-Asp (A11.37 according to http://www.peptidoglycan-types.info). *Cellulosimicrobium cellulans* contains galactose, rhamnose, glucose, fucose, and mannose (Stackebrandt et al., 2004) whereas galactose is the only whole-cell sugar in *Cellulosimicrobium funkei* (Brown et al., 2006). On peptone-yeast extract-glucose agar, the colonies of *Cellulosimicrobium cellulans* are circular, convex, yellow-whitish, and glistening with entire edges. On other media, colonies of *Cellulosimicrobium cellulans* are cream in color (Metcalfe and Brown, 1957). On trypticase soy agar (BBL) and heart infusion agar (Difco), colonies of *Cellulosimicrobium funkei* have substrate hyphae and vary from 1 mm to 2 mm in diameter after 24 h. Young colonies were filamentous with distinct centers, and mature colonies develop dense centers with a filamentous fringe that is so short that it is barely visible. No aerial mycelia occur and a pale yellow, nonsoluble pigment is formed (Sottnek et al., 1977). *Cellulosimicrobium cellulans* DSM 43879[T] and *Cellulosimicrobium terreum* grow at 25–28°C on medium No. 65 (www.dsmz.de) containing 4 g of glucose, 4 g of yeast extract, 10 g of malt extract, 2 g of $CaCO_3$, and 12 g of agar per 1000 ml of distilled water (pH 7.2). Cells grow well on nutrient agar

(Difco) or tryptic soy agar (Difco). *Cellulosimicrobium funkei* W6122^T is cultivated at 35°C on heart infusion agar and trypticase soy agar.

The organisms are chemo-organotrophic with aerobic and facultatively anaerobic metabolism. Nitrate is reduced to nitrite by *Cellulosimicrobium cellulans* (Metcalfe and Brown, 1957) but not by *Cellulosimicrobium funkei* (Sottnek et al., 1977). *Cellulosimicrobium* (*Nocardia*) *cellulans* is reported to fix atmospheric nitrogen and to decompose cellulose (Metcalfe and Brown, 1957). However, serial transfer on media such as yeast-extract peptone results in a very rapid loss of fixing ability and of the ability to decompose cellulose. Passage through sterile soil may restore these properties occasionally. The organism survives and retains both properties over a period of years in damp or air-dry sterile soil (Metcalfe and Brown, 1957).

Strains of *Cellulosimicrobium cellulans* are hosts of the actinophages O5 (=DSM 49112; host strain DSM 43881; Stackebrandt and Prauser, 1991) and O13 (=DSM 49139; host strain DSM 43879^T; Prauser, 1986).

All hitherto known strains of *Cellulosimicrobium funkei* and the type strain of *Cellulosimicrobium cellulans* are resistant to amikacin (MIC ≥64 μg/ml) and ciprofloxacin (MIC ≥4 μg/ml). All strains of *Cellulosimicrobium funkei* are sensitive to imipenem (MIC ≥16 μg/ml). *Cellulosimicrobium cellulans* ATCC 51964^T is resistant to this antibiotic. The type strain of *Cellulosimicrobium cellulans* is sensitive to trimethoprim-sulfamethoxazole (MIC ≥4–76 μg/ml), whereas the strains of *Cellulosimicrobium funkei* are resistant to it (Brown et al., 2006).

Strains of *Cellulosimicrobium cellulans* were isolated from fetal tissues or placentas from cases of equine abortion, premature birth, and term pregnancies of horses, suggesting the causative role of these bacteria (Bolin et al., 2004). *Cellulosimicrobium cellulans* was discussed as etiological agent of chronic tongue ulcerations in an immunocompromised patient (Heym et al., 2005). The strains of *Cellulosimicrobium funkei* are isolates from human specimens sent to the Special Bacteriology Section and the Actinomycete Reference Laboratory at the Center for Disease Control (Atlanta, Georgia, USA) between 1957 and 1977 and classified earlier as strains of *Oerskovia turbata* (McNeil et al., 2004). The type strain W6122^T and strain W4083 were isolated from blood from patients in Colorado and California, respectively, and the lung isolate W2796 and strain W6123 originate from patients in New York. Although the isolation sites were suggestive of invasive infections, the clinical significance of these strains could not be elucidated since no satisfactory case histories were available. The only strain of *Cellulosimicrobium terreum* was isolated from a Korean soil sample (Yoon et al., 2007).

Enrichment and isolation procedures

For isolation of *Cellulosimicrobium* (*Nocardia*) *cellulans* DSM 43879^T the following method was used (Metcalfe and Brown, 1957): Silica gel was impregnated with basal medium (2.5 g of KNO_3; 1.0 g of K_2HPO_4; 0.1 g of $CaCl_2$; 0.3 g of $MgSO_4 \cdot 7H_2O$; 0.1 g of NaCl; 0.01 g of $FeCl_3$, 1000 ml of distilled water; pH 7.0–7.2). Washed filter paper placed on the surface of the gel was seeded with minute grains of chalk grassland soil. After incubation at 25°C for 2–3 d, further plates were inoculated from the areas of decomposition around the grains. *Cellulosimicrobium* (*Nocardia*) *cellulans* was isolated as one of the most vigorous strains of mixed cultures by repeated plating on yeast-extract peptone agar. The type strain W6122^T of *Cellulosimicrobium funkei* was identical to the clinical isolates sent to the Center for Disease Control between 1972 and 1974 (Reller et al., 1975). Details of the isolation procedure were not reported. *Cellulosimicrobium terreum* was isolated by means of standard dilution plating techniques at 25°C on 10× diluted nutrient agar (Difco).

Maintenance procedures

For preservation, cells are serially transferred at 4-week intervals using cultivation conditions specified above, maintained at 4°C, and stored as 20% (w/v) glycerol suspensions at −20°C and at −80°C. Long-term preservation methods include freeze drying in skim milk and maintenance in liquid nitrogen at −196°C.

Differentiation of the genus *Cellulosimicrobium* from other genera

The genus *Cellulosimicrobium* shares with its closest phylogenetic neighbors *Isoptericola*, *Xylanimonas*, *Xylanimicrobium*, and *Xylanibacterium* the major menaquinone MK-9(H_4), the occurrence of mainly *iso*- and *anteiso*- branched cellular fatty acids, the ability to decompose polysaccharides and to grow as an aerobe or facultative anaerobe, as well as the occurrence of one or several cell-wall sugars. Members of the genus *Cellulosimicrobium* can be differentiated from all genera of the family *Promicromonosporaceae* by their peptidoglycan variation (L-Lys←D-Ser/L-Thr←D-Asp). With respect to morphological features, members of the genus *Cellulosimicrobium* differ from those of the genera *Isoptericola*, *Xylanimonas*, *Xylanimicrobium*, and *Xylanibacterium* by the development of primary mycelia which fragment later into irregular rods. Fucose as cell-wall sugar was detected only in *Cellulosimicrobium* and *Xylanibacterium* (see Table 177).

Taxonomic comments

Nocardia cellulans (Metcalfe and Brown, 1957) and *Oerskovia xanthineolytica* were proposed among other taxa as synonyms of *Cellulomonas cartae* (Stackebrandt and Kandler, 1980), a species with an illegitimate name since the specific epithet *cellulans* antedates the epithet *cartae* (Rules 38 and 42 of the Bacteriological Code; Lapage et al., 1992). As *Nocardia cellulans* was formally reclassified as *Cellulomonas cellulans* (Stackebrandt and Keddie, 1986), the nonmotile strains of *Nocardia cellulans* were combined with the motile strains of *Oerskovia xanthineolytica* into one and the same taxon. *Cellulomonas cellulans* embraces the additional organisms *Brevibacterium lyticum* (Takayama et al., 1960), *Brevibacterium fermentans* (Chatelain and Second, 1966), "*Arthrobacter luteus*" (Kaneko et al., 1969), "*Corynebacterium manihot*" (Collard, 1963), and *Cellulomonas cartae* (Stackebrandt et al., 1978; Stackebrandt and Kandler, 1980). These organisms were united because they share the peptidoglycan variation L-Lys←D-Ser←D-Asp (Seidl et al., 1980), similar menaquinone and fatty acid profiles, and show a close genetic relationship (Stackebrandt and Keddie, 1986). The description of several new genera between 1997 and 2000 provided new insight into the phylogenetic structure of the suborder *Micrococcineae* and revealed that *Cellulomonas cellulans* clustered outside the authentic genus *Cellulomonas*. This observation and the

difference in peptidoglycan type between these and all other representatives of the genus *Cellulomonas* led to the proposal of the genus *Cellulosimicrobium* and reclassification of *Cellulomonas cellulans* as *Cellulosimicrobium cellulans* (Schumann et al., 2001). The second species *Cellulosimicrobium variabile* was described for a cellulolytic bacterium isolated from the hindgut of an Australian termite (Bakalidou et al., 2002). However, its phylogenetic distance to *Cellulosimicrobium cellulans* (see Figure 202 in the chapter on *Xylanimicrobium*), the re-examination of its peptidoglycan structure which revealed the variation L-Lys←D-Asp, and some additional differentiating phenotypic characteristics (Table 177, Table 179, and Table 180) led to the proposal of the genus *Isoptericola* and to the reclassification of *Cellulosimicrobium variabile* as *Isoptericola variabilis* (Stackebrandt et al., 2004). The inclusion of "nonmotile organism" in the definition of the genus *Cellulosimicrobium* by Schumann et al. (2001) did not account for motile strains of *Cellulomonas cellulans* earlier classified as *Oerskovia xanthineolytica*. Studies on motile clinical isolates have revealed recently that these organisms represent a new species of the genus *Cellulosimicrobium*, *Cellulosimicrobium funkei* (Brown et al., 2006). The genus *Cellulosimicrobium* (Schumann et al., 2001) was emended consequently to include motile organisms and strains that are unable to reduce nitrate (Brown et al., 2006).

Differentiation of the species of the genus *Cellulosimicrobium*

Characteristics that differentiate the species *Cellulosimicrobium cellulans* and *Cellulosimicrobium funkei* from one another and from related taxa are listed in Table 177, Table 179, and Table 180.

List of species of the genus *Cellulosimicrobium*

1. **Cellulosimicrobium cellulans** (Metcalfe and Brown 1957) Schumann, Weiss and Stackebrandt 2001, 1009[VP] (*Nocardia cellulans* Metcalfe and Brown 1957).

cel′lu.lans. N.L. part. adj. *cellulans* cell-making. Basonym *Nocardia cellulans*.

The following description is based on that of *Nocardia cellulans* DSM 43879[T] (Funke et al., 1995; Metcalfe and Brown, 1957; Schumann et al., 2001; Stackebrandt et al., 1980; Stackebrandt and Keddie, 1986) *Cellulomonas cartae* DSM 20106, "*Corynebacterium manihot*" DSM 20155, *Brevibacterium fermentans* CIP 6611, and *Brevibacterium lyticum* ATCC 15921 (Stackebrandt and Kandler, 1980; Stackebrandt et al., 1982), and that of *Oerskovia xanthineolytica* (Funke et al., 1995; Stackebrandt et al., 1980). In addition to the properties given in the genus description, this species has the following characteristics. A primary mycelium is produced which fragments later in the growth cycle. After exhaustion of the medium, the rods transform into shorter rods or even spherical cells. On peptone-yeast extract-glucose agar, colonies are circular, 0.9–5 mm in diameter, convex, yellow-whitish, and glistening, with entire edge. Catalase is produced. Nitrite is produced from nitrate. Aerobic and facultatively anaerobic. Alkaline phosphatase, esterase (C4), esterase lipase (C8), acid phosphatase, naphthol-AS-BI-phosphohydrolase, and α-glucosidase are present. Casein, gelatin, hypoxanthine, xanthine, and starch are hydrolyzed. Negative for hydrolysis of tyrosine, acid production from L-rahmnose, D-mannitol, inositol and D-sorbitol, utilization of L-malate, lipase (C14) leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-glucoronidase, α-mannosidase, and α-fucosidase (Yoon et al., 2007). Glucose, mannose, maltose, sucrose, D-xylose, L-arabinose, D-ribose, D-xylose, *m*-inositol, glycerol, cellobiose, lactose, sucrose, gluconate, mannitol, D-mannose, L-lactate, acetate, pyruvate, propionate, pentanoate, capronate, heptanoate, caprylate, glyoxylate, proline, asparagine, aspartate, and histidine but not raffinose, DL-malate, and D-lactate are used as sole carbon sources. Acid is produced from glucose, mannose, sucrose, D-xylose, L-arabinose, ribose, gluconate, glycerol, lactose, pyruvate, and cellobiose. Acetic acid is the main acidic intermediary product of aerobic glucose dissimilation. Resting cells ferment glucose anaerobically predominantly to CO_2, acetic acid, and L-lactic acid. Ethanol and formic acid are minor end products. The major cell-wall sugar is rhamnose, while fucose and galactose are minor components. The major menaquinone is MK-9(H_4); the minor menaquinones are MK-9(H_2), MK-8(H_4), and MK-7(H_4). The predominant fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{16:0}$, and $C_{15:0}$ iso.

Sequence accession no. (16S rRNA gene): X83809.

2. **Cellulosimicrobium funkei** Brown, Steigerwalt, Morey, Daneshvar, Romero and McNeil 2006, 804[VP]

fun′ke.i. N.L. gen. masc. n. *funkei* of Funke, to honor the contributions of Guido Funke, a distinguished microbiologist, who recognized the heterogeneity within the yellow-pigmented coryneform bacteria.

Cells are short (1 µm), thin, Gram-stain-positive and non-sporulating rods. Motile by polar and/or lateral flagella (Sottnek et al., 1977). Growth occurs at 35°C and 45°C, but not at 25°C. Pale-yellow pigment. Substrate hyphae are present. Catalase-positive. Esculin, adenine, casein, gelatin, hypoxanthine, urea, and xanthine are decomposed. Nitrate is not reduced to nitrite (Sottnek et al., 1977). Catalase is produced. Aerobic and facultatively anaerobic. Alkaline phosphatase, esterase (C4), esterase lipase (C8), acid phosphatase, naphthol-AS-BI-phosphohydrolase, and α-glucosidase are present. Casein, gelatin, hypoxanthine, xanthine, and starch are hydrolyzed. Negative for hydrolysis of tyrosine, acid production from L-rhamnose, D-mannitol, inositol and D-sorbitol, utilization of L-malate, lipase (C14) leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-glucoronidase, α-mannosidase, and α-fucosidase. Utilization of D-glucose, D-fructose, D-galactose, D-cellobiose, D-mannose, D-trehalose, D-xylose, L-arabinose, sucrose, maltose, and salicin (Yoon et al., 2007). Acid is produced from L-arabinose, cellobiose, fructose, D-galactose, D-glucose, glycerol, lactose, maltose, mannose, salicin, sucrose, D-trehalose, and D-xylose but not from adonitol, dulcitol, *i*-erythritol, *myo*-inositol, inulin, D-mannitol, melezitose, melibiose, raffinose, L-rhamnose, or D-sorbitol. Predominant fatty acids are 12-methyltetradecanoic acid ($C_{15:0}$ anteiso), 14-methylpentadecanoic acid ($C_{16:0}$ iso), hexadecanoic acid ($C_{16:0}$), and 13-methyltetradecanoic acid ($C_{15:0}$ iso). The characteristic whole-cell sugar is galactose; ribose is present.

Type strain: W6122, ATCC BAA-886, DSM 16025, CCUG 50705, JCM 14302.

Sequence accession no. (16S rRNA gene): AY501364.

3. **Cellulosimicrobium terreum** Yoon, Kang, Schumann and Oh 2007, 2496[VP]

ter′re.um. L. neut. adj. *terreum* of the earth.

Cells are Gram-stain-positive, non-spore-forming rods or cocci (0.4–0.8 µm × 0.4–2.0 µm); in older cultures, cells are Gram-stain-variable and most cells are cocci. Colonies on TSA are circular, convex, smooth, glistening, yellow in color, and 1.5–2.0 mm in diameter after 7 d incubation at 25°C. Substrate hyphae are present. Optimal temperature for growth is 25°C. Growth occurs at 4°C and 34°C, but not at 35°C. Optimal pH for growth is 6.5–7.5; growth occurs at pH 6.0 and 9.0, but not at pH 5.5 and 9.5. Growth occurs in the presence of 0–9 % (w/v) NaCl; optimal growth occurs in the presence of 1.0% (w/v) NaCl. Anaerobic growth does not occur on TSA and on TSA supplemented with nitrate. Oxidase-negative. Tweens 20, 40, 60, and 80 are hydrolyzed. H_2S and indole are not produced. L-Glutamate is utilized as a sole carbon and energy sources, but succinate, benzoate, and formate are not. Alkaline phosphatase, esterase (C4), esterase lipase (C8), acid phosphatase, naphthol-AS-BI-phosphohydrolase, and α-glucosidase are present. Esculin, casein,

hypoxanthine, xanthine, and starch are hydrolyzed. Negative for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, hydrolysis of tyrosine, acid production from L-rhamnose, D-mannitol, inositol, and D-sorbitol, utilization of citrate, L-malate, lipase (C 14) leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-glucoronidase, α-mannosidase and α-fucosidase. Utilization of D-glucose, D-fructose, D-galactose, D-cellobiose, D-mannose, D-trehalose, D-xylose, L-arabinose, acetate, pyruvate, sucrose, maltose, and salicin. Acid production from D-glucose and sucrose. Susceptible to cephalothin, chloramphenicol, neomycin, novobiocin, oleandomycin, penicillin G, streptomycin, tetracycline, but not to carbenicillin, gentamicin, kanamycin, lincomycin, and polymyxin B. The cell-wall peptidoglycan type is L-Lys←L-Thr←D-Asp. The whole-cell sugar is galactose. The predominant menaquinone is MK-9(H_4). The major fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso. Major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and an unidentified phospholipid.

Genus III. **Isoptericola** Stackebrandt, Schumann and Cui 2004, 686[VP]

Erko Stackebrandt and Peter Schumann

I.sop.te.ri′co.la. N.L. n. *Isoptera* order of termites; L. masc. or fem. suff. *-cola* (from L. masc. or fem. n. *incola*), inhabitant; N.L. masc. n. *Isoptericola* inhabitant of termites.

Gram-stain-positive. Cells rod-shaped, V-shaped, or coccoid and **nonmotile**. **Primary mycelium may be formed**. **Cellulolytic and xylanolytic**; facultatively anaerobic, acid is produced from some carbohydrates. **The peptidoglycan type is A4α, L-Lys←D-Asp, variation A11.31.** *N*-glycolylmuramic acid, mycolic acids, and hydroxy fatty acids are absent. The acyl type is acetyl. Whole cell sugars are galactose, rhamnose, and glucose (ratio 4:2:1); ribose and minor amounts of mannose may occur. **The main menaquinones are MK-9(H_2) and/or MK-9(H_4). Major fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso**. Some strains have in addition $C_{16:0}$, $C_{17:0}$ anteiso, and $C_{14:0}$ and in some strains $C_{16:0}$ iso. Smaller amounts of $C_{14:0}$ iso, $C_{17:0}$ iso, and $C_{15:0}$ are present. The **phospholipids include phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol**; unknown glycolipids and/or phospholipids may occur.

DNA G+C content (mol%): 70.0–74.1 (HPLC).

Type species: **Isoptericola variabilis** (*Cellulosimicrobium variabile* Bakalidou, Kämpfer, Berchtold, Kuhnigk, Wenzel and König 2002, 1189[VP]) Stackebrandt, Schumann and Cui 2004, 686[VP].

Further descriptive information

Isoptericola embraces four species, *Isoptericola variabilis*, *Isoptericola halotolerans, Isoptericola hypogeus*, and *Isoptericola dokdonensis*, which share 98–98.5% 16S rRNA gene sequence similarity. The nearest phylogenetic neighbors (Figure 204) are *Xylanimicrobium* [*Promicromonospora*] *pachnodae* (Cazemier et al., 2004; Stackebrandt and Schumann, 2004), *Xylanimonas cellulosilytica* (Rivas et al., 2003), and *Xylanibacterium ulmi* (Rivas et al., 2004), sharing 97.0–97.3% gene sequence similarities: less than 97.6%

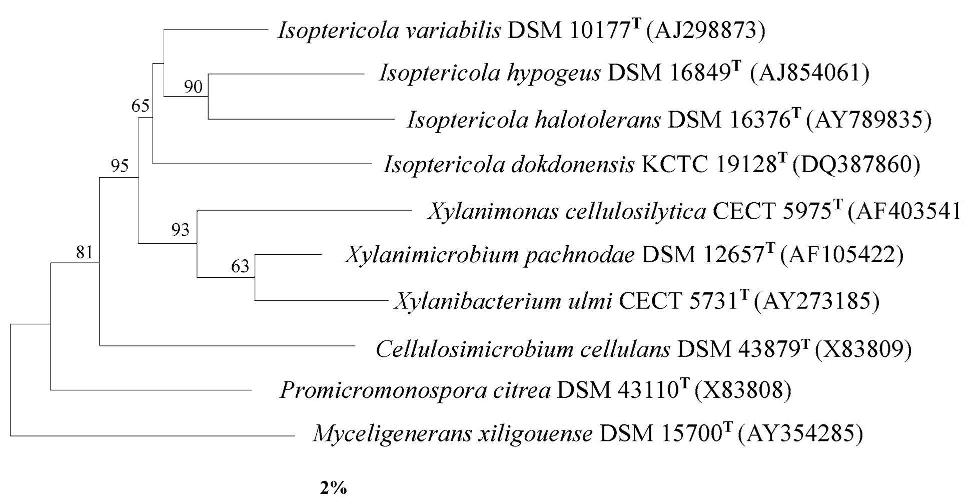

FIGURE 204. Distance matrix dendrogram of 16S rRNA gene sequence relationship (DeSoete, 1983), displaying the relatedness of the four *Isoptericola* species with their nearest neighbors. Bar = 2 inferred changes per hundred nucleotides. Numbers at the branch points are bootstrap values (on the basis of 1000 samplings) (Felsenstein, 1985).

are shared between *Isoptericola* type strains and members of other genera of the order *Micrococcales*.

The DNA–DNA relatedness between the type strains *Isoptericola variabilis* DSM 10177^T and *Isoptericola hypogeus* DSM 16849^T, and between *Isoptericola variabilis* DSM 10177^T and *Isoptericola halotolerans* DSM 16376^T were 31.7% and 27.4%, respectively, as determined by the spectroscopic method (Huss et al., 1983).

Chemotaxonomically the strains are similar (with only small differences in menaquinone and fatty acid composition) as expected from their affiliation to the same genus. However, their growth characteristics differ: *Isoptericola variabilis* DSM 10177^T is a facultative anaerobic organism (Bakalidou et al., 2002), while *Isoptericola hypogeus* DSM 16849^T (Groth et al., 2005) and *Isoptericola halotolerans* DSM 16376^T (2005) are aerobic to microaerophilic organisms that do not grow in an anaerobic atmosphere. *Isoptericola dokdonensis* DS-3^T grows anaerobically on tryptic soy agar (TSA) and on TSA supplemented with nitrate (Yoon et al., 2006). Morphologically, *Isoptericola hypogeus* forms wrinkled, circular, smooth, and pale yellow colonies on medium 79 of about 1–2 mm in diameter. In young cultures (8–24 h), a well developed primary mycelium (width 0.6–0.7 µm) was observed to fragment in the stationary growth phase (48–72 h) into irregular nonmotile short rods and cocci (diameter 0.8–1.0 µm). In contrast to stationary cultures of *Isoptericola variabilis*, both cell types were mainly arranged in short flexible chains or in clusters. A primary mycelium was also observed in *Isoptericola halotolerans* and *Isoptericola dokdonensis*. *Isoptericola variabilis* and *Isoptericola hypogeus* have been characterized in detail (Bakalidou et al., 2002; Groth et al., 2005), while less information on morphological properties is available for *Isoptericola halotolerans* (Zhang et al., 2005) and *Isoptericola dokdonensis* (Yoon et al., 2006).

The type strains of *Isoptericola variabilis* and *Isoptericola hypogeus* are resistant to ampicillin 10 µg, ciprofloxacin 5 µg, kanamycin 30 µg, lincomycin 2 µg, methicillin 5 µg, norfloxacin 10 µg, and penicillin G 10 IU. All type strains are susceptible to neomycin (30 µg), tetracycline (30 µg), and chloramphenicol (100 µg). *Isoptericola hypogeus* but not *Isoptericola variabilis* and *Isoptericola dokdorensis* is susceptible to 10 µg streptomycin. No information on antibiotic sensitivity and resistance is available for *Isoptericola halotolerans*.

Enrichment and isolation procedures

Isoptericola [*Cellulosimicrobium*] *variabilis* was isolated from the hindgut of the Australian termite *Mastotermes darwiniensis* (Froggatt). *Isoptericola hypogeus* CD12-119^T was isolated from a sample of tufa collected in the burial chamber of the first arcosolium behind the entrance of the catacomb Domitilla using PY-BHI agar (Yokota et al., 1993) and a standard dilution plate procedure. *Isoptericola halotolerans* YIM 70177^T was isolated from saline soil by the dilution plating method on modified Horikoshi medium (Horikoshi and Grant, 1998; Zhang et al., 2005). *Isoptericola dokdonensis* DS-3^T is a soil isolate from Dokdo, Korea.

Maintenance procedures

Stock cultures of strains in liquid organic DSM medium 92 (DSMZ, 2001) supplemented with 5% DMSO were maintained in either the vapor phase of liquid nitrogen or at −80°C by adding a glycerol-medium (1:1) that consisted of K_2HPO_4 (1.26%), KH_2PO_4 (0.36%), $MgSO_4$ (0.01%), Na-citrate (0.09%), $(NH_4)_2SO_4$ (0.18%), and glycerol (8.8%).

Differentiation from closely related taxa

Table 177 lists the characteristics useful to distinguish *Isoptericola* from other genera of the family *Promicromonosporaceae*. A comparison of phenotypic properties between *Isoptericola variabilis* DSM 10177^T, *Myceligenerans xiligouense* XLG9A10.2^T, members of *Promicromonospora*, *Xylanimicrobium* (*Promicromonospora*) *pachnodae* DSM 12657^T, and *Xylanimonas cellulosilytica* $XIL07^T$ has been published by Cui et al. (2004).

Taxonomic comments

As already noted in the original publication (Bakalidou et al., 2002), the type strain of the species *Cellulosimicrobium variabile* DSM 10177^T does not phylogenetically cluster unambiguously with the type species *Cellulosimicrobium cellulans* DSM 43879^T (96.6% 16S rRNA gene sequence similarity). The type strains of the two *Cellulosimicrobium* species resembled each other in morphology, the composition of fatty acids, base composition of DNA, phospholipids, and the presence of lysine in position 3 of the peptide subunit of peptidoglycan. They differed from each other in cell-wall sugars and in the amino acid composition of the A4α-type peptidoglycan, which contains serine and aspartic acid in the interpeptide bridge of *Cellulosimicrobium cellulans*, and only aspartic acid in the interpeptide bridge of *Cellulosimicrobium variabile*. As the presence of different peptidoglycan variations is rarely encountered in genera of the order *Micrococcales* (formerly suborder *Micrococcineae* (Stackebrandt and Schumann, 2004), the peptide structure of *Isoptericola* [*Cellulosimicrobium*] *variabilis* was reinvestigated. As published originally, the peptidoglycan contained L-lysine, aspartic acid, glutamic acid, and alanine in the molar ratio 1:0.9:2:2, which raised the question about the position of the second molecule of glutamic acid (one molecule is positioned at pos. 2 of the peptide subunit). The reanalysis of purified peptidoglycan revealed the ratio of L-lysine:aspartic acid:glutamic acid:alanine to be 1:0.9:1:2, and analysis of partial hydrolysis fragments (Schleifer and Kandler, 1972) indicated the presence of the peptide L-Lys←Asp. Thus, the A4α type of variation A11.31 (http://www.peptidoglycan-types.info) was proposed for *Isoptericola variabilis* DSM 10177^T in the formal reclassification. Several new members of the family *Promicromonospora* were described in the following years, which demonstrated strain DSM 10177^T to be moderately related to *Xylanimonas cellulosilytica*, *Xylanimicrobium pachnodae*, and *Xylanibacterium ulmi*, forming a lineage that forms a sister lineage of the *Promicromonospora*-*Myceligenerans* lineage.

Differentiation of the species of the genus *Isoptericola*

Differential characters of the type strains of the four type strains are shown in Table 181.

List of species of the genus *Isoptericola*

1. **Isoptericola variabilis** (Bakalidou, Kämpfer, Berchtold, Kuhnigk, Wenzel and König 2002) Stackebrandt, Schumann and Cui 2004, 686[VP]

va.ri.a′bi.lis. L. masc. adj. *variabilis* variable, because cells are rods or cocci.

Gram-stain-positive. Cells are rod-shaped (0.3 × 0.7 μm) V-shaped or coccoid (diameter 0.25 μm) and nonmotile. Yellow, smooth colonies on TSA (Difco) about 2 mm in diameter after 48 h at 28°C. Catalase-positive, oxidase-negative. Nitrate reduction and esculin hydrolysis positive. Cellulolytic and xylanolytic. Utilizes of D-glucose, D-galactose, gentobiose, D-gluconic acid, D-cellobiose, D-lactose, lactulose, D-mannose, maltose, maltotriose, mannan, D-mannitol, D-xylose, L-arabinose, acetate, citrate, propionic acid, pyruvic acid, D-arabitol, glycerol, adenosine, dextrin, aconitate, starch, glycogen, amygdalin, arbutin, D-galactose, D-psicose, D-ribose, *N*-acetylglucosamine, D-melezitose D-melibiose, methyl α-D-galactoside, methyl-β-D-galactoside, 3-methylglucose, D-raffinose, stachyose, D-trehalose, sucrose, L-asparagine, L-glutamic acid, L-pyroglutamic acid, L-serine, 2′-deoxyadenosine, inosine, and salicin. Acid produced from D-glucose, L-arabinose, raffinose, L-rhamnose, D-xylose, D-cellobiose, D-melibiose, D-arabitol, and D-mannose. No acid produced from sucrose, D-mannitol, dulcitol, salicin, adonitol, inositol, sorbitol, maltose, methyl β-D-glucose, or erythritol. According to the substrate panels of commercial systems the following reactions are positive: peptonization of milk, adenine, casein, gelatin, hypoxanthine, potato, starch, tyrosine, xanthine, xylan, succinate, alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine, arylamidase, cystine arylamidase, urease, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase, β-glucosidase, and *N*-acetyl-β-glucosamidase, α-galactosidase, methyl α-D-mannoside, and β-gentiobiose. Other properties are indicated in Table 181. Susceptible to imipenem (10 μg), ofloxacin (10 μg), oxytetracycline (30 μg), polymyxin B 300 IU, rifampin (30 μg), sulfonamide (200 μg), vancomycin (30 μg), neomycin (30 μg), tetracycline (30 μg), and chloramphenicol (100 μg).

Source: the hindgut of the Australian termite *Mastotermes darwiniensis* (Froggatt).

DNA G+C content (mol%): 70–72 (T_m).

Type strain: MX5, DSM 10177, ATCC BAA-303, JCM 11754.

Sequence accession no. (16S rRNA gene): AJ298873.

2. **Isoptericola dokdonensis** Yoon, Schumann, Kang, Jung and Oh 2006, 2896[VP]

dok.do.nen′sis. N.L. masc. adj. *dokdonensis* of Dokdo, Korea, where the organism was first isolated.

Cells are Gram-stain-positive, nonmotile rods or cocci (0.8–1.1 × 0.8–4.5 μm). Primary mycelium is formed. Colonies on TSA are circular, convex, smooth, yellow in color,

and 1.0–2.0 mm in diameter after 3 d of incubation at 30°C. Optimal temperature for growth is 30°C. Growth occurs at 10°C and 40°C, but not at 4°C or 41°C. Optimal pH for growth is between 7.0 and 8.0; growth occurs at pH 6.5, but not at pH 6.0. Growth occurs in the presence of 0–9 % (w/v) NaCl. Catalase- and oxidase-positive. Nitrate reduction and esculin hydrolysis positive. Anaerobic growth occurs on TSA and on TSA supplemented with nitrate. Tweens 20, 40, and 60 are not hydrolyzed. H_2S and indole are not produced. D-Glucose, D-galactose, D-cellobiose, D-mannose, D-xylose, L-arabinose, and salicin are utilized. Esterase (C4), esterase lipase (C8), leucine arylamidase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase, and β-glucosidase are present. Arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase are absent. Pyruvate but not benzoate, citrate, L-malate, succinate, or formate is utilized as a carbon source. Other phenotypic characteristics are given in Table 181. The whole-cell sugars are galactose, glucose, rhamnose, and ribose. The predominant menaquinone is MK-9(H_4). The major fatty acids (>10% of total fatty acids) are $C_{15:0}$ anteiso and $C_{15:0}$ iso. The major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and two unidentified glycolipids. Resistant to polymyxin B, 100 U; streptomycin, 50 µg; penicillin G, 20 U; ampicillin, 10 µg; cephalothin, 30 µg; gentamicin, 30 µg; novobiocin, 5 µg; kanamycin, 30 µg; lincomycin, 15 µg; oleandomycin, 15 µg; carbenicillin, 100 µg. Susceptible to neomycin, 30 µg; tetracycline, 30 µg; chloramphenicol, 100 µg.

Source: soil in Dokdo, Korea.

DNA G+C content (mol%): 74.1 (HPLC).

Type strain: DS-3, KCTC 19128, CIP 108921, JCM 15137.

Sequence accession no. (16S rRNA gene): DQ387860.

3. **Isoptericola halotolerans** Zhang, Schumann, Li, Cheng, Tian, Stackebrandt, Xu and Jiang 2005, 1869[VP]

ha.lo.to′le.rans. Gr. n. *hals halos* salt; L. part. adj. *tolerans* tolerating; N.L. part. adj. *halotolerans* salt-tolerating, referring to the organism's ability to tolerate high salt concentrations.

Cells are Gram-stain-positive, coccoid or rod-shaped, nonmotile, and do not form spores. Primary mycelium is formed. Colonies are pale-yellow, circular, opaque, and approximately 1.0 mm in diameter after 24 h growth at 28°C. Optimal growth occurs at 10% NaCl, pH 8.0–9.0, and 28°C. Catalase-positive and oxidase-negative. Nitrate reduction and esculin hydrolysis positive. Milk coagulation, melanin production, H_2S production, Voges–Proskauer, and indole production negative. The following substrates are utilized: glucose, ribose, arabinose, maltose, sucrose, mannose, fructose, salicin, galactose, cellobiose, trehalose, sorbitol, lactose, xylose, and dextrin; acid is produced from maltose. Does not utilize rhamnose, acetamide, inositol, mannitol, adonitol, and sorbitol. Negative for Tween 20 and Tween 80 utilization, gelatin liquefaction, ammonia production, milk peptonization, and casein and starch hydrolysis. Trehalose is not utilized. Positive for esterase (C4), esterase lipase (C8), leucine arylamidase, naphthol-AS-BI-phosphohydrolase, α-glucosidase, β-glucosidase, β-galactosidase, α-maltosidase, and cellulose; negative for arginine dihydrolase, ornithine decarboxylase, lysine decarboxylase, and L-aspartic arylamidases. Other phenotypic characteristics are given in Table 181. The cell-wall sugar is galactose. Phospholipids are phosphatidylinositol, phosphatidylglycerol, and diphosphatidylglycerol. The predominant menaquinones are MK-9(H_4) and MK-9(H_2). Susceptible to neomycin, 30 µg; tetracycline, 30 µg; chloramphenicol, 100 µg.

Source: a saline soil sample collected from Qinghai Province, North-West China.

DNA G+C content (mol%): 72.8 (HPLC).

Type strain: YIM 70177, DSM 16376, JCM 13590, KCTC 19046.

Sequence accession no. (16S rRNA gene): AY789835.

4. **Isoptericola hypogeus** Groth, Schumann, Schütze, Gonzalez, Laiz, Saiz-Jiminez and Stackebrandt 2005, 1718[VP]

hy.po′ge.us. L. masc. adj. *hypogeus* underground, referring to the site of isolation.

Gram-stain-positive, aerobic to microaerophilic actinomycete with a well developed primary mycelium (diameter of hyphae 0.6–0.7 µm) that undergoes fragmentation into short irregular nonmotile rods and cocci (diameter 0.8–1.0 µm) in the stationary growth phase. Aerial mycelium is absent. Colonies on organic medium 79 are wrinkled, circular, smooth, and pale yellow (diameter about 1–2 mm). Growth between 10°C and 40°C (optimal growth at 28°C) and at pH values in the range of 6–9. NaCl in the culture medium is tolerated up to 10%. Catalase-positive and oxidase-negative. Nitrate reduction and esculin hydrolysis positive. The following reactions are distinctly positive: peptonization of milk, adenine, casein, gelatin, hypoxanthine, potato, starch, tyrosine, xanthine, xylan, succinate, and nitrate reduction. Utilizes acetate, propionic acid, pyruvic acid, glycerol, adenosine, dextrin, L-arabinose, arbutin, D-galactose, α-D-glucose, D-galactose, L-arabinose, salicin, D-mannose, malate, D-psicose, D-ribose, salicin, D-xylose, *N*-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, maltose, lactose, methyl α-D-mannoside, starch, glycogen, β-gentiobiose, D-arabitol. Negative for D-mannitol, D-melezitose, D-melibiose, methyl-α-D-galactoside, methyl-β-D-galactoside, 3-methyl-glucose, D-raffinose, stachyose, acetic acid, D-trehalose, sucrose, L-asparagine, L-glutamic acid, L-pyroglutamic acid, L-serine, 2′-deoxyadenosine, and inosine. Positive for alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine, arylamidase, cystine, arylamidase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosamidase, and α-galactosidase. Other phenotypic characteristics are given in Table 181. Susceptible to imipenem (10 µg), ofloxacin (10 µg), oxytetracycline (30 µg), polymyxin B (300 IU), rifampin (30 µg), sulfonamide (200 µg), and vancomycin (30 µg), neomycin (30 µg), tetracycline (30 µg), and chloramphenicol (100 µg).

Source: a tufa sample of a burial chamber in the catacomb Domitilla, Rome, Italy.

DNA G+C content (mol%): 73.8 (HPLC).

Type strain: CD12-119, HKI 0342, DSM 16849, JCM 14325, NCIMB 14033.

Sequence accession no. (16S rRNA gene): AJ854061.

Genus IV. **Myceligenerans** Cui, Schumann, Stackebrandt, Kroppenstedt, Pukall, Xu, Rohde and Jiang 2004, 1292[VP]

Erko Stackebrandt and Peter Schumann

My.ce.li.ge′ne.rans. N.L. neut. n. *mycelium* filamentous cell; L. part. adj. *generans* producing; N.L. neut. subst. *Myceligenerans* hyphae-forming microbe.

Gram-stain-positive, mycelium-and spore-forming organism. **Substrate mycelia are well developed and branched in and on the media**. Aerial mycelium absent. **The surface of substrate mycelium bears fragmented cells and spore chains with one or two spores at the tips of the mycelium. Spores are coccoid to rod-shaped, and nonmotile**. Aerobic to microaerophilic. **Peptidoglycan type is A4α, variation L-Lys←L-Thr←D-Glu**. The acyl type is acetyl. Cell-wall sugars are glucose, mannose, and galactose. **Major menaquinones are MK-9(H_4)** and MK-9(H_6); **predominant fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso**; C_{16} may occur. Cells contain phosphatidylglycerol, diphosphatidylglycerol, phospatidylinositol, three unidentified phospholipids, and one unidentified glycolipid. Mycolic acids are absent.

The 16S rRNA gene sequence analysis places the genus in the family *Promicromonosporaceae*.

DNA G+C content (mol%): 72–72.3.

Type species: **Myceligenerans xiligouense** Cui, Schumann, Stackebrandt, Kroppenstedt, Xu, Rohde and Jiang 2004, 1292[VP].

Further descriptive information

16S rRNA gene sequence analysis indicates that the two species of *Myceligenerans* constitute a distinct lineage within the family *Promicromonosporaceae*, sharing with other genera of this family between 93.0 and 95.0% similarity. The 16S rRNA gene sequences of the two *Myceligenerans* species contain the signature nucleotides of the family *Promicromonosporaceae* (Stackebrandt and Schumann, 2000) as emended by Cui et al. (2004). The relatedness between the two species *Myceligenerans xiligouense* and *Myceligenerans crystallogenes* is 97.9% 16S rRNA gene sequence similarity and 14% DNA–DNA reassociation similarity. The three strains of *Myceligenerans crystallogenes* shared almost identical riboprint patterns which affiliated them to the same ribogroup. The riboprint patterns of *Myceligenerans crystallogenes* show close similarity to that of *Myceligenerans xiligouense* (Groth et al., 2006).

The morphology of the two species is similar (Figure 205 for *Myceligenerans xiligouense*) but they differ in the colony pigmentation. In liquid culture *Myceligenerans crystallogenes* forms a well-developed primary mycelium within 8–24 h which undergoes fragmentation into irregular nonmotile rods and cocci after about 48 h of cultivation (Groth et al., 2006).

Differential characteristics for the two species are shown in Table 182. Strains grow at 10°C and 35°C and at pH 6 and 9. They do not grow at 42°C, and at pH 5 or 10. The strain from the salt marsh grows between 4°C and 50°C, between pH 4 and 13, and in up to 17.5% NaCl (w/v). The other strains grow in 2% or less NaCl. All strains decompose casein, xylan, esculin, gelatin, potato starch, and Tween 80, and they utilize acetate. Detailed analysis of physiological properties for the type strain strains of *Myceligenerans crystallogenes* and two additional strains and the type strain of *Myceligenerans xiligouense* are listed as supplementary data in the publication of Groth et al. (2006).

Enrichment and isolation procedures

The type strain of *Myceligenerans xiligouense* has been isolated from a pasture nearby an alkaline salt marsh in Qinghai province, western China, while strains of *Myceligenerans crystallogenes* originate from tufa and stone surface and from a fresco of two different Roman catacombs (Domitilla and San Callisto).

Strains were isolated by standard dilution plating. Strain DSM 15700[T] from the alkaline salt marsh was plated on Bacto Marine Broth agar, pH 7.2 at 28°C, while strains from stones and fresco were obtained on PY-BHI agar (Yokota et al., 1993), humic acid agar (Hayakawa and Nonomura, 1987), or on medium 79 (Prauser and Falta, 1968) at 28°C and neutral pH.

Maintenance procedures

Strains can be stored for some weeks on slants at 4°C and in 20% (w/v) glycerol suspensions at −20°C and at −80°C. Long-term preservation methods include freeze drying in skim milk and in liquid nitrogen at −196°C.

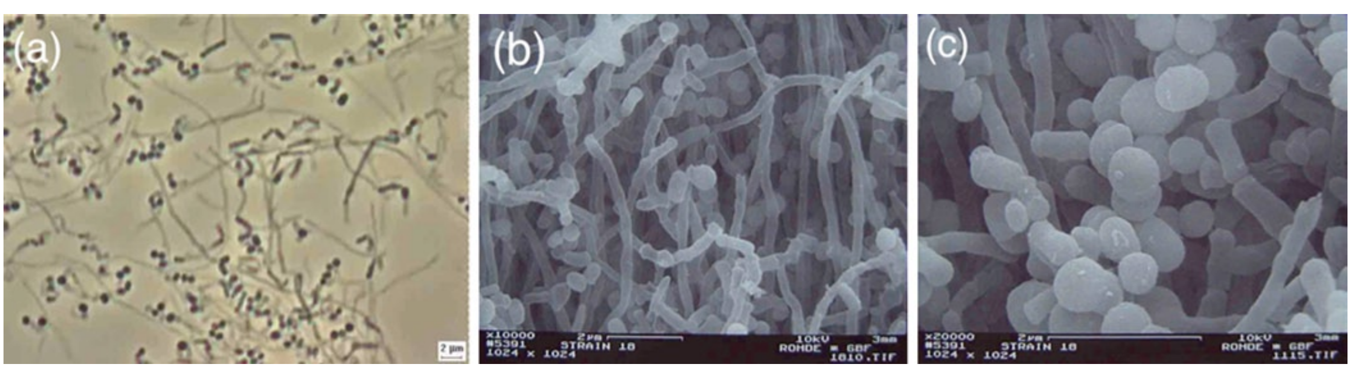

FIGURE 205. Micrographs of cells of *Myceligenerans xiligouense* DSM 15700[T] showing (a) the well-developed mycelia with abundant coccoid to rod-shaped spores on TSBA medium (7 d at 28°C) and (b) and (c) scanning electron micrographs. Differentiation of the genus *Myceligenerans* from other genera

Table 177 of the chapter *Promicromonosporaceae* indicates the characters useful in the differentiation of members of the genus *Myceligenerans* from other genera of the family *Promicromonosporaceae*. The use of 16S rRNA gene sequence analysis is recommended to affiliate new members to the genus, followed by determination of chemotaxonomic properties that circumscribe the genus.

List of species of the genus *Myceligenerans*

1. **Myceligenerans xiligouense** Cui, Schumann, Stackebrandt, Kroppenstedt, Xu, Rohde and Jiang 2004, 1292[VP]

xi.li.gou.en′se. N.L. neut. adj. *xiligouense* pertaining to Xiligou, a location in China where the type strain was isolated.

Gram-positive, aerobic, nonmotile, mycelium- and spore-forming microorganism. Colonies are brilliant yellow light (about 1–5 mm in diameter) on Bacto Marine Broth agar and yellowish (about 1.5–5 mm in diameter) on Tryptone Soy Broth agar (Difco) media after 7 d incubation at 28°C. Mycelia are well developed in and on the surface of the agar media. The tip of the mycelia bear fragmented cells and one to two coccoid nonmotile spores (0.5 μm in diameter). Grows between 4°C and 50°C and optimally between 20°C and 30°C; grows between pH 4 and 13 with optimal growth at pH values between 7 and 9; grows at salt concentrations between 2% and 8% (NaCl, w/v), with optimum growth between 2% and 7%.

The following compounds were utilized by all strains in API 50CHE tests: glycerol, L-arabinose, rhamnose, D-xylose, mannitol, arbutin, salicin, melibiose, melezitose, galactose, D-glucose, D-fructose, D-mannose, amygdalin, esculin, cellobiose, lactose, saccharose, trehalose starch, glycogen, D-lyxose, D-tagatose, D-turanose, L-arabitol, and D-arabitol. The following substrates were not utilized: erythritol, D-arabinose, ribose, L-xylose, adonitol, methyl-β-xyloside, L-sorbose, methyl-D-mannoside, methyl-α-D-glucoside, *N*-acetylglucosamine,

D-raffinose, D-fucose, gluconate, and 2-ketogluconate. The following compounds were utilized by all strains in BIOLOG GP2 tests: β-cyclodextrin, glycogen, mannan, Tween 40, Tween 80, amygdalin, D-arabitol, D-galacturonic acid, D-gluconic acid, D-lactose, lactulose, D-mannitol, D-mannose, D-melizitose, methyl D-galactoside, methyl D-glucoside, 3-methyl glucose, D-psicose, D-raffinose, D-ribose, sedoheptulose, D-sorbotil, stachyose, D-tagatose, D-trehalose, acetic acid, *p*-hydroxyphenylacetic acid, L-lactic acid, methyl pyruvate, propionic acid, pyruvic acid, succinamic acid, succinic acid, *N*-acetyl-L-glutamic acid, L-alaninamide, L-serine, 2,3-butanediol, 2′-deoxyadenosine, inosine, uridine, fructose 6-phosphate, glucose 1-phosphate, glucose 6-phosphate, and D-L-α-glycerol phosphate. Chemotaxonomic characteristics are as described for the genus.

Source: a pasture near an alkaline salt marsh, Qinghai Province, western China.

DNA G+C content (mol%): 71.9 (HPLC),

Type strain: XLG9A10.2, DSM 15700, CGMCC 1.3458, JCM 14112.

Sequence accession no. (16S rRNA gene): AY354285.

2. **Myceligenerans crystallogenes** Groth, Schumann, Schütze, Gonzalez, Laiz, Suihko and Stackebrandt 2006, 286[VP]

crys.tal.lo.ge′nes. Gr. n. *krustallos* crystal; Gr. v. *gennaio* to produce; N.L. part. adj. *crystallogenes* producing crystals of iodinin (1,6-phenazine-diol 5,10-dioxide).

Gram-positive, aerobic to microaerophilic actinomycete with a well-developed primary mycelium (diameter of hyphae 0.5–0.7 μm) that undergoes fragmentation into short, irregular, non-motile rods and cocci in the stationary growth phase. Aerial mycelium is absent. Spore-like cells occur in the substrate mycelium. Colonies on organic medium 79 are wrinkled, circular, smooth, and white to cream (diameter about 1–4 mm). Grows between 10°C and 40°C (optimal growth is at 28°C) and at pH values in the range 6–9. NaCl in the culture medium is well tolerated up to 5%. No growth at 8% NaCl. The type strain utilizes dextrin, D-cellobiose, α-ketovaleric acid, methyl pyruvate, pyruvic acid, and thymidine. Does not utilize glycogen, inulin, D-arabitol, arbutin, methyl-α-D-galactoside, methyl-α-D-glucoside, 3 methyl glucose, D-sorbitol, D-tagatose, L-lactic acid, propionic acid, L-alaninamide, uridine, thymidine 5′-monophosphate, and α- and β-hydroxybutyric acid. The major menaquinones are MK-9(H_8), MK-9(H_4), MK-9(H_6), and MK-9(H_2), and the minor menaquinones are MK-8(H_4), MK-9, and MK-8(H_2).

Source: the catacomb of Domitilla in Rome, Italy.

DNA G+C content (mol%): 72.0–72.3 (72.3 for the type strain; HPLC).

Type strain: CD12E2-27, HKI 0369, JCM 14326, DSM 17134, NCIMB 14061, VTT E-032285.

Genus V. **Xylanibacterium** Rivas, Trujillo, Schumann, Kroppenstedt, Sánchez, Mateos, Martínez-Molina and Velázquez 2004, 560[VP]

Encarna Velázquez, Martha E. Trujillo and Eustoquio Martínez-Molina

Xylanibacterium (Xy.la.ni.bac.te′ri.um N.L. neut. n. *xylanum* xylan, a polysaccharide; L. neut. n. *bacterium* small rod; N.L. neut. n. *Xylanibacterium* xylan hydrolyzing small rod).

Gram-stain-positive, non-spore forming small rod-shaped bacterium**.** Aerial mycelium is not formed. **Aerobic or facultatively anaerobic**, chemo-organotrophic and **xylanolytic bacterium.** Optimum temperature 30°C and pH 7. Oxidase-positive and catalase-negative. Phylogenetically related to members of the family *Promicromonosporaceae* on the basis of 16S rRNA gene sequence. **Peptidoglycan type is A4α, L-Lys–L-Ala–D-Glu**. The cell-wall sugars are **rhamnose in great amounts**, fucose, mannose, galactose and traces of arabinose and glucose. Major menaquinones are **MK-9(H_4)** and **MK-8(H_4).** Predominant fatty acids are $C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{16:0}$, and $C_{14:0}$. Mycolic acids are absent. The polar lipids are phosphatidylglycerol (PG), diphosphatidylglycerol (DPG), phosphatidylinositol (PI), and phosphatidylinositol mannosides (PIM).

DNA G+C content (mol%): 72.3 (T_m).

Type species: **Xylanibacterium ulmi** (Rivas, Trujillo, Schumann, Kroppenstedt, Sánchez, Mateos, Martínez-Molina and Velázquez 2004, 560[VP].

Further descriptive information

The genus *Xylanibacterium* is currently represented by a single species, *Xylanibacterium ulmi*, which was isolated from a decayed tree (*Ulmus nigra*). Cells of *Xylanibacterium ulmi* typically appear as nonmotile and non-sporulated rods and are 0.9 μm × 0.3 μm.

The cell-wall composition of *Xylanibacterium* is recorded in Table 183 and constitutes the main source of differences among the genera from family *Promicromonosporaceae*. The peptidoglycan composition of *Xylanibacterium* corresponds to the type A4α, L-Lys–L-Ala–D-Glu and coincides with that reported for genus *Promicromonospora* by Evtushenko et al. (1984), although Kalakoutskii et al. (1989) did not report glutamic acid in the peptidoglycan composition for *Promicromonospora*. The peptidoglycan of *Xylanibacterium* differs from the remaining genera encompassed within the family *Promicromonosporaceae*. The cell-wall sugars present in *Xylanibacterium* are rhamnose in high amounts, fucose, mannose, galactose and traces of arabinose and glucose. This profile is different to that presented by the remaining genera in the family *Promicromonosporaceae* although all genera of this family contain high amounts of rhamnose and galactose. The major polar lipids of the genus *Xylanibacterium* are phosphatidylglycerol (PG), diphosphatidylglycerol (DPG), phosphatidylinositol (PI), phosphatidylinositol mannoside (PIM) and other unidentified phosphoglycolipids (PGL) This profile is basically identical to that obtained for the genus *Xylanimonas* (Rivas et al., 2003) and differs from that of the remaining

genera of the family *Promicormonosporaceae*. Phosphatidylglycerol and diphosphatidylglycerol are present in all genera from this family but the presence of phosphatidylinositol mannoside was only reported in genus *Xylanimonas* (Rivas et al., 2003). The main fatty acid detected in *Xylanibacterium* is $C_{15:0}$ anteiso, followed by $C_{15:0}$ iso, $C_{14:0}$ and $C_{16:0}$ in lower amounts. According to the published data, this cellular fatty acid pattern is similar to that of *Xylanimicrobium pachnodae* (Stackebrandt and Schumann, 2004) but differs from that of the remaining genera of the family *Promicormonosporaceae*, although the main fatty acid in all these genera is also $C_{15:0}$ anteiso. The main menaquinone present in *Xylanibacterium* as well as in the remaining genera of family *Promicormonosporaceae* is MK-9(H_4), nevertheless MK-8(H_4) is also present in *Xylanibacterium* as well as in *Xylanimonas* (Rivas et al., 2003).

Cells of *Xylanibacterium ulmi* grow as white to cream colored colonies on XED (0.7% Xylan, 0.5% Yeast Extract, 2% Agar) medium that are smooth and mostly flat.

Xylanibacterium ulmi shows high xylanase and β-xylosidase activity, however no cellulase production has been observed. It utilizes a wide range of carbohydrates as carbon source which are listed in the species description.

Xylanibacterium is phylogenetically related to the family *Promicromonosporaceae* (Figure 202) and contains many of the nucleotide signatures as defined by Stackebrandt et al. (1997) and Stackebrandt and Schumann (2000). Nevertheless, *Xylanibacterium* presents five differences at nucleotide positions 384 (A for G), 648 (G for A), 615 (A for U), 624 (C for U), and 1263–1272 (G-C for A-U).

During the last decade *Ulmus nigra* trees were extensively affected by the Dutch elm disease in Spain. Consequently elm trees were eliminated from parks and gardens and the remaining stumps were reduced to a powdery material by the action of humidity. *Xylanibacterium ulmi* was isolated in Spain from one of these stumps.

Enrichment and isolation procedures

For isolation, a sample of wood decay from a stump of an elm tree was collected in aseptic conditions and 1 g was suspended in sterile water and stirred during 60 min. From this suspension, 100 μl were spread on XED medium (xylan, 0.7%; yeast extract, 0.3%; agar, 2.5%) and incubated at 28°C. This organism does not require special conditions to be cultivated although the best growth is obtained on solid media XED incubated at 28°C.

Maintenance procedures

Xylanibacterium ulmi can be maintained in the laboratory by transfer on the same medium used for isolation. For long-term conservation the recommended conditions are storage at −70°C in glycerol suspension (25%, v/v) or lyophilization in the presence of stabilizers such as 50% skim milk.

Procedures for testing special characters

Xylanases are detected on XED plates by direct visualization of hydrolysis haloes and cellulases are detected after 7 d incubation on plates containing 0.5% carboxymethylcellulose as the carbon source, 0.3% yeast extract and 1.5% agar. Plates are stained with a 1% Congo red water solution.

Differentiation of the genus *Xylanibacterium* from other genera

The genus *Xylanibacterium* can be differentiated from other genera of family *Promicromonosporaceae* by comparative analysis of 16S rRNA gene sequence as well as on the basis of chemotaxonomic characteristics recorded in Table 183.

Taxonomic comments

The genus *Xylanibacterium* was created to accommodate the single species *Xylanibacterium ulmi* which at the moment contains a single strain, XIL08 which is the type strain of this species (Rivas et al., 2004). The placement within the family *Promicromonosporaceae* is based on the 16S rRNA gene sequence signatures as well as chemotaxonomic analyses.

Acknowledgements

We thank June M. Brown and colleagues for providing information on the description of *Cellulosimicrobium funkei*.

List of species of the genus *Xylanibacterium*

1. **Xylanibacterium ulmi** Rivas, Trujillo, Schumann, Kroppenstedt, Sánchez, Mateos, Martínez-Molina and Velázquez 2004, 560[VP]

   ul′mi. L. masc. n. *ulmus* elm tree; L. gen. n. *ulmi* of the elm tree, referring to the isolation source of this micro-organism, rotten stump of an elm tree.

   Coccoid cells, 1.1 μm length and 0.8 μm in diameter. Nonmotile.

   Optimal growth in media containing 0.7% xylan as only carbon source. Optimal growth temperature 28°C.

   Xylanases, β-xylosidase and β-galactosidase are produced. Gelatinase production is weak. Esculin is hydrolysed. Nitrate reduction is negative. Arginine dehydrolase, caseinase, tryptophan deaminase or urease are not produced. Acetate, *N*-acetylglucosamine, L-arabinose, cellobiose, D-fructose, galactose, gentiobiose, gluconate, 2 and 5-ketogluconate, glycerol, L-lyxose, D-mannose, ribose, L-sorbose, sucrose, trehalose, D-turanose, xylitol, D-xylose and xylan are used as sole carbon sources. Adipate, adonitol, amygdalin, D-arabinose, D and L-arabitol, arbutin, caproate, citrate, dulcitol, erythritol, D and L-fucose, gluconate, glycogen, inositol, inulin, lactose, malate, maltose, mannitol, melibiose, melezitose, phenylacetate, raffinose, rhamnose, salicin, sorbitol, L-sorbose, starch, D-tagatose, L-xylose methyl α-D-glucoside, methyl α-D-mannoside, *N*-acetylglucosamine or methyl β-xyloside were not used as carbon sources.

Genus VI. **Xylanimicrobium** Stackebrandt and Schumann 2004, 1385[VP]

Peter Schumann and Erko Stackebrandt

Xy.la.ni.mi.cro′bi.um. N.L. neut. n. *xylanum* xylan, a polysaccharide; N.L. neut. n. *microbium* microbe; N.L. neut. n. *Xylanimicrobium* xylan (-hydrolyzing) microbe.

Gram-stain-positive, non-spore-forming, irregular rod-shaped cells, nonmotile, occurring singly or in pairs. Aerial mycelium not formed. Catalase, oxidase, and aminopeptidase-positive. **Xylanolytic**; facultative anaerobic, acid is produced from some carbohydrates. The murein contains the amino acids lysine, glutamic acid, and serine, belonging to the **peptidoglycan type A4α, variation D-Lys←L-Ser←D-Glu**. *N*-glycolylmuramic acid, mycolic acids, and hydroxy fatty acids are absent. Whole cell sugars are rhamnose, galactose, and glucose. The main **menaquinone is MK-9(H_4). Major fatty acid is $C_{15:0}$anteiso**. **Phospholipids are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol**, and three unknown phospholipids. Phylogenetically, the genus *Xylanimicrobium* is a member of the family *Promicromonosporaceae* with close relationship to *Xylanibacterium* and *Xylanimonas*.

DNA G+C content (mol%): 70.

Type species: **Xylanimicrobium pachnodae (**Cazemier, Verdoes, Reubsaet, Hackstein, van der Drift and Op den Camp 2004) Stackebrandt and Schumann 2004, 1385[VP] (*Promicromonospora pachnodae* Cazemier, Verdoes, Reubsaet, Hackstein, van der Drift and Op den Camp 2004, 1).

Further descriptive information

The genus *Xylanimicrobium* was established as member of the family *Promicromonosporaceae* as consequence of the reclassification of *Promicromonospora pachnodae* Cazemier et al., (2004) as *Xylanimicrobium pachnodae* (Stackebrandt and Schumann, 2004), which in turn was due to only moderate phylogenetic relationship and phenotypic differences when compared to *Promicromonospora citrea*, *Promicromonospora aerolata*, *Promicromonospora sukumoe*, and *Promicromonospora vindobonensis*. *Xylanimicrobium pachnodae* shares with its phylogenetic neighbors *Xylanibacterium ulmi* and *Xylanimonas cellulosilytica* the ability to produce xylanases. Growth of *Xylanimicrobium pachnodae* occurs under aerobic and under anaerobic conditions. Under aerobic conditions in basal medium II (see *Enrichment and isolation procedures*, below) with glucose (5 g/l) as carbon source, nocardioform mycelium-like fringes were formed which were not detected under anaerobic conditions. In the exponential phase of growth, the cells were pleomorphic rods, while in the stationary phase (after 48 h) coccobacilli dominated (Cazemier et al., 2004). *Xylanimicrobium pachnodae* contains a peptidoglycan of type A4α, variation L-Lys←L-Ser←D-Glu (A11.48, according to http://www.peptidoglycan-types.info). The cellular fatty acid profile consists of $C_{15:0}$ anteiso (58.7%), $C_{16:0}$ iso (8.5%), $C_{14:0}$ (8.0%), $C_{15:0}$ iso (6.8%), $C_{16:0}$ (6.1%), $C_{14:0}$ (5.5%), $C_{14:0}$ iso (3.9%), and $C_{17:0}$ anteiso (1.9%) (Cazemier et al., 2004).

Enrichment and isolation procedures

Xylanimicrobium pachnodae VPCX2[T] was isolated after enrichment of bacteria originating from flora of the hindgut of the rose chafer *Pachnoda marginata* larvae in the following media under aerobic and anaerobic conditions (Cazemier et al., 2004):

Medium I: peptone, 5 g/l; yeast extract, 2 g/l; K_2HPO_4, 1 g/l; $MgSO_4 \cdot 7H_2O$, 0.2 g/l; $Na_2S \cdot 9H_2O$, 0.16 g/l; cysteine, 0.32 g/l; Na_2CO_3, 10 g/l (sterilized separately); pH 10.3.

Medium II, modified from Yamin (1978): K_2HPO_4, 1.9 g/l; KH_2PO_4, 0.94 g/l; $NaHCO_3$, 1.68 g/l; KC1, 1.6 g/l; NaCl, 1.43 g/l; NH_4Cl, 0.15 g/l; $MgSO_4 \cdot 7H_2O$, 0.037 g/l; $CaC1_2 \cdot 2H_2O$, 0.017 g/l; yeast extract, 0.1 g/l; $Na_2S \cdot 9H_2O$, 0.16 g/l, and cysteine, 0.32 g/l; 0.2 ml/l trace element solution (Vishniac and Santer, 1957); pH 7–7.2.

Resazurin (0.0001%, w/v) was added as a redox indicator to the anaerobic media. Anaerobic incubations were usually performed in 50-ml serum bottles closed with butyl rubber stoppers and aluminum caps. The gas phase was N_2/CO_2 (80/20, at 0.5 atm overpressure). For cultivation under aerobic conditions $Na_2S \cdot 9H_2O$, cysteine, and resazurin were omitted from media I and II. In addition, $NaHCO_3$ was not added to medium II under aerobic conditions. Cultures were incubated on a rotary shaker (100 r.p.m.) at 30°C.

The hindgut suspension in medium I was plated on solidified medium II containing xylan (1 g/l) or carboxymethylcellulose (10 g/l). Colonies showing cellulolytic or hemicellulolytic activity and penetrating into the agar surface were selected for restreaking on medium II plates containing xylan or carboxymethylcellulose. Incubation under aerobic conditions resulted in a pure culture of strain VPCX2[T].

Maintenance procedures

For preservation, cells are serially transferred at 4-week intervals on medium 92 (http://www.dsmz.de) consisting of 30 g of trypticase soy broth, 3 g of yeast extract, and 15 g of agar per 1000 ml distilled water at 28°C, maintained at 4°C, and stored as 20% (w/v) glycerol suspensions at −20°C and at −80°C. Long-term preservation methods include freeze drying in skim milk and maintenance in liquid nitrogen at −196°C.

Differentiation of the genus *Xylanimicrobium* from other genera

The 16S rRNA gene sequence similarities of the type strain of *Promicromonospora pachnodae* strain VPCX2[T] (Cazemier et al., 2003) to those of *Promicromonospora citrea*, *Promicromonospora aerolata*, *Promicromonospora sukumoe*, and *Promicromonospora vindobonensis* are only in the range 95.5–96.1% whereas the authentic members of the genus *Promicromonospora* share similarity values between 98.4 and 99.2%. The closest phylogenetic neighbors of *Xylanimicrobium pachnodae* are *Xylanibacterium ulmi* XIL08[T] (Rivas et al., 2004) and *Xylanimonas cellulosilytica* XIL07[T] (Rivas et al., 2003), showing 16S rRNA gene sequence similarity of >97.5% (see Figure 202). This observation gave rise to search for additional differentiating characteristics to support the separate generic status of strain VPCX2[T]. These are, besides morphological differences to separate them from authentic *Promicromonospora* members, facultative anaerobic growth, a significantly lower metabolic activity, the absence of the fatty acid $C_{17:0}$ iso as well as the occurrence of L-serine instead of L-alanine in the peptidoglycan interpeptide bridge of strain VPCX2[T]. The peptidoglycan variation L-Lys←L-Ser←D-Glu differentiates *Xylanimicrobium pachnodae* from all members of the family *Promicromonosporaceae*. *Xylanimicrobium pachnodae* differs from its closest phylogenetic

neighbors *Xylanibacterium ulmi* and *Xylanimonas cellulosilytica* additionally in morphological characteristics, the absence of phosphatidylinositol mannosides, the absence of MK-8(H_4) as a minor isoprenoid quinone component (Table 177), and utilization of *N*-acetylglucosamine but not 5-ketogluconate (Stackebrandt and Schumann, 2004). *Xylanimicrobium pachnodae* differs from members of *Myceligenerans* in the lack of a primary mycelium and the presence of serine instead of threonine in the interpeptide bridge of peptidoglycan. It differs from *Cellulosimicrobium* species in the lack of a fragmenting primary mycelium and in the presence of glutamic acid, rather than aspartic acid, in the interpeptide bridge of peptidoglycan. Also, *Xylanimicrobium pachnodae* lacks $C_{16:0}$ iso as a major fatty acid.

List of species of the genus *Xylanimicrobium*

1. **Xylanimicrobium pachnodae** (Cazemier, Verdoes, Reubsaet, Hackstein, van der Drift and Op den Camp 2004) Stackebrandt and Schumann 2004, 1385[VP] (Basonym: *Promicromonospora pachnodae* Cazemier, Verdoes, Reubsaet, Hackstein, van der Drift and Op den Camp 2004.).

pach.no′da.e. N.L. gen. n. *pachnodae* of *Pachnoda* referring to the source of the micro-organism, *Pachnoda marginata*.

In addition to the properties given in the genus description, the description is that of *Promicromonospora pachnodae*, and data included in the publication of Cazemier et al. (2004), supplemented with data of Stackebrandt and Schumann (2004). In the exponential phase of growth, cells are pleomorphic rods (0.4–0.6 × 0.6–3.0 μm), whereas, in the stationary phase, spherical cells dominate (diameter 0.5–0.7 μm). Under aerobic conditions in basal medium II with glucose as carbon source, nocardioform mycelia-like fringes predominate; these forms are absent under anaerobic conditions. In rich media, cells are more homogeneously distributed. Aerobic to facultatively anaerobic, fermenting glucose, xylose, maltose, lactose (weak), and sucrose; fermentation products of glucose or xylose are formate, lactate, ethanol, and acetate but not succinate. Aerobically, cells grow with high densities in media with beach litter, NaOH-pretreated beach litter, xylan, carboxymethylcellulose, cellobiose, glucose, xylose, and brain heart infusion medium. Optimum growth at pH 7.5 and 35°C. Similar pH and temperature optima are found under anaerobic conditions. Nitrate reduction is positive, gelatin is hydrolyzed. Major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{14:0}$, and $C_{15:0}$ iso. The following compounds of the API 50 CHE gallery were used: glycerol, L-arabinose, D-xylose, D-lyxose, galactose, D-fructose, D-mannose, esculin, cellobiose, sucrose, trehalose, β-gentiobiose, D-turanose, acetate, *N*-acetylglucosamine, amygdalin, lactose, maltose, and tagatose. The following reactions are observed in the Biolog GP2 microtiter plate substrate panel (only strong positive reactions that are not already indicated for the API 50 CHE test are listed): glycogen, mannan, Tween 40, D-glucose, lactulose, methyl β-D-galactoside, 3-methyl glucose, methyl-α-D-glucoside, palatinose, D-psicose, D-ribose, methyl pyruvate, 2′-deoxyadenosine, inosine, uridine, adenosine 5′-monophosphate, thymidine 5′-monophosphate, fructose 6-phosphate, glucose 1-phosphate, and glucose 6-phosphate.

Source: intestine of the rose chafer *Pachnoda marginata* (Scarabaeidae, Coleoptera).

DNA G+C content (mol%): 70.0 (HPLC).

Type strain: VPCX2, DSM 12657, JCM 13526, NCCB 100020.

Sequence accession no. (16S rRNA gene): AF105422.

Genus VII. **Xylanimonas** Rivas, Sánchez, Trujillo, Zurdo-Piñeiro, Mateos, Martínez-Molina and Velázquez 2003, 102[VP]

Encarna Velázquez, Raúl Rivas and Pedro F. Mateos

Xy.la.ni.mo′nas. N.L. n. *xylanum* xylan a polysaccharide; Gr. fem. n. *monas* a monad, unit; N.L. fem. n. *Xylanimonas* a monad from xylan.

Gram-stain-positive, non-spore forming coccoid cells. Aerial mycelium is not formed. **Aerobic or facultatively anaerobic**, chemo-organotropic, **and xylanolytic.** Optimum temperature 30°C and pH 7. Oxidase-positive. Catalase weak positive. Phylogenetically related to members of the family *Promicromonosporaceae* on basis of the 16S rRNA gene sequence. **Peptidoglycan type is A4α, L-Lys–D-Asp.** Cell-wall sugars are **galactose and rhamnose.** Major menaquinones are **MK-9(H_4)** and **MK-8(H_4)**. Predominant fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso. Mycolic acids are absent. The polar lipids detected were phosphatidylglycerol (PG), diphosphatidylglycerol (DPG), phosphatidylinositol (PI), and phosphatidylinositol mannoside (PIM).

DNA G+C content (mol%): 73.

Type species: **Xylanimonas cellulosilytica** Rivas, Sánchez, Trujillo, Zurdo-Piñeiro, Mateos, Martínez-Molina and Velázquez 2003, 102[VP].

Further descriptive information

The genus is currently represented by a single species, *Xylanimonas cellulosilytica*, which was isolated from a decayed tree (*Ulmus nigra*). *Xylanimonas cellulosilytica* typically appears as nonmotile and non-sporulated coccoid cells that are 1.1 μm × 0.8 μm.

The cell-wall composition of *Xylanimonas cellulosilytica* (Table 177) differs from that of other genera in the family *Promicromonosporaceae*. The peptidoglycan type of *Xylanimonas* is A4α, L-Lys–D-Asp, which is identical to that reported for the genus *Isoptericola* (Stackebrandt et al., 2004). Nevertheless, it differs from the composition reported for the remaining genera within this family. Although other genera in the family *Promicromonosporaceae* contain high amounts of rhamnose and galactose, these are the principal cell-wall sugars of *Xylanimonas*. The major polar lipids of the genus *Xylanimonas* are phosphatidylglycerol (PG), diphosphatidylglycerol (DPG), phosphatidylinositol (PI), phosphatidylinositol mannoside (PIM), and other unidentified phosphoglycolipids (PGL). This profile is basically identical to that obtained for the genus *Xylanibacterium* (Rivas et al., 2004) but not for the remaining genera of the family *Promicromonosporaceae*. PG and DPG are present in all genera of this family, but PIM is present only in

the genus *Xylanibacterium* (Rivas et al., 2004). The main fatty acids detected in *Xylanimonas* are $C_{15:0}$ anteiso, $C_{15:0}$ iso, and $C_{14:0}$. According to the published data, this cellular fatty acid pattern differs from that of the remaining genera of the family *Promicromonosporaceae*, although $C_{15:0}$ anteiso is the main fatty acid in all genera of the family. The main menaquinone in all genera of the family *Promicromonosporaceae* is MK-9(H_4), but MK-8(H_4) is also present in *Xylanimonas* and *Xylanibacterium* (Rivas et al., 2004).

Colonies of *Xylanimonas cellulosilytica* on XED medium (0.7% xylan, 0.5% yeast extract, and 2% agar) are circular, convex, white, opaque, and usually 1–3 mm in diameter within 7 d at 28°C. *Xylanimonas cellulosilytica* shows high xylanase and cellulase activity. It utilizes a wide range of carbohydrates as carbon sources listed in the species description.

Xylanimonas is phylogenetically related to the family *Promicromonosporaceae* (Please refer to Figure 202 in the chapter on *Promonomicrosporaceae*) and contains many of the nucleotide signatures as defined by Stackebrandt et al. (1997) and Stackebrandt and Schumann (2000).

Enrichment and isolation procedures

For isolation, a sample of sawdust from a decayed tree, *Ulmus nigra*, was collected under aseptic conditions. One gram was suspended in sterile water and stirred 30 min. This suspension (100 µl) was spread on XED medium (xylan 0.7%, yeast extract 0.3%, and agar 2.5%) and incubated at 28°C. Cultivation of this organism does not require special conditions although growth is better on solid XED medium after incubation at 28°C.

Maintenance procedures

The organism can be maintained in the same medium used for isolation. For long-term conservation, the recommended conditions are storage at −70°C in 25% (v/v) glycerol or lyophilization in the presence of stabilizers such as 50% skim milk.

Procedures for testing special characters

Xylanases are detected on XED plates by direct visualization of hydrolysis haloes, and cellulases are detected after 7 d incubation on plates containing 0.5% carboxymethylcellulose as the carbon source, 0.3% yeast extract, and 1.5% agar. Plates are stained with a 1% aqueous Congo red.

Differentiation of the genus *Xylanimonas* from other genera

This genus can be differentiated from other related genera of family *Promicromonosporaceae* by comparative analysis of 16S rRNA gene sequences as well as on basis of chemotaxonomic and physiological characteristics (Table 177).

List of species of the genus *Xylanimonas*

1. **Xylanimonas cellulosilytica** (Rivas, Sánchez, Trujillo, Zurdo-Piñeiro, Mateos, Martínez-Molina and Velázquez 2003, 102[VP]

cel.lu.lo.si.ly′ti.ca. N.L. n. *cellulosum* cellulose; N.L. adj. *lyticus -a -um* (from Gr. adj. *lutikos -ê -on*) able to loosen, able to dissolve; N.L. fem. adj. *cellulosilytica* cellulose-dissolving.

Coccoid cells, 1.1 µm in length and 0.8 µm in diameter. Nonmotile. Grows optimally in media containing 0.7% xylan as carbon source. Optimal growth temperature is 28°C.

Amylases, cellulases, gelatinase, xylanases, and β-galactosidase are produced. Esculin is hydrolyzed. Nitrate reduction and acetoin production (Voges–Proskauer medium) are positive. Arginine dihydrolase, caseinase, indole, lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, and urease are negative. Arabinose, carboxymethylcellulose, mannose, maltose, rhamnose, starch, and xylan are used as sole carbon sources. No growth in acetate, adonitol, D-arabinose, citrate, dulcitol, erythritol, gluconate, inositol, inulin, malate, mannitol, raffinose, sorbitol, L-sorbose, L-xylose, methyl α-D-glucoside, methyl α-D-mannoside, *N*-acetylglucosamine or methyl β-D-xyloside. Acid production from amygdalin, L-arabinose, arbutin, cellobiose, fructose, galactose, gentobiose, glucose, glycerol, glycogen, lactose, lyxose, maltose, mannose, melezitose, rhamnose, salicin, sucrose, trehalose, turanose, and D-xylose.

Source: a stump of *Ulmus nigra* affected by the Dutch elm disease in Spain.

DNA G+C content (mol%): 73 (T_m).

Type strain: XIL07, CECT 5975, JCM 12276, LMG 20990.

Sequence accession no. (16S rRNA gene): AF403541.

Family XIII. **Rarobacteraceae** Stackebrandt and Schumann 2000, 1284^VP emend. Zhi, Li and Stackebrandt 2009, 598

Peter Kämpfer

Ra.ro.bac.te.ra.ce′a.e. N.L. masc. n. *Rarobacter* type genus of the family; L. suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Rarobacteraceae* the *Rarobacter* family.

The family *Rarobacteraceae* belongs to the order *Micrococcales* (reclassified for this volume from suborder *Micrococcineae* Stackebrandt, Rainey and Ward-Rainey 1997 of the class *Actinobacteria* Stackebrandt, Rainey and Ward-Rainey 1997.

Chemotaxonomically, the family is defined by peptidoglycan type A4β, MK-9(H_4) as predominant menaquinone and iso- and anteiso-branched cellular fatty acids. The pattern of 16S rRNA gene sequence signatures consists of nucleotides at positions: 120 (A), 131:231 (C–G), 196 (A), 342:347 (C–G), 444:490 (A–U), 580:761 (C–G), 602:636 (G–U), 670:736 (A–U), 822:878 (G–C), 823:877 (G–C), 826:874 (C–G), 827 (U), 843 (U), 950:1231 (U–A), 1047:1210 (G–C), 1109 (C), 1145 (G), 1309:1328 (G–C), 1361 (G), 1383 (C) (Zhi et al., 2009).

Type genus: **Rarobacter** Yamamoto, Sato, Saito, Hasuo, Tadenuma, Suzuki, Tamaoka and Komagata 1988, 10^VP.

Taxonomic comments

The family *Rarobacteraceae* Stackebrandt and Schumann (2000) was established to accommodate *Rarobacter* as the only genus because of its distinct phylogenetic position within the suborder *Micrococcineae* and the presence of a taxon-specific set of 16S rRNA signature nucleotides (Stackebrandt and Schumann, 2000). Phylogenetically, it is most closely related to the family *Sanguibacteraceae* Stackebrandt and Schumann 2000.

Genus I. **Rarobacter** Yamamoto, Sato, Saito, Hasuo, Tadenuma, Suzuki, Tamaoka and Komagata 1988, 10[VP]

Peter Kämpfer

Ra.ro.bac′ter. L. adj. *rarus* curious; N.L. masc. n. *bacter* masculine form from Gr. neut. n. *baktron* a rod; N.L. masc. n. *rarobacter* curious rod.

Cells are irregular rods, 0.2–0.3 × 0.8–1.0 μm. **Gram-stain-positive, but readily decolorized. Not acid-fast. Motile by multitrichous flagella.** Nonsporeforming. Optimal temperature is 30°C, and optimal pH is 6–8 for growth. **Facultatively anaerobic.** Chemo-organotrophic. **Mesophilic. Requires hemin of hemoproteins for growth.** Ammonium salts are utilized as nitrogen source, but nitrate is not utilized. Acid is produced aerobically and anaerobically from D-glucose and D-mannose, but not from L-arabinose or L-rhamnose. Organic acids studied thus far are not assimilated. Starch, casein, and gelatin are hydrolyzed, but cellulose is not hydrolyzed. Oxidase-positive. **Diamino acid of cell wall is L-ornithine. Amino acid composition of the cell-wall peptidoglycan is D-Ala, L-Ala, D-Glu, and L-Orn (and D-Ser) corresponding to type A4β.** Mycolic acids and cell-wall teichoic acids are lacking. Branching fatty acids of the iso and anteiso types ($C_{16:0}$ iso and $C_{15:0}$ anteiso) predominate. Major **menaquinone** is **MK-9(H_4)**.

The genus *Rarobacter* is the type genus of the family *Rarobacteraceae* in the order *Micrococcales*.

DNA G+C content (mol%): 64.6–66.1.

Type species: **Rarobacter faecitabidus** Yamamoto, Sato, Saito, Hasuo, Tadenuma, Suzuki, Tamaoka and Komgata 1988, 10[VP].

Further descriptive information

The genus *Rarobacter* was established by Yamamoto et al. (1988) to harbor what was at that time the only species, *Rarobacter faecitabitus*. It was described on the basis of four yeast-lysing bacteria from wastewater. One additional species, *Rarobacter incanus*, was described later (Goto-Yamamoto et al., 1993).

Members of the genus are yeast-lysing, facultatively anaerobic bacteria which require hemin or hemoproteins as essential factors for aerobic growth and carbon dioxide for anaerobic growth. Members of the genus *Rarobacter* form motile, irregular rods. Sometimes V-shaped elements are observed. Cells are motile by multitrichous flagella. *Rarobacter* cells can adhere to and agglutinate yeast cells and subsequently lyse them to utilize the digested cells as nutrients. A number of lytic enzymes have been identified, one of which recognizes mannose chains of mannoproteins (Hasuo et al., 1984). Strains of *Rarobacter faecitabidus* were isolated from wastewater treatment systems of alcoholic beverage factories (Yamamoto et al., 1988). Species are considered nonpathogenic, and they are characterized by the peptidoglycan variation A4β with L-ornithine as diagnostic diamino acid (Schleifer and Kandler, 1972) and unsaturated menaquinones with nine isoprenoid units. Branching fatty acids of the iso- and anteiso- types ($C_{16:0}$ iso and $C_{15:0}$ anteiso) are predominant. Colonies are pale-grayish cream and are usually circular, and convex. *Rarobacter faecitabitus* grows under aerobic conditions well on YM- catalase-agar containing 5 g yeast extract, 5.0 g malt extract, 5.74 g K_2HPO_4, 205 mg $MgSO_4 \cdot 7H_2O$, 1.15 g $NH_4H_2PO_4$, 60 mg catalase C-10 (Sigma), and 15 g of agar (Yamamoto et al., 1988). Strains of *Rarobacter incanus* grow under aerobic conditions at 28–30°C on TYMC agar containing 5 g trypticase peptone, 3.0 g yeast extract, 3.0 g malt extract, 5.8 g K_2HPO_4, 1.15 g $MgSO_4 \cdot 7H_2O$, 0.12 g catalase C-10 (Sigma), and 15 g agar per liter. Members of the genus *Rarobacter* were isolated from wastewater treatment systems of alcoholic beverage factories.

Phylogenetically, they are most closely related to *Sanguibacter* with 16S rRNA gene sequence similaries ranging from 94.6–95.5%. *Rarobacter faecitabitus* and *Rarobacter incanus* share approximately 96.8% 16S rRNA gene sequence similarity. The ranges of DNA–DNA similarity values between both species are below 40%. Species of the genus *Rarobacter* can be differentiated unambiguously by chemotaxonomic characteristics such as the amino acid compositions of the cell-wall peptidoglycan, the G+C content of the DNA, and catalase activity.

Enrichment and isolation procedures

The strains of *Rarobacter faecitabitus* and *Rarobacter incanus* were isolated from the wastewater of wastewater treatment systems of alcoholic beverage factories on YM-catalase agar and TYMC agar. (Goto-Yamamoto et al., 1993; Yamamoto et al., 1988). They have a requirement for hemin of hemoproteins.

Maintenance procedures

Serial transfers at 3-months intervals followed by maintenance at 4°C and storage of cells as 20% (w/v) glycerol suspensions at −20°C and at −80°C were suitable provisions for preservation. Long term preservation methods are freeze-drying in skim milk and maintenance in liquid nitrogen at −196°C.

Differentiation of the genus *Rarobacter* from other genera

Authentic members of the genus *Rarobacter* represent a distinct cluster within the phylogenetic tree of the family *Rarobacteraceae* (Stackebrandt and Schumann, 2000). The genus can be differentiated from the most closely related genus *Sanguibacter* by several chemotaxonomic features (Table 184).

TABLE 184. Characteristics differentiating *Rarobacter* and *Sanguibacter*[a,b]

Characteristic	*Rarobacter*	*Sanguibacter*
Diamino acid	L-Orn	L-Lys
Interpeptide bridge	Ser–Glu or Glu	Ser–D-Glu
Major menaquinone	MK-9	MK-9(H_4)
Predominant cellular fatty acids	$C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{14:0}$ (aerobic)	$C_{16:0}$, $C_{15:0}$ anteiso, $C_{18:0}$
DNA G+C content (mol%)	65–66	69–70

[a]Abbreviations: L-Orn, L-ornithine; L-Lys, lysine; Ser, serine; Glu, glutamic acid.
[b]Data from Goto-Yamamoto et al. (1993), Fernández-Garayzábal et al. (1995), and Pascual et al. (1996).

List of species of the genus *Rarobacter*

1. **Rarobacter faecitabidus** Yamamoto, Sato, Saito, Hasuo, Tadenuma, Suzuki, Tamaoka and Komagata 1988, 10[VP]

fa.e.ci.ta′bi.dus. L.fem.n. *faex*, *faecis* dregs; L.adj. *tabidus* dissolving; N.L. masc. adj. *faecitabidus* dreg dissolving.

In addition to the properties given in the genus description, the species has the following characteristics. Facultative anaerobic. Requires hemin or hemoproteins besides biotin and thiamine as growth factors in the aerobic condition. Requires carbon dioxide but not hemin or hemoproteins for anaerobic growth. Colonies on nutrient-catalase are pale yellow, opaque, circular, convex, entire, and smooth. Acid is produced aerobically and anaerobically from D-glucose, D-fructose, D-mannose, maltose, cellobiose, dextrin, arbutin, and salicin, but not from L-arabinose, L-rhamnose, D-galactose, L-sorbose, lactose, trehalose, raffinose, inulin, glycerol, erythritol, adonitol, mannitol, dulcitol, D-sorbitol, inositol, esculin, or α-methyl-D-glucoside. Hydrogen sulfide is not produced. DNase and urease are negative. Catalase positive. Amino acid composition of cell-wall peptidoglycan is D-Ala, L-Ala, D-Glu, L-Orn, and D-Ser (1:1:2:1:1). Adheres to viable yeast cells of genera *Saccharomyces* and *Hansenula*, agglutinates with them, and lyses them.

DNA G+C content (mol%): 65.7–66.1 (HPLC).

Type strain: YLM-1, ATCC 49628, CIP 103380, DSM 4813, NBRC 14760, JCM 6097.

Sequence accession no. (16S rRNA gene): AB056127, Y17870.

2. **Rarobacter incanus** Goto-Yamamoto, Sato, Miki, Park and Tadenuma 1994, 370[VP] (Effective publication: Goto-Yamamoto, Sato, Miki, Park and Tadenuma 1993, 274.)

in.ca′nus. L. masc. adj. *incanus* grayish white.

In addition to the properties given in the genus description, the species has the following characteristics. Hemin or hemoproteins are required as growth factors under aerobic condition. Carbon dioxide but not hemin or hemoproteins are required for anaerobic growth. Colonies on nutrient-catalase agar are pale grayish cream, opaque, circular, convex, entire, and smooth. Acid is produced aerobically and anaerobically from D-glucose, D-fructose, D-mannose, maltose, dextrin, arbutin and salicin, but not from L-arabinose, L-rhamnose, D-galactose, L-sorbose, lactose, trehalose, raffinose, inulin, glycerol, erythritol, adonito, mannitol, dulcitol, D-sorbitol, or α-methyl-D-glucoside. Type strain does not produce hydrogen sulfide, and produces acid from cellobiose, however, some strains produce hydrogen sulfide, and do not produce acid from cellobiose. DNase, urease, and catalase were negative. Amino acid composition of cell-wall peptidoglycan is D-Ala–L-Ala–D-Glu–L-Orn (1:1:2:1 ratio). Adheres to viable yeast cells of the genera *Saccharomyces* and *Hansenula*, agglutinates with them, and lyses them. The other description of the type strain is the same as that of the species *Rarobacter incanus*.

DNA G+C content (mol%): 64.6–65 (HPLC).

Type strain: YLM-32, ATCC 51544, CIP 104132, DSM 10596, NBRC 16558, JCM 6350, NBRC 101357.

Sequence accession no. (16S rRNA gene): AB056129.

Family XIV. **Ruaniaceae** Tang, Zhi, Wang, Wu, Lee, Kim, Lou, Xu and Li 2010, 2118[VP]

Shu-Kun Tang, Xiao-Yang Zhi and Wen-Jun Li

Ru.a.ni.a.ce′a.e. N.L. fem. n. *Ruania* type genus of the family; suff. -*aceae* ending to denote a family; N.L. fem. pl. n. *Ruaniaceae* the *Ruania* family.

The family *Ruaniaceae* was circumscribed for this volume based mainly on signature nucleotide patterns and phylogenetic criteria; the family contains the genera *Ruania* and *Haloactinobacterium*. Members of the family *Ruaniaceae* are Gram-stain-positive, aerobic and facultatively anaerobic, nonmotile, halophilic or halotolerant, and short rod or coccoid actinobacteria. MK-8(H_4) is the predominant menaquinone and A4α is the peptidoglycan type. The pattern of 16S rRNA signature nucleotides is shown in Table 185.

DNA G+C content (mol%): 68–70.

Type genus: **Ruania** Gu, Paściak, Luo, Gamian, Liu and Huang 2007, 811[VP].

Taxonomic comments

The genus *Ruania* was first proposed by Gu et al. (2007), but it was not classified within a family in the suborder *Micrococcineae*, now order *Micrococcales*. Another novel genus *Haloactinobacterium*, also now in the order *Micrococcales*, was established by Tang et al. (2010).

Representatives of known families in the order *Micrococcales* showed 16S rRNA gene sequence similarities to those of the genera *Ruania* and *Haloactinobacterium* of between 92.0 and 95.2%. Although the genera *Ruania* and *Haloactinobacterium* clearly belong to the order *Micrococcales*, they did not belong to any of the previously described families. Comparative 16S rRNA gene sequence analysis showed that the genera *Ruania* and *Haloactinobacterium* formed a deep branch that could be clearly distinguished from members of other described families (Figure 206). The 16S rRNA gene sequences of 15 families of the suborder *Micrococcineae* (Zhi et al., 2009), in this volume reclassified as the order *Micrococcales*, and the genera *Ruania* and *Haloactinobacterium* were scanned for the signature nucleotide patterns (Table 185). However, only one difference was found between the genera *Ruania* and *Haloactinobacterium*: at position 602:636 *Haloactinobacterium* has a C–G pair and *Ruania* has a G–U pair. However, members of both genera have many unique 16S rRNA gene signature nucleotides compared to the known family lineages (Table 185). There is only one unique signature: C–U at 444:490. All other signatures were found in at least one other family of the order *Micrococcales*. Higher hierarchical taxa in the class *Actinobacteria* are defined based mainly on signature nucleotide patterns and phylogenetic criteria (Stackebrandt et al., 1997; Zhi et al., 2009). Accordingly, the genera *Ruania* and *Haloactinobacterium* are phylogenetically closely related and are clearly distinct from members of other families in the order *Micrococcales*. Thus, the novel family *Ruaniaceae* was proposed to accommodate the genera *Ruania* and *Haloactinobacterium* (Tang et al., 2010).

[b]*Yaniella* is now classified within the *Micrococcaceae* and is shown for comparison.

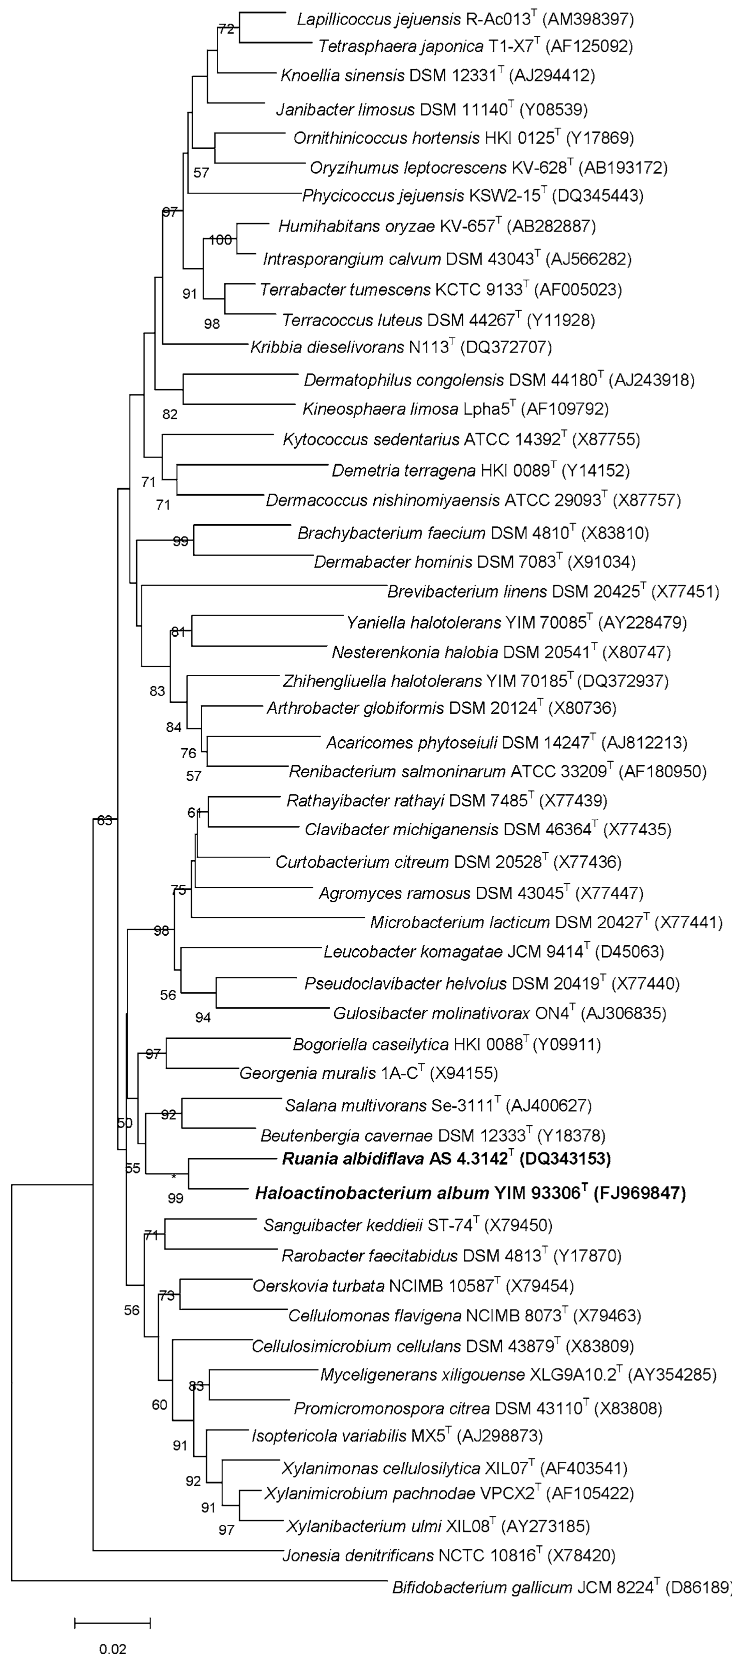

FIGURE 206. Phylogenetic dendrogram obtained by distance matrix analysis of 16S rRNA gene sequences showing the position of the genera *Ruania* and *Haloactinobacterium* and their phylogenetic neighbors. Asterisks indicate branches of the tree that were also found using the maximum-likelihood (Felsenstein, 1981) and maximum-parsimony (Fitch, 1971) tree-making algorithms. Numbers at nodes indicate levels of bootstrap support (%) based on a neighbor-joining analysis of 1000 resampled datasets (1000 resamplings, only values over 50% are given). The sequence of *Bifidobacterium gallicum* JCM 8224^{T} (D86189) was used as an outgroup. Bar = 0.2 substitutions per nucleotide position.

Genus I. **Ruania** Gu, Paściak, Luo, Gamian, Liu and Huang 2007, 811[VP]

Hans-Jürgen Busse

Ru.a.n′i.a. N.L. fem. n. *Ruania* named after Ji-Sheng Ruan, a Chinese microbiologist who has made great contributions to the development of actinomycete taxonomy in China.

Gram-stain-positive, aerobic, mesophilic, moderately halotolerant, non-acid-fast, nonmotile, non-spore-forming cocci. The rod–coccus life cycle is not detected. The **peptidoglycan type is A4α** with an **L-Lys–Gly–L-Glu–L-Glu interpeptide bridge**. The predominant menaquinone **is MK-8(H_4)**. The **main fatty acid is $C_{15:0}$ anteiso**. The major **polar lipids are phosphatidylglycerol, diphosphatidylglycerol**, and one **unknown glycolipid**. Mycolic acids are absent. Phylogenetically, the genus belongs to the order *Micrococcales*.

DNA G+C content (mol%): 69.8.

Type species: **Ruania albidiflava** Gu, Paściak, Luo, Gamian, Liu and Huang 2007, 812[VP].

Further descriptive information

The single species of the genus *Ruania*, *Ruania albidiflava* has been identified as a member of the suborder *Micrococcineae*, now order *Micrococcales* in the taxonomic outline to the present volume, based on its phylogenetic position (Gu et al., 2007) and the genera *Georgenia* and *Bogoriella* were identified as nearest related genera. The species shares with representatives of these two genera the peptidoglycan type A4α, which is based on the presence of the diamino acid L-lysine and an interpeptide bridge containing a dicarboxylic amino acid (L-glutamic acid), a quinone system with the predominant compound MK-8(H_4), a fatty acid profile with $C_{15:0}$ anteiso as the major compound, a polar lipid profile containing among other components diphosphatidylglycerol and phosphatidylglycerol, and a similar G+C content (70 mol%). Hence, this genus was initially considered as a member of the *Bogoriellaceae* (Stackebrandt and Schumann, 2000). Subsequent analyses suggested that it should be placed in a novel family, *Ruaniaceae* (Tang et al., 2010).

Differentiation of the genus *Ruania* from related genera

The genus *Ruania* is so far represented by a single species, *Ruania albidiflava*, which can be distinguished from its close phylogenetic relatives in the genera *Beutenbergia*, *Bogoriella*, *Georgenia*, and *Salana* by a set of signature nucleotides in the 16S rRNA coding gene (Table 185), differences in the interpeptide bridge of the peptidoglycan, and differences in the major fatty acid profile components (Table 186).

Enrichment and isolation procedures

Enrichment of *Ruania* may be done at approximately 28°C on R-agar* (Yamada and Komagata, 1972), nutrient agar, or trypticase soy agar. Isolation from soil can be done on yeast extract-starch agar (JCM medium no. 42) incubated for 1 week under humid conditions at 28°C.

Pathogenicity

No reports on pathogenicity have been found in the literature.

Maintenance procedures

Cultures of *Ruania albidiflava* can be maintained on nutrient agar slants at 4°C.

TABLE 186. Differential characteristics of the genera *Ruania*, *Beutenbergia*, *Borgoriella*, *Georgenia*, and *Salana*

1. **Ruania albidiflava** Gu, Paściak, Luo, Gamian, Liu and Huang 2007, 812[VP]

   al.bi.di.fla′va. L. adj. *albidus* white; L. fem. adj. *flava* yellow; N.L. fem. adj. *albidiflava* whitish yellow.

   Cells are 0.5–0.8 µm in diameter. Colonies are convex, moist, and pale yellow in color. Growth occurs at 20–37°C, with an optimum at 28°C, and at a wide initial pH range of 5.5–12.5, with an optimum at pH 6.5–10.5. Can tolerate up to 10% (w/v) NaCl. Catalase-positive, oxidase-negative. The methyl red test is positive, but indole and Voges–Proskauer reactions are negative. Nitrate is reduced to nitrite. H_2S is not produced. Potato starch is decomposed, but adenine, casein, esculin, gelatin, hippurate, hypoxanthine, tyrosine, urea, and xanthine are not. Acid is produced from arbutin, salicin, D-ribose, methyl β-D-xylopyranoside, D-fructose, esculin, maltose, D-arabinose, L-arabinose, D-xylose, L-rhamnose, D-lyxose, and L-fucose, but not from glycerol, erythritol, L-xylose, D-adonitol, D-galactose, D-glucose, D-mannose, L-sorbose, dulcitol, inositol, D-mannitol, D-sorbitol, methyl α-D-mannopyranoside, methyl α-D-glucopyranoside, *N*-acetylglucosamine, amygdalin, D-cellobiose, D-lactose, melibiose, sucrose, trehalose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, D-turanose, D-tagatose, D-fucose, DL-arabitol, potassium 2-ketogluconate, or potassium 5-ketogluconate. Utilizes the following substrates as sole carbon sources: acetate, D-lactose, melezitose, L-alanine, L-cysteine, L-leucine, L-methionine, L-proline, methyl α-D-glucoside, oxalate, D-fructose, D-glucose, D-glutamic acid, maltose, D-ribose, D-sorbitol, trehalose, glycerol, L-arginine, L-fucose, and sucrose. The following substrates are not utilized: citrate, cellobiose, D-galactose, D-inulin, D-lactulose, D-mannitol, D-mannose, raffinose, D-rhamnose, D-sorbose, D-xylose, dulcitol, erythritol, glycogen, inositol, L-arabinose, L-leucinamide, L-ornithine, L-phenylalanine, L-tyrosine, L-valine, malate, malonate, nicotinamide, salicin, and succinate. In the API ZYM assay, tests are positive for cystine arylamidase, α-fucosidase, alkaline phosphatase, esterase lipase (C8), leucine arylamidase, valine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, and α-mannosidase, but negative for esterase (C4), lipase (C14), trypsin, chymotrypsin, and β-glucuronidase. Cells are susceptible to ampicillin (10 µg), chloramphenicol (30 µg), ciprofloxacin (5 µg), erythromycin (15 µg), gentamicin (10 µg), kanamycin (30 µg), neomycin (30 µg), polymyxin B (300 IU), rifampin (15 µg), and streptomycin (10 µg). Not susceptible to nitrofurantoin (300 µg) or oxacillin (1 µg). Whole-cell sugars are galactose and glucose. Other chemotaxonomic characteristics are as described for the genus.

   Source: isolated from farmland soil collected in Shandong Province, China.

   DNA G+C content (mol%): 69.8 (T_m).

   Type strain: 3-6, CGMCC 4.3142, DSM 18029, JCM 13910, PCM 2644.

   Sequence accession no. (16S rRNA gene): DQ343153.

Genus II. **Haloactinobacterium** Tang, Zhi, Wang, Wu, Lee, Kim, Lou, Xu and Li 2010, 2118[VP]

Shu-Kun Tang, Xiao-Yang Zhi and Wen-Jun Li

Ha.lo.ac.ti.no.bac.te′ri.um. Gr. n. *hals*, *halos* salt; Gr. n. *actis*, *actinos* a ray; L. neut. n. *bacterium* a rod; N.L. neut. n. *Haloactinobacterium* a halophilic actinobacterium.

Short rods. Gram-stain-positive. Nonmotile. Moderately halophilic. Facultatively anaerobic in the presence of KNO_3. The peptidoglycan is type A4α with L-Lys–L-Glu interpeptide bridges.

DNA G+C content (mol%): 68–69.

Type species: **Haloactinobacterium album** Tang, Zhi, Wang, Wu, Lee, Kim, Lou, Xu and Li 2010, 2118[VP].

Further descriptive information

Phylogenetic analysis of the 16S rRNA gene sequence places the genus within the family *Ruaniaceae*, order *Micrococcales*. Its closest relative is *Ruania albidiflava*. The peptidoglycan is type A4α with L-Lys–L-Glu interpeptide bridges. The whole-cell sugars are glucosamine, arabinose, mannose, and two unknown sugars. The predominant menaquinone is MK-8(H_4). The polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, one unknown phosphoglycolipid, and one unknown phospholipid. The major fatty acids are $C_{15:0}$ iso, $C_{15:0}$ anteiso, and $C_{17:0}$ anteiso.

Isolation procedures

The only species in the genus was isolated from a soil sample collected from Qijiaojing Lake, which is a salt lake in Xinjiang province, north-west China (GPS coordinates for the sampling site are 43°26′48″N 91°29′13″E), after 3 weeks incubation at 37°C on glucose-tryptone-yeast (GTY) medium, consisting of 1.0 g/l glucose, 0.5 g/l tryptone, 2.0 g/l yeast extract, 1.0 g/l $CaCl_2$, 100.0 g/l NaCl, and 15.0 g/l agar, final pH not adjusted. The NaCl was sterilized separately before being added to the medium.

Maintenance procedures

The type strain was maintained on GTY agar slants at 4°C and in 20% (v/v) glycerol suspensions of well-grown liquid cultures and stored frozen at −80°C or in liquid nitrogen.

Differentiation of the genus *Haloactinobacterium* from other genera

Table 187 lists characteristics that differentiate between *Haloactinobacterium* and its relative *Ruania albidiflava*, which is the sole recognized species of the genus *Ruania*. *Haloactinobacterium* is a halophilic bacterium and this characteristic distinguishes it from *Ruania*. In addition, the whole cell sugars, interpeptide bridge of the peptidoglycan, polar lipids, and the major fatty acids further distinguish the two genera.

TABLE 187. Features differentiating *Haloactinobacterium* and *Ruania*[a]

Characteristic	*Haloactinobacterium album* YIM 93306[T]	*Ruania albidiflava* AS 4.3142[T]
Cell morphology	Rods	Coccoid
Color of colonies	Cream white	Pale yellow
Facultative anaerobe	+	–
Growth in NaCl:

[a]Data were taken from Gu et al. (2007) and Tang et al. (2010).

List of species of the genus *Haloactinobacterium*

1. **Haloactinobacterium album** Tang, Zhi, Wang, Wu, Lee, Kim, Lou, Xu and Li 2010, 2118[VP]

al′bum. L. neut. adj. *album* white.

Cells are short rods (0.3–0.4 × 0.6–0.7 µm). Colonies are cream white, circular, smooth, opaque, and non-pigmented on GTY agar containing 10% NaCl. Temperature, pH, and NaCl tolerances ranges for growth are 10–40°C, pH 6.0–10.0, and 2–16% (w/v), respectively, and optimal growth occurs at 37°C, pH 7.0–8.0, and 7–10% (w/v) NaCl. Catalase-positive. Oxidase, methyl red, and Voges–Proskauer tests are negative. Cellulose and esculin are hydrolyzed. Gelatin, casein, dextrin, starch, DNA, chitin, urea, and Tweens 20, 40, 60, and 80 are not hydrolyzed. H_2S, melanin, and indole production are negative. In the API ZYM system, positive for esterase (C4), esterase lipase (C8), cystine arylamidase, β-galactosidase, β-glucosidase, α-mannosidase, and *N*-acetyl-β-glucosaminidase, but negative for alkaline phosphatase, leucine arylamidase, valine arylamidase, trypsin, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, β-glucuronidase, α-glucosidase, lipase (C14), α-galactosidase, and α-fucosidase. The following substrates are oxidized on Biolog microplates GP2: D-fructose, L-fucose, methyl β-D-galactoside, D-psicose, α-D-glucose, maltose, D-mannose, D-ribose, sucrose, D-xylose, pyruvic acid, L-arabinose, D-galactose, pyruvic acid methyl ester, DL-α-glycerolphosphate, L-lactic acid, acetic acid, glycerol, and amygdalin. Acid is produced from glycerol, erythritol, DL-arabinose, D-ribose, D-xylose, D-adonitol, methyl β-D-xylopyranoside, D-galactose, D-glucose, D-fructose, D-mannose, L-rhamnose, *N*-acetylglucosamine, esculin, salicin, cellobiose, maltose, D-turanose, D-tagatose, and L-fucose, but not from amygdalin, DL-arabitol, arbutin, dulcitol, D-fucose, gentiobiose, glycogen, inositol, inulin, D-lactose, D-lyxose,

D-mannitol, melezitose, melibiose, raffinose, D-sorbitol, L-sorbose, starch, L-xylose, methyl α-D-mannopyranoside, methyl α-D-glucopyranoside, xylitol, sucrose, trehalose, potassium 5-ketogluconate, potassium gluconate, or potassium 2-ketogluconate. Cellular fatty acid profile contains branched fatty acids as major components and straight fatty acids as minor components: $C_{15:0}$ iso (33.1%), $C_{15:0}$ anteiso (34.4%), $C_{16:0}$ iso (2.3%), $C_{16:0}$ (2.1%), $C_{15:0}$ iso 3-OH (0.9%), $C_{15:0}$ iso 2-OH (0.9%), $C_{17:0}$ (8.7%), and $C_{17:0}$ anteiso (14.8%). Other fatty acids were present in amounts less than 0.5%. For all other characteristics, refer to the genus description.

Source: isolated from a soil sample collected from Qijiaojing Lake, a salt lake in Xinjiang province, north-west China.

DNA G+C content (mol%): 68–69 (HPLC).

Type strain: YIM 93306, DSM 21368, KCTC 19413, CCTCC AB 208069.

Sequence accession no. (16S rRNA gene): FJ969847.

Family XV. **Sanguibacteraceae** Stackebrandt and Schumann 2000, 1284[VP]

Cristina Pascual Ramos and José Francisco Fernández-Garayzábal

San.gui.bac.te.ra.ce′a.e. N.L. masc. n. *Sanguibacter* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Sanguibacteraceae* the *Sanguibacter* family.

Cells consist of regular or irregularly shaped **short rods**. **Gram-stain-positive**. Nonsporeforming. **Motile**. **Aerobic or facultatively anaerobic**. **Catalase-positive**.

The **cell-wall murein** is of the type **A4α** (L-Lys–Ser–D-Glu) and the **major menaquinone** is **MK-9(H_4)**. The cellular **fatty acid profile** consists mainly of **anteiso-methyl-branched chain and straight-chain saturated components**. Species have been isolated from animals and the environment; they have been not associated with diseases in humans or animals.

The pattern of 16S rRNA gene signatures that describe the above–mentioned family consists of nucleotides at position 69:99 (G–U), 140:223 (G–C),144:178 (C–G), 248:276 (C–G), 258:268 (A–U), 379:384 (C–G), 407:435 (A–U), 502:543 (G–C), 586:755 (C–G), 589:650 (U–A), 602:636 (G–U), 610 (U), 612:628 (U–A), 615:625 (A–U), 616:624 (G–C), 630 (C), 668:738 (U–A), 839:847 (U–A), 863 (U), 1133:1141 (A–U) and 1134:1140 (C–G).

DNA G+C content (mol%): 69.5–73.4.

Type genus: **Sanguibacter** Fernández-Garayzábal, Domínguez, Pascual, Jones and Collins 1995b, 619[VP] (Effective publication: Fernández-Garayzábal, Domínguez, Pascual, Jones and Collins 1995a, 73.).

Further descriptive information

The family *Sanguibacteraceae* contains the single genus *Sanguibacter*. It was proposed on the basis of 16S rRNA gene sequence data and the presence of specific signature nucleotides (Stackebrandt and Schumann, 2000). However, it should be noted that the recently described species *Sanguibacter antarcticus*, *Sanguibacter marinus*, and *Sanguibacter soli* do not display the signature nucleotides at positions 258:268 (G–C instead of A–U); *Sanguibacter marinus* and *Sanguibacter soli* do not display the signature nucleotides at positions 140:223 (C–G instead of G–C), 407:435 (A–C instead of A–U); *Sanguibacter antarcticus* and *Sanguibacter soli* do not display the signature nucleotide at position 863 (A instead of T).

The phylogenetic position of the family *Sanguibacteraceae* in relation to the *Cellulomonadaceae*/*Promicromonosporaceae* clade is not clear as demonstrated by low bootstrap values (see Figure 207). However, the close relatedness between these three families is also supported by chemotaxonomic traits such as quinone systems and cellular fatty acid profiles (see Table 188).

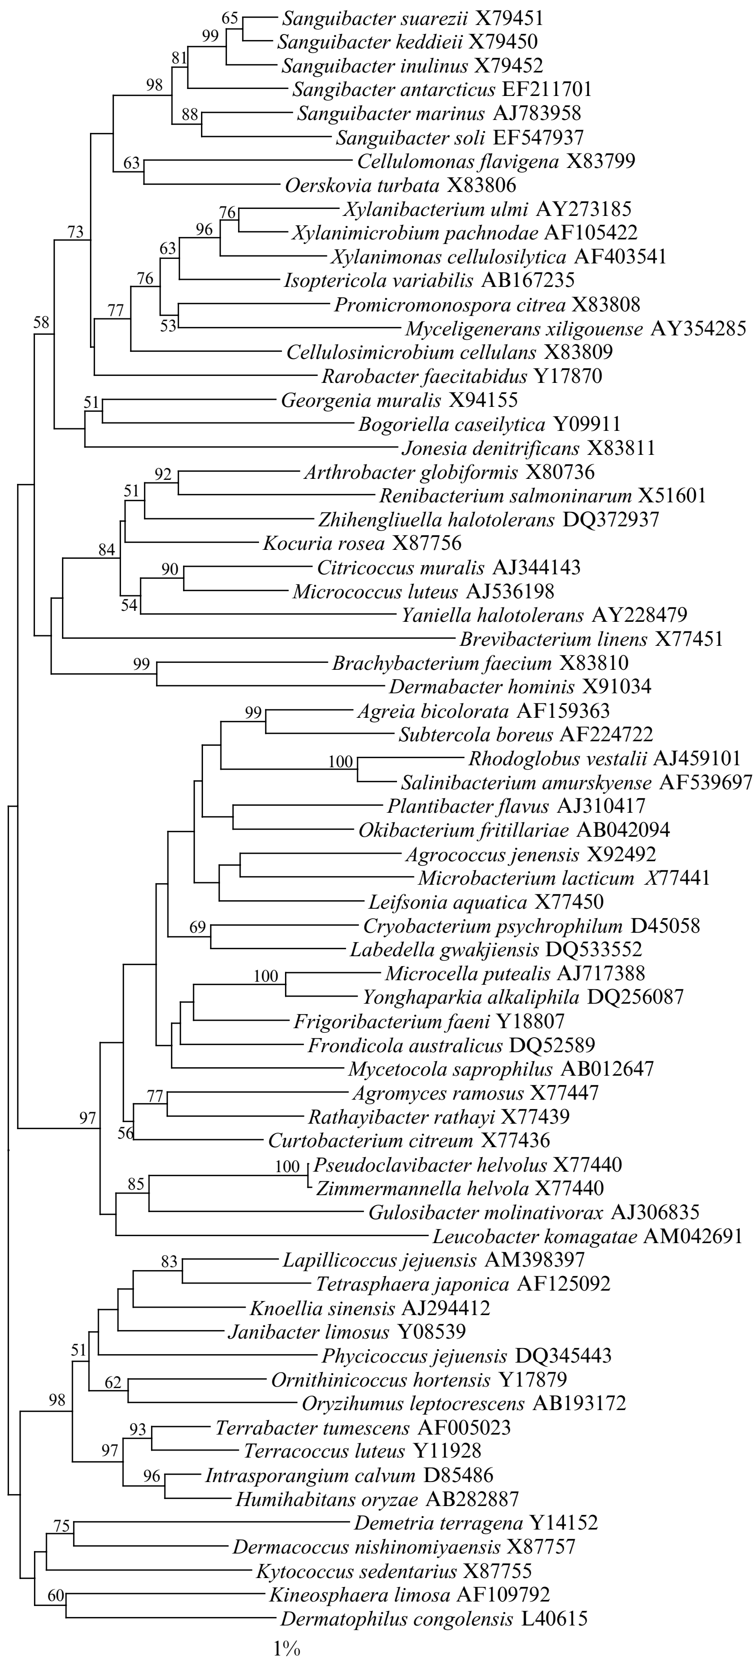

FIGURE 207. 16S rRNA gene sequence-based phylogenetic tree reconstructed from evolutionary distances by the neighbor-joining method (Saitou and Nei, 1987) showing the phylogenetic position of the family *Sanguibacteraceae* in relation to representatives of the order *Micrococcales*. Numbers at branching points refer to bootstrap values (1000 trees resampled); only values above 50% are indicated. Scale bar, 1 inferred nucleotide substitutions per 100 nucleotides.

TABLE 188. Characteristics differentiating the genus *Sanguibacter* from other phylogenetically related genera of the order *Micrococcales*

San.gui.bac′ter. L. n. *sanguis*, *-inis* blood; N.L. masc. n. *bacter* a rod; N.L. masc. n. *Sanguibacter* (*sic*) a blood rod.

Species of the genus share the characteristics listed in the family description. Not hemolytic on sheep blood agar. Esculin is hydrolyzed. Acid is produced from glycogen, sucrose, D-cellobiose, D-fructose, D-glucose, L-arabinose, D-maltose, D-trehalose, and D-xylose. Acid is not produced from dulcitol, erythritol, inositol, xylitol, D-adonitol, D-arabitol, D-arabinose, D-fucose, D-melezitose, D-tagatose, and L-sorbose.

DNA G+C content (mol%): 69.5–73.4.

Type species: **Sanguibacter keddieii** Fernández-Garayzábal, Domínguez, Pascual, Jones and Collins 1995b, 619[VP] (Effective publication: Fernández-Garayzábal, Domínguez, Pascual, Jones and Collins 1995a, 74.).

Further descriptive information

Phylogeny. The genus *Sanguibacter* was proposed in 1995 on the basis of 16S rRNA gene sequence analysis (Fernández-Garayzábal et al., 1995a) and depending on the outgroups, the species, and/or the tree-making algorithms selected, it appeared phylogenetically related to the cellulomonad/oerskoviae/promicromonosporae clade or to the LL-diaminopimelic-containing genera *Terrabacter tumescens*, *Terracoccus luteus*, and *Intrasporangium calvum* (Fernández-Garayzábal et al., 1995a). With the inclusion of numerous genera in the rapidly growing suborder *Micrococcineae*, the genus *Sanguibacter* constitutes a tight monophyletic group (maximum 4.0% 16S rRNA gene sequence divergence) with chemotaxonomic coherence and a polyamine pattern unique among taxa of the suborder *Micrococcineae* (Busse and Schumann, 1999), elevated to order Microoccales in the taxonomic outline for the present volume, branching within the vicinity of the *Cellulomonas*/*Oerskovia*/*Pro micromonospora* clade.

Three species isolated from blood of apparently healthy cows (*Sanguibacter keddieii*, *Sanguibacter inulinus*, and *Sanguibacter suarezii*) are forming a subclade within the *Sanguibacter* branch (Figure 207). The species *Sanguibacter marinus* and *Sanguibacter soli* form another tight subclade, while *Sanguibacter antarcticus*, isolated from sea sand of Antarctica, constitutes a distinct line that branches at the periphery of the *Sanguibacter keddieii* subcluster.

Chemotaxonomy. *Sanguibacter* species display a cell-wall murein of the A4α type, variation L-Lys–Ser–D-Glu: the diamino acid and the amino acid at position 1 of the peptidoglycan peptide side chain is L-lysine and L-alanine, respectively, and the interpeptide bridge consists of serine and D-glutamic acid (Fernández-Garayzábal et al., 1995a). Mycolic acids are not detected. Polyamine analysis shows members of the genus *Sanguibacter* to possess spermine as the predominant compound and, when compared to members of the family *Intrasporangiaceae*, a significantly reduced amount of putrescine (Busse and Schumann, 1999). Similar to taxa of the genera *Cellulomonas*, *Oerskovia*, and *Promicromonospora*, *Sanguibacter* species contain MK-9(H_4) as the predominant isoprenoid quinone. Minor amounts of MK-9(H_6) are found in *Sanguibacter marinus* (Huang et al., 2005) whereas *Sanguibacter suarezii* exhibits minor amounts of MK-7 and MK-8 (Brown et al., 2005), and *Sanguibacter soli* contains minor amounts of MK-8 (Kim et al., 2008). *Sanguibacter suarezii* displays a whole cell sugar composition that consists of galactose, mannose, and ribose (Brown et al., 2005).

Predominant cellular fatty acids in most *Sanguibacter* species are of the straight-chain saturated and the anteiso-methyl-branched types. Significant levels of iso-methyl-branched fatty acids are also present. This cellular fatty acid pattern is also shared by species of the genera *Cellulomonas*, *Oerskovia*, and *Promicromonospora*. *Sanguibacter soli* has a different cellular fatty acid profile with two unidentified fatty acids (equivalent chain-length 13.961 and 14.966), $C_{17:0}$ anteiso, and $C_{18:0}$ iso as the major fatty acids (Kim et al., 2008).

Colonial and cultural characteristics. *Sanguibacter* strains are non-fastidious microorganisms and do not have special nutritional requirements. They grow perfectly on ordinary media such as Columbia blood or tryptone soy agars producing circular and convex colonies with entire edges and yellow or pale yellow color. The colonies are generally small with a diameter of 0.5–2.0 mm after 48 h of incubation at the optimum temperatures described in Table 189. No hemolysis is observed on sheep blood agar.

Genetics. In the mid-1990s, the genus *Sanguibacter* was examined by applying molecular genetic studies (Pascual et al., 1996). The results of the DNA–DNA hybridization experiments identified the genomically homogeneous ST-50 group of strains as a distinct species. Representative strains belonging to the ST-50 group were shown to exhibit more than 72% DNA reassociation with isolate ST-50 at 70°C with insignificant divergence (ΔT_m <2.5°C). The results provided by Pascual et al. (1996) indicate that isolate ST-50 is more closely related to *Sanguibacter keddieii* (36–41% DNA reassociation) than to *Sanguibacter suarezii* (14–23% DNA reassociation). Based on these results, the name *Sanguibacter inulinus* was proposed for the ST-50 group of strains. In addition, *Sanguibacter keddieii* and *Sanguibacter suarezii* were confirmed as genotypically homogeneous and highly related species. The level of reassociation (generally <41%) confirms their status as separate species.

At genomic level, so far only the gene *chit58* (encoding the enzyme chitinase) from *Sanguibacter* sp. C4 has been characterized (GenBank accession no. DQ282126).

Antibiotic sensitivity. Minimum inhibitory concentrations (MICs) of selected antimicrobial agents for *Sanguibacter suarezii* have been reported by Brown et al. (2005). Clarithromycin, clindamycin, imipenem, minocycline, rifampin, and vancomycin appear to be active against the type strain of *Sanguibacter suarezii* (ATCC 51766[T]).

Ecology and pathogenicity. With the exception of *Sanguibacter antarcticus*, *Sanguibacter marinus*, and *Sanguibacter soli*, the remaining three species of the genus *Sanguibacter* have been isolated from the blood of apparently healthy cows. *Sanguibacter antarticus* has been isolated from sea sand of Antarctica, *Sanguibacter marinus* from coastal sediment in China, and *Sanguibacter soli* from soil of a ginseng field in South Korea.

TABLE 189. Characteristics differentiating the species of the genus *Sanguibacter*[a]

[a]Symbols: +, 90% or more of the strains are positive within incubation period; d, 11–89% of the strains are positive within incubation period); –, 10% or fewer of the strains are positive within incubation period.

[b]Phenotypic characteristics of *Sanguibacter keddieii*, *Sanguibacter antarticus*, *Sanguibacter inulinus Sanguibacter marinus*, *Sanguibacter soli*, and *Sanguibacter suarezii* are based on three strains, one strain, six strains, one strain, one strain, and three strains, respectively.

[c]Fermentation of carbohydrates was performed on API 50CH strips (bioMérieux) according to the manufacturer`s instructions.

[d]Weak or delayed reaction.

[e]Not reported.

Data provided with deposited 16S rRNA gene sequences in public databases indicate the occurrence of *Sanguibacter* strains in different habitats such as subsurface environments (oil reservoirs: *Sanguibacter* sp. SG-4, accession no. AB126692), mudflow deposits (*Sanguibacter* sp. 1161, accession no. AB054900), plants (tomato leaves: *Sanguibacter* sp 12AD12, accession no. AB242791); alpine subnival plants (*Sanguibacter* sp Enf10, accession no. DQ339590); potatoes (*Sanguibacter suarezii* iCTE629, accession no. DQ122334) and in invertebrates (gut of the millipede *Cylindrojulus boleti* (Julidae, Diplopoda): *Sanguibacter inulinus* dtb 62, accession no. AJ309914). In addition, recent studies in microbial diversity have genotypically identified *Sanguibacter* isolates in the roots of wheat *Triticum aestivum* L. (Conn and Franco, 2004), in maple sap (Lagacé et al., 2004), and in the pig gastrointestinal tract (Leser et al., 2002). Although the genus *Sanguibacter* seems to be widely disseminated in terrestrial and aquatic ecosystems as well as in animals, insight into their natural distribution is still limited.

Until now, *Sanguibacter* has never been associated with disease in animals or humans. However, a chitinase producing *Sanguibacter* strain, *Sanguibacter* sp. C4 isolated from soil and tested as biocontrol agent for insect pests, has been reported to be pathogenic to locusts (Yong et al., 2005).

Isolation and maintenance procedures

Sanguibacter strains were originally isolated on *Listeria* selective agar (Domínguez Rodríguez et al., 1984) containing nalidixic acid (40 mg/l) and acriflavin (6 mg/l). Selective media including these concentrations of antimicrobials may be used for primary isolation of *Sanguibacter* strains from natural environments.

Sanguibacter species can survive without loss of viability for about 2 months on nutrient agar or tryptone soy agar slants stored at 4°C. Long-term survival procedures include either lyophilization or frozen stocks maintained at −20°C/−80°C in nutrient broth containing 20% glycerol.

Differentiation of the genus *Sanguibacter* from other genera

The genus *Sanguibacter* can be differentiated from other phylogenetically related genera of the order *Micrococcales* by the

phenotypic characteristics depicted in Table 188. Two species, including the type species of the genus, can also be differentiated from genera of the family *Intrasporangiaceae* on the basis of their polyamine pattern. *Sanguibacter keddieii* and *Sanguibacter suarezii* have been found to display a low polyamine content when compared to members of the above-mentioned family and to exhibit spermine as the predominant compound and significantly reduced amount of putrescine (Busse and Schumann, 1999).

Taxonomic comments

In 1997, the genus *Sanguibacter* was placed in the newly introduced family *Intrasporangiaceae* based on 16S rRNA phylogeny and signature nucleotides within the 16S rRNA gene (Stackebrandt et al., 1997). However, using a polyphasic approach and considering chemotaxonomic as well as phylogenetic data, the inclusion of *Sanguibacter* in the above-mentioned family was seriously questioned (Busse and Schumann, 1999; Prauser et al., 1997). *Sanguibacter* was then reported as the deepest branching lineage of the family *Intrasporangiaceae* (Prauser et al., 1997) differing from members of the family in respect to their peptidoglycan diamino acid (L-lysine), their menaquinone [MK-9(H_4)], their fatty acid profile (see Table 188), and their polyamine pattern (spermine predominant; Busse and Schumann, 1999). Recently, the genus *Sanguibacter* was reclassified in the newly proposed family *Sanguibacteriaceae* (Stackebrandt and Schumann, 2000) on the basis of 16S rRNA phylogenetic analysis and signature nucleotides. Indeed, with the subsequent addition of novel taxa into the rapidly growing suborder *Micrococcineae* (now order *Micrococcales*), the phylogenetic coherence of the family *Instrasporangiaceae* was disrupted, leading to the appearance of the genus *Sanguibacter* as a novel deeply branching lineage equivalent to those of neighboring families.

Differentiation of the species of the genus *Sanguibacter*

Phylogenetically, the six established species of *Sanguibacter* form a distinct line of descent with 96.0–99.2% 16S rRNA gene sequence similarities among them**.** Their 16S rRNA gene sequences are deposited in public databases (GenBank, EMBL). Therefore, if sequencing facilities are available, preliminary allocation of isolates to the genus *Sanguibacter* could be accomplished if 16S rRNA gene sequence similarities to established species of the genus are higher than 96.0%. Phenotypic characteristics useful for differentiation of species of *Sanguibacter* are provided in Table 189. However, correct allocation of isolates to the newly described species *Sanguibacter marinus*, *Sanguibacter antarcticus*, and *Sanguibacter soli* based on the phenotype may be problematic since the phenotypic characterizations of these species are each based on a single strain and, hence, neither stable nor variable traits of the species are known.

List of species of the genus *Sanguibacter*

1. **Sanguibacter keddieii** Fernández-Garayzábal, Domínguez, Pascual, Jones and Collins 1995b, 619[VP] (Effective publication: Fernández-Garayzábal, Domínguez, Pascual, Jones and Collins 1995a, 74.)

ked.di.e′i.i. N.L. gen. masc. n. *keddieii* of Keddie, named in honor of R.M. Keddie, a British bacteriologist.

Cells consist of Gram-stain-positive, short, irregularly shaped, motile rods. Colonies are circular, convex with entire edges, and yellow in color. Colony sizes range from 1.0–2.0 mm in diameter after 48 h of incubation on Tryptone Soy Agar. Facultatively anaerobic. Oxidase negative. In addition to the features common to all members of the genus and characteristics listed in Table 189, strains of the species share the following biochemical characteristics. Voges–Proskauer test is negative. Casein, esculin, and gelatin are hydrolyzed. Cellulose and Tween 80 are not decomposed. Acid is produced from arbutin and D-galactose. Some strains produce acid from gluconate. Acid is not produced from L-arabitol and L-fucose. Predominant fatty acids consist of $C_{16:0}$ (43.9%), $C_{15:0}$ anteiso (17.0%), and $C_{18:0}$ (12.0%).

Source: blood samples of apparently healthy dairy cows.

DNA G+C content (mol%): 70 (T_m).

Type strain: ST-74, ATCC 51767, CCUG 36690, CECT 4540, CIP 106323, DSM 10542, JCM 11429, NBRC 16158, NCIMB 703025.

Sequence accession no. (16S rRNA gene): X79450.

2. **Sanguibacter antarcticus** Hong, Lee, Yim, Chun and Lee 2008, 51[VP]

an.tarc′ti.cus. L. masc. adj. *antarcticus* southern, pertaining to the Antarctic, the geographical origin of the type strain.

Cells consist of Gram-stain-positive, irregularly shaped motile rods with sparse peritrichous flagella. Colonies are yellow, circular, and convex with entire edges. Diffusible pigments are not produced. Facultatively anaerobic. Oxidase negative. Growth is observed in a wide range of temperatures (4–30°C). Growth occurs at pH 4–9 (optimum pH 5–6) and with 0–7% NaCl (optimum 2–5%). Nitrate is reduced to nitrite and nitrogen. In addition to the features common to all members of the genus and characteristics listed in Table 189, strains of the species exhibit the following biochemical characteristics. Citrate is utilized and Voges–Proskauer reaction is weak. Gelatin is not hydrolyzed. Acid is not produced from arbutin, D-galactose, L-arabitol, L-fucose, and 2-ketogluconate. Arginine dihydrolase, cytochrome oxidase, β-galactosidase, gelatinase, H_2S, indole, lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, and urease are not produced. The predominant fatty acids are $C_{15:0}$ anteiso (50.5%), $C_{16:0}$ (9.6%), $C_{13:0}$ anteiso (7.6%), $C_{16:0}$ iso (7.5%), and $C_{17:0}$ anteiso (6.4%).

Source: a sea sand sample from King George Island, Antarctica.

DNA G+C content (mol%): 69.5 (T_m).

Type strain: KOPRI 21702, DSM 18966, JCM 14623, KCTC 13143.

Sequence accession no. (16S rRNA gene): EF211071.

3. **Sanguibacter inulinus** Pascual, Collins, Grimont, Domínguez and Fernández-Garayzábal 1996, 812[VP]

i.nu.li′nus. N.L. n. *inulum* (*sic*) inulin; L. masc. suff. *-inus* suffix used with the sense of pertaining to; N.L. masc. adj. *inulinus* pertaining to inulin.

Cells consist of Gram-stain-positive, short, irregularly shaped, motile rods. Colonies are circular, convex with entire edges, and pale yellow in color. Colony sizes range from 0.5–1.0 mm in diameter after 48 h of incubation on Tryptone Soy Agar. Facultatively anaerobic. Oxidase negative. Some strains reduce nitrate. In addition to the features common to all members of the genus and characteristics listed in Table 189, strains of the species share the following biochemical characteristics. Strains are negative in the Voges–Proskauer test. Esculin is hydrolyzed. Cellulose and Tween 80 are not hydrolyzed. Acid is produced from arbutin and D-galactose. Some strains produce acid from D-mannitol and methyl-β-D-xyloside. Acid is not produced from L-sorbose and 2-keto-gluconate. The predominant fatty acids are $C_{15:0}$ anteiso (59.8%), $C_{17:0}$ anteiso (8.1%), and $C_{16:0}$ (7.3%).

Source: blood samples of apparently healthy dairy cows.

DNA G+C content (mol%): 70.5 (T_m).

Type strain: ST-50, CCUG 36689, CIP 104915, JCM 11442, NCIMB 703024.

Sequence accession no. (16S rRNA gene): X79451.

4. **Sanguibacter marinus** Huang, Dai, He, Wang, Wang, Liu and Liu 2005, 1756[VP]

ma.ri′nus. L. masc. adj. *marinus* pertaining to the sea, where the isolate was found.

Cells are Gram-stain-positive, nonsporeforming, short, irregular, motile rods with sparse peritrichous flagella. Colonies are circular, convex with entire edges, and pale yellow. Diffusible pigments are not produced. Facultatively anaerobic. Oxidase negative. Growth is observed in a wide range of temperatures (15–37°C), pH (5.5–9.0), and NaCl concentrations (0–7% (w/v)). No growth is detected at 42°C and 10% NaCl. In addition to the features common to all members of the genus and characteristics listed in Table 189, strain of the species exhibit the following biochemical reactions. Citrate is not utilized. Esculin, gelatin, and starch are hydrolyzed, but casein, cellulose, and Tween 80 are not decomposed. Methyl red and indole tests are positive, but Voges–Proskauer test is negative. Acid is produced from arbutin and D-galactose. Acid is not produced from L-arabitol, L-fucose, and 2-keto-gluconate. The predominant fatty acids are $C_{15:0}$ anteiso (46.7%), $C_{15:1}$ anteisoA (17.7%), $C_{16:0}$ (10.7%), and $C_{15:0}$ (9.3%).

Source: coastal sediment collected in the Fujian province of China.

DNA G+C content (mol%): 73.4 (T_m).

Type strain: 1-19, CGMCC 1.3457, JCM 12547.

Sequence accession no. (16S rRNA gene): AJ783958.

5. **Sanguibacter soli** Kim, Pulla, Kim, Yi, Soung and Yang 2008, 540[VP]

so′li. L. neut. gen. n. *soli* of soil, the source of the type strain.

Cells consist of Gram-stain-positive motile rods. Colonies are yellow pigmented and circular. Aerobic. Oxidase positive. Growth is observed in a wide range of temperatures (25–42°C). No growth is detected at 4°C. Growth occurs at pH 5–9. In addition to the features common to all members of the genus and characteristics listed in Table 189, strains of the species exhibit the following biochemical reactions. Acid is produced from arbutin and D-galactose but not from L-arabitol, L-fucose, and 2-keto-gluconate. Positive for *N*-acetyl-β-glucosaminidase, acid phosphatase, alkaline phosphatase, α-chymotrypsin, cystine arylamidase, esterase (C4), esterase (C8), β-galactosidase, α-glucosidase, β-glucosidase (esculin hydrolysis), β-glucuronidase, leucine arylamidase, lipase (C14), α-mannosidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase. Arginine dihydrolase, α-fucosidase, α-galactosidase, protease (gelatin hydrolysis), and urease are not produced. Assimilates acetate, L-arabinose, D-glucose, maltose, D-mannose, sucrose, glycogen, and salicin, but not 3-hydroxybenzoate, 4-hydroxybenzoate, DL-3-hydroxybutyrate, 4-hydroxybenzoate, 2-ketogluconate, 5-ketogluconate, adipate, caprate, citrate, gluconate, itaconate, L-lactate, L-malate, malonate, phenyl acetate, propionate, suberate, n-valerate, L-fucose, melibiose, L-rhamnose, D-ribose, *myo*-inositol, D-mannitol, D-sorbitol, *N*-acetyl-D-glucosamine, L-alanine, L-histidine, L-proline, or L-serine. The predominant fatty acids are ECL 13.961 (45.81%), $C_{17:0}$ anteiso (23.46%), and $C_{18:0}$ iso (15.42%).

Source: soil of a ginseng field in South Korea.

DNA G+C content (mol%): 69.9 (T_m).

Type strain: DCY 22, JCM 14841, KCTC 13155.

Sequence accession no. (16S rRNA gene): EF547937.

6. **Sanguibacter suarezii** Fernández-Garayzábal, Domínguez, Pascual, Jones and Collins 1995b, 619[VP] (Effective publication: Fernández-Garayzábal, Domínguez, Pascual, Jones and Collins 1995a, 74.)

su.ar.é.zi.i. N.L. gen. masc. n. *suarezii* of Suarez, named in honor of G. Suarez, a Spanish veterinary microbiologist.

Cells are Gram-stain-positive, short, irregularly shaped, motile rods. Colonies are circular, convex with entire edges, and pale yellow in color. Colony sizes are approximately 0.5 mm in diameter after 48 h of incubation on Tryptone Soy Agar. Facultatively anaerobic. Oxidase-negative. Voges–Proskauer reaction is negative. Nitrate is reduced by most strains. In addition to the features common to all members of the genus and characteristics listed in Table 189, strains of the species share the following biochemical characteristics. Esculin is hydrolyzed. Casein, gelatin, cellulose, and Tween 80 are not hydrolyzed. Acid is produced from arbutin and D-galactose. Some strains produce acid from D-raffinose. Acid is not produced from L-arabitol and L-fucose. The predominant fatty acids are $C_{15:0}$ anteiso (40.5%), $C_{16:0}$ (34.3%), and $C_{14:0}$ (13.9%).

Source: blood samples of apparently healthy dairy cows.

DNA G+C content (mol%): 69.5 (T_m).

Type strain: ST-26, ATCC 51766, CCUG 36691, CECT 4539, CIP 106322, DSM 10543, JCM 11430, NBRC 16159, NCIMB 703023.

Sequence accession no. (16S rRNA gene): X79452.

Order XI. **Micromonosporales** ord. nov.

Olga Genilloud

Mi.cro.mo.no.spo′ra.les. N.L. fem. n. *Micromonospora* type genus of the order; suff. *-ales* ending to denote a order; N.L. fem. pl. n. *Micromonosporales* the *Micromonospora* order.

The order was formed by elevation of the suborder *Micromonosporineae* Stackebrandt, Rainey and Ward-Rainey 1997, 486[VP] emend. Zhi, Li and Stackebrandt 2009, 599. It contains the family *Micromonosporaceae*. The recognition of this taxon is based on the distinct phylogenetic position of its constituent members as determined by 16S rRNA gene sequence analysis and by the presence of a family-specific pattern of 16S rRNA nucleotide positions. The pattern of 16S rRNA gene signature nucleotides for the order is as indicated for the family by Zhi et al. (2009).

Type genus: **Micromonospora** Ørskov 1923, 156[AL].

Family I. **Micromonosporaceae** Krasil'nikov 1938, 272[AL] emend. Zhi, Li and Stackebrandt 2009, 599

Olga Genilloud

Mi.cro.mo.no.spo.ra.ce′a.e. N.L. fem. n. *Micromonospora* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Micromonosporaceae* the *Micromonospora* family.

Aerobic, **Gram-stain-positive**, **non-acid-fast organisms that form a non-fragmenting**, **branched, and septate mycelium that rarely carry scant aerial hyphae**. The family is a member of the order *Micromonosporales* and cannot be distinguished from other suprageneric groups of *Actinomycetales* by using a set of exclusive phenotypic characters. The family encompasses a chemotaxonomically and morphologically diverse group of filamentous bacteria that, at the time of writing, included 17 phylogenetically closely related genera that present distinctive morphological and chemotaxonomic characteristics. **The organisms are mesophilic, showing optimum growth between 20 and 30°C, and grow well at pH 7;** growth can be observed in some genera from10 to 40°C and from pH 4.5 to 12. Colonies on agar media are flat to elevated with smooth or wrinkled surfaces and show a large variety of pigments. **Most strains contain carotenoid mycelial pigments**, but some produce blue-green and maroon to purple pigments. Diffusible pigments may be formed depending on the media. **Single spores**, **short spore chains, or sporangia borne directly from the substrate hyphae may be formed**. Spores may be motile with tufts of polar flagella. With few exceptions, cell walls contain ***meso*-2,6-diaminopimelic acid and glycolated muramic acid**. Predominant menaquinones may include all types of the MK-9 and MK-10 series. **Phosphatidylethanolamine is the diagnostic phospholipid**. Mycolic acids are absent. Members of the family *Micromonosporaceae* are widely distributed in the environment and have been found in sediments, soils, rhizospheres, colonizing living and decaying plant material, and in freshwater and marine habitats.

DNA G+C content (mol%): 69–73 (T_m, HPLC).

Type genus: **Micromonospora** Ørskov 1923, 156[AL].

Further descriptive information

The family *Micromonosporaceae* currently comprises the genera *Micromonospora, Actinocatenispora, Actinoplanes, Asanoa, Catellatospora, Catenuloplanes, Couchioplanes, Dactylosporangium, Krasilnikovia, Longispora, Luedemannella, Pilimelia, Polymorphospora, Salinispora, Spirilliplanes, Verrucosispora*, and *Virgisporangium*. These genera can be distinguished on the basis of their chemotaxonomic, phenotypic, and phylogenetic characteristics.

Phylogeny. Members of the family *Micromonosporaceae* are phylogenetically related as determined by 16S rRNA gene sequence analysis and form a coherent cluster within the actinomycete subphylum of Gram-stain-positive bacteria that is well separated from other families classified in the order *Actinomycetales* (Embley and Stackebrandt, 1994). The 16S rRNA gene sequence similarity values for members within the family *Micromonosporaceae* are above 91% (Matsumoto et al., 2003). The distribution of genus-specific properties and signature nucleotides that define the genera correlate with the phylogenetic distinctness of each genus. The relationships between the constituent genera of the family are shown in Figure 208.

Cell morphology. Members of the family *Micromonosporaceae* show three major types of sporulating structures, namely single spores, spore chains, and sporangia. The type genus *Micromonospora* Ørskov 1923 is characterized by the production of nonmotile spores that are borne singly, sessile, or on short or long sporophores, often in clusters on extensively branched substrate hyphae. Spores are spherical, ovoid, or ellipsoidal with a thick wall that may carry blunt spiny ornamentations (Kawamoto, 1989). The genus *Salinispora* Maldonado et al. 2005 cannot be distinguished morphologically from members of the genus *Micromonospora. Salinispora* strains do not produce aerial hyphae, but form spores singly or in clusters; the spores have smooth surfaces and are sessile or borne on short sporophores. Salinisporae are abundant and widespread in marine sediments and other marine substrates and will only grow on 20–25% seawater or on a sodium-enriched medium. The genus *Verrucosispora* Rheims et al. 1998 does not produce aerial hyphae, but does form granular structures on the mycelial surface. Nonmotile spores are borne singly and may be sessile or carried on short sporophores. Initially, the spores are warty, but turn hairy in older cultures.

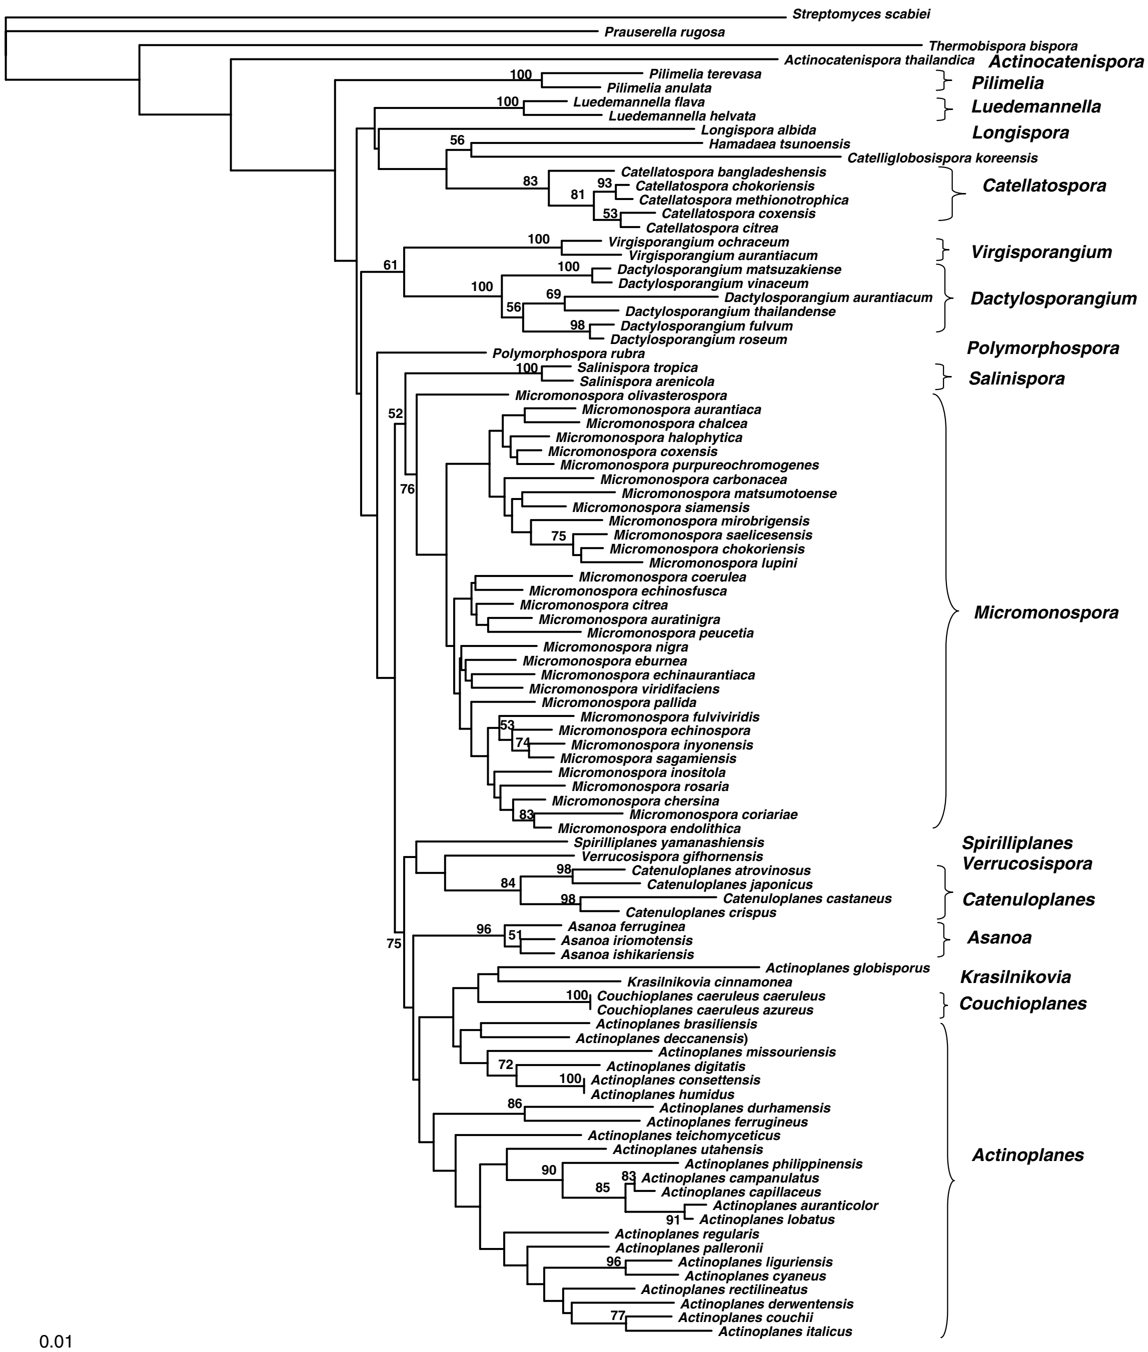

FIGURE 208. Neighbor-joining tree (Saitou and Nei, 1987) based on almost complete 16S rRNA gene sequences showing relationship between type strains classified in the family *Micromonosporaceae*. The tree is based on the Kimura two-parameter method with the confidence values of the branches determined by bootstrap analyses (Felsenstein, 1985) based on 1000 replicates. Only values >50% are shown at the nodes. Sequence accession numbers of type strains are given in the text. Bar = 0.01 substitutions per nucleotide position.

The genera *Actinoplanes* Couch 1950 emend. Stackebrandt et al. 1997, *Dactylosporangium* Thiemann et al. 1967, *Pilimelia* Kane 1966, and *Virgisporangium* Tamura et al. 2001 produce spore vesicles (sporangia) in which motile spores develop at the tips of short or long sporangiophores on the surface of substrate mycelia. The spores are formed within a sporangial envelope by fragmentation of branched or unbranched, straight or coiled sporogenous hyphae. The spore vesicles of the genera *Actinoplanes* and *Pilimelia* may be campanulate, cylindrical, digitate, lobate, ovoid, spherical, or irregular. Members of the genus *Pilimelia* can be differentiated from *Actinoplanes* strains by their keratinophilic character and their slow growth.

The genus *Dactylosporangium* produces two different types of spores: motile spores inside spore vesicles (sporangia) and non-motile spores borne singly on substrate hyphae. Motile spores are formed within finger-shaped to claviform, oligosporous spore vesicles that contain a single row of 2–5 spores. The sporangiospores are spherical, rod-shaped or oblong, ellipsoidal,

or ovoid to pyriform. The spores are motile with polar or lateral tufts of flagella. The spore walls are single-layered and are not ornamented. The nonmotile spores are spherical and are formed terminally on short branches of the substrate hyphae (Vobis, 1989b, 1991). Members of the genus *Virgisporangium* Tamura et al. 2001 produce rod-shaped spore vesicles that develop singly or in clusters on the substrate mycelium. Each spore vesicle contains a single row of six or more oval to short-rod-shaped motile spores. In contrast, members of the genus *Luedemannella* Ara and Kudo 2007d form spherical spore vesicles on short sporangiophores that arise singly or in clusters from the substrate mycelium; each sporangiophore carries several nonmotile spherical to oval spores.

Members of the genera *Actinocatenispora* Thawai et al. 2006a, *Asanoa* Lee and Hah 2002, *Catellatospora* Lee and Hah 2002, *Catenuloplanes* Yokota et al. 1993, *Couchioplanes* Tamura et al. 1994, *Krasilnikovia* Ara and Kudo 2007a, *Longispora* Matsumoto et al. 2003, *Polymorphospora* Tamura et al. 2006, and *Spirilliplanes* Tamura et al. 1997 are non-sporangiate and produce chains of spores. Members of the genus *Catellatospora* do not form aerial hyphae, but produce short chains of nonmotile spores that emerge singly or in tufts from the vegetative mycelium (Asano and Kawamoto, 1986; Koch et al., 1996a). *Couchioplanes* strains form chains of motile spores that, together with aerial mycelia, are often aggregated into clusters that resemble sporangia, though true spore vesicles are not observed. Members of the genus *Krasilnikovia* also form globose pseudosporangial structures (Ara and Kudo, 2007a) that contain nonmotile spores.

Catenuloplanes strains form motile arthrospores in short chains that are arranged in one or two spirals that are often aggregated with normally sparse aerial mycelia. The spores are rod-shaped, straight, or curved with smooth surfaces (Kudo et al., 1999; Tamura et al., 1995; Yokota et al., 1993). Members of the genus *Spirilliplanes* produce long spore chains that are in spirals of five to ten turns. Spores are oval or rod-shaped with smooth surfaces and are motile in the presence of 10% soil extract or distilled water (Tamura et al., 1997).

The genus *Asanoa* was described to accommodate two species that were initially assigned to the genus *Catellatospora*, but it was found subsequently that these species could be clearly differentiated from members of the genus *Catellatospora* and other genera with validly published names classified in the family *Micromonosporaceae*. *Asanoa* strains sporulate poorly on tap-water and glycerol/calcium malate agars (Lee and Hah, 2002). Members of the taxon do not produce aerial mycelia or globose bodies, which are observed in some *Catellatospora* species. Members of the genus *Longispora* Matsumoto et al. 2003 produce a sparse aerial mycelium and only sporulate when grown on gellan gum; spores are borne on short sporophores that arise from the vegetative mycelium. The spores are cylindrical, have smooth surfaces, and are carried in short straight chains of 20 or more spores. Members of the genus *Polymorphospora* Tamura et al. 2006 develop short chains of nonmotile spores of varying shapes that differentiate into rods. Finally, members of the genus *Actinocatenispora* Thawai et al. 2006a produce aerial hyphae on oatmeal-nitrate agar; these develop into cylindrical spore chains containing more than 10 spores.

Chemotaxonomy. The phenotypic heterogeneity of the family *Micromonosporaceae* is further increased when chemotaxonomic markers are considered, namely the amino acids of the peptidoglycan, whole-organism sugar patterns, phospholipid types, and menaquinone and fatty acid composition (Table 190). Most members of the family are characterized by a cell-wall chemotype II *sensu* Lechevalier and Lechevalier (1970a); the wall peptidoglycan contains *meso*-diaminopimelic acid (*meso*-A_2pm) and/or 3-hydroxy-A_2pm. The first amino acid of the peptide side chain is glycine in all members of the family, apart from *Pilimelia* which contains acetate. The genus *Pilimelia* can be differentiated from other members of the family as it contains *N*-acetylated, as opposed to *N*-glycolated, muramic acid (Koch et al., 1996a). Deviations from this wall chemotype have been observed in *Micromonospora* species that contain LL-A_2pm (Kawamoto et al., 1981) and in *Couchioplanes* and *Catenuloplanes* species that have L-lysine and D- and L-serine as diagnostic amino acids in the peptidoglycan rather than *meso*-A_2pm acid (Horan and Brodsky, 1986a; Tamura et al., 1994; Yokota et al., 1993).

Arabinose, galactose, and xylose are the major sugars present in whole-organism hydrolysates [sugar pattern D *sensu* Lechevalier and Lechevalier (1970a)] with variable amounts of other sugars. The diagnostic phospholipid of the cell membrane is phosphatidylethanolamine [phospholipid type II *sensu* Lechevalier et al. (1977)], but diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol may be present. However, *Catenuloplanes* strains also contain phosphatidylcholine (Yokota et al., 1993) and, hence, have a phospholipid type III (Table 190).

Members of the family *Micromonosporaceae* contain complex and highly variable fatty acids, although saturated iso- and anteiso-branched fatty acids are predominant in nearly all genera, apart from the genus *Pilimelia*. Unsaturated fatty acids may or may not be present, although they are major components in *Longispora* strains (Matsumoto et al., 2003). 10-Methyl-branched fatty acids are found in certain strains of *Micromonospora*; cyclic fatty acids are absent from all strains, as are mycolic acids. The menaquinone composition is heterogeneous. Major amounts of tetra-, hexa- and/or octahydrogenated menaquinones with 9, 10, and 12 isoprene units are distributed among genera and species (Koch et al., 1996a; Vobis, 1989b) (Table 190).

Genetics. A family-specific pattern of 16S rRNA gene signatures was defined by Stackebrandt et al. (1997) to distinguish members of the family *Micromonosporaceae* from all other actinomycetes. The 11 16S rRNA gene signatures detected in representatives of *Actinoplanes*, *Catellatospora*, *Couchioplanes*, *Catenuloplanes*, *Dactylosporangium*, *Micromonospora*, and *Pilimelia* consist of nucleotides at positions 66:103 (G–C), 127:234 (A–U), 153:168 (C–G), 502:543 (G–C), 589:650 (C–G), 747 (A), 811 (U), 840:846 (C–G), 952:1229 (C–G), 1116:1184 (C–G), and 1133:1141 (G–C) (Stackebrandt et al., 1997). Since then, genus-specific signature nucleotides have been described for *Actinocatenispora* [positions 502:543 (U–G), 747 (G), and 811 (C)], *Krasilnikovia* [positions 445:489 (C–G), 446:488 (C–G), 1011:1018 (U–A), and 1263:1272 (G–U)], *Longispora* [position 502 (A); Matsumoto et al., 2003], *Luedemannella* [positions 139:224 (U–A), 381 (A), 656:750 (A/G–C), and 999:1041 (C–U)], *Polymorphospora* at position 1244 (U) (Tamura et al., 2006), *Verrucosispora* [positions 1133:1141 (A–U); Rheims et al., 1998], and *Virgisporangium* [positions 502:543 (G–C) and 1116:1184 (C–G); Tamura et al., 2001].

Acknowledgements

I am especially grateful to Dr Oscar Salazar for the updated phylogenetic tree of the family *Micromonosporaceae*.

Genus I. **Micromonospora** Ørskov 1923, 156^AL

Olga Genilloud

Mi.cro.mo.no.spo'ra. Gr. adj. *mikros* small; Gr. adj. *monos* single, solitary; Gr. fem. n. *spora* a seed and in biology a spore; N.L. fem. n. *Micromonospora* small, single-spored (organism).

Well-developed, branched, substrate mycelium (0.2–0.6 μm diameter). **Nonmotile spores are borne singly, sessile, or terminally on short sporophores**. Sporophore development is monopodial or in some cases sympodial. Spores are spherical to oval in shape (0.7–1.5 μm) and in most species have blunt spiny projections. The spores are often carried in branched clusters on short hyphae of the substrate mycelium. **Aerial mycelium is usually absent**, but some cultures develop sterile short aerial hyphae. Gram-stain-positive, mesophilic, non-acid-fast. Aerobic to microaerophilic. Chemo-organotrophic. Sensitive to pH below 5.0. Growth usually occurs between 20 and 40°C, but not above 50°C. **Cell wall contains *meso*-diaminopimelic acid and/or 3-OH-diaminopimelic acid**. **Arabinose and xylose are the characteristic sugars present in whole-organism hydrolysates of most species**, but variable amounts of galactose, glucose, mannose, and rhamnose can also be found depending on the species. **The major phospholipids are phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides**. Saturated and unsaturated fatty acids are present, mostly $C_{15:0}$ iso, $C_{17:0}$ iso, $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{17:0}$ 10-methyl, and $C_{17:0}$ 10-methyl. Mycolic acids are absent. Major menaquinones are MK-9(H_4), MK-9(H_6), MK-10(H_4), MK-10(H_6), or MK-12(H_6). Isolated from soil, plant materials, freshwater, and marine environments.

DNA G+C content (mol%): 68–75 (T_m, HPLC).

Type species: **Micromonospora chalcea** (Foulerton 1905) Ørskov 1923, 156^AL ("*Streptothrix chalcea*" Foulerton 1905, 1199).

Further descriptive information

The genus *Micromonospora* is well defined in terms of morphological, chemotaxonomic, and phylogenetic criteria (Kawamoto, 1989; Koch et al., 1996a; Kroppenstedt, 1985) that distinguish it from other members of the family *Micromonosporaceae* (Table 191). *Micromonospora* species are defined based on chemotaxonomic markers, physiological characteristics, and on phylogenetic relationships.

Phylogeny. The intrageneric structure of the genus *Micromonospora* was described first by Koch et al. (1996b) in an analysis of 16S rRNA gene sequences of representatives of 15 species with validly published names, four subspecies, and 19 species with names that have not been validly published. This and later phylogenetic studies based on 16S rRNA gene sequences of the type strains of the genus have shown that *Micromonospora* species form a tight clade within the family *Micromonosporaceae*; they show 16S rRNA similarity values within the range 96.7–99% (Koch et al., 1996b). These high values cannot be used to confirm the species status of closely related strains, not least because nucleotide substitutions in variable regions of RNA genes may induce errors when establishing their relative phylogenetic position. However, *Micromonospora* species tend to group consistently into subclusters, the relative positions of which are generally conserved in the topology of phylogenetic trees, although *Micromonospora olivasterospora* represents an unrelated line of descent (Koch et al., 1996b; Kroppenstedt et al., 2005a; Thawai et al., 2005b). Nevertheless, few internal relationships can be confirmed by bootstrap values higher than 50%. The phylogenetic relationships between *Micromonospora* species are presented in Figure 209.

Cell morphology. *Micromonospora* strains frequently form raised and folded colonies on agar media. Colonies are initially pale yellow to light orange and, depending on the strain, they develop a blue-green, brown, dark orange, purple, or red pigmentation with age. Soluble pigments may be formed. Older colonies tend to be covered by a black, brown-black, or green-black mucous mass of spores (Kawamoto, 1989). Spores often occur in dense clusters and may be produced in distinct areas on the surface or be completely embedded in the substrate. Mycelial pigments sensitive to pH changes have been observed in *Micromonospora coerulea* (blue-green) and *Micromonospora echinospora* (maroon-purple) (Kawamoto, 1989). Other species characterized by soluble pigments are *Micromonospora chalcea* (yellow), *Micromonospora halophytica* (red-brown), *Micromonospora olivasterospora* (olive-green), *Micromonospora purpureochromogenes* (dark-brown), and *Micromonospora rosaria* (wine-red) (Horan and Brodsky, 1986b; Kawamoto, 1989). Nevertheless, mycelial pigmentation, mycelial development, and sporophore morphology have little diagnostic value for the identification of *Micromonospora* species.

Micromonosporae often produce short sporophores which occur in branched clusters on short hyphae of the substrate mycelium (Luedemann and Casmer, 1973). The sympodial sporophore of *Micromonospora carbonacea* (Luedemann and Brodsky, 1964) has also been observed in other species. The formation of single spores on the substrate mycelium is the main morphological characteristic of the genus *Micromonospora*. Occasionally, spores have been found longitudinally in pairs or in larger groups of spores (Luedemann and Casmer, 1973) and a sporulation process resembling sporangial formation has been described in *Micromonospora purpureochromogenes* NRRL B-2671 (Stevens, 1975).

The spore surface ornamentations formed on the outer layer of the spore wall differ from those observed in the sheath of some *Streptomyces* spores (Luedemann and Casmer, 1973). Spore ornamentations of *Micromonospora* strains described originally on the basis transmission electron microcopy as "smooth", "warty", or "blunt-spiny" have been shown by scanning electron microscopy to have blunt-spiny surfaces with variable spine sizes, but this characteristic is not a diagnostic characteristic for the differentiation of *Micromonospora* species (Kawamoto, 1989) (Figure 210).

Sporogenesis involves the formation of a sporulation septum that is followed by spore maturation with a thickening of wall layers (Hardisson and Suarez, 1979; Luedemann and Casmer, 1973). Spore dehiscence is favored by a stretching of the hyphal wall near the sporulation septum. The thickened walls may explain the high refractility and the relative differential resistance of mature spores to physical and chemical treatments, such as sonication or heat treatment up to 75°C

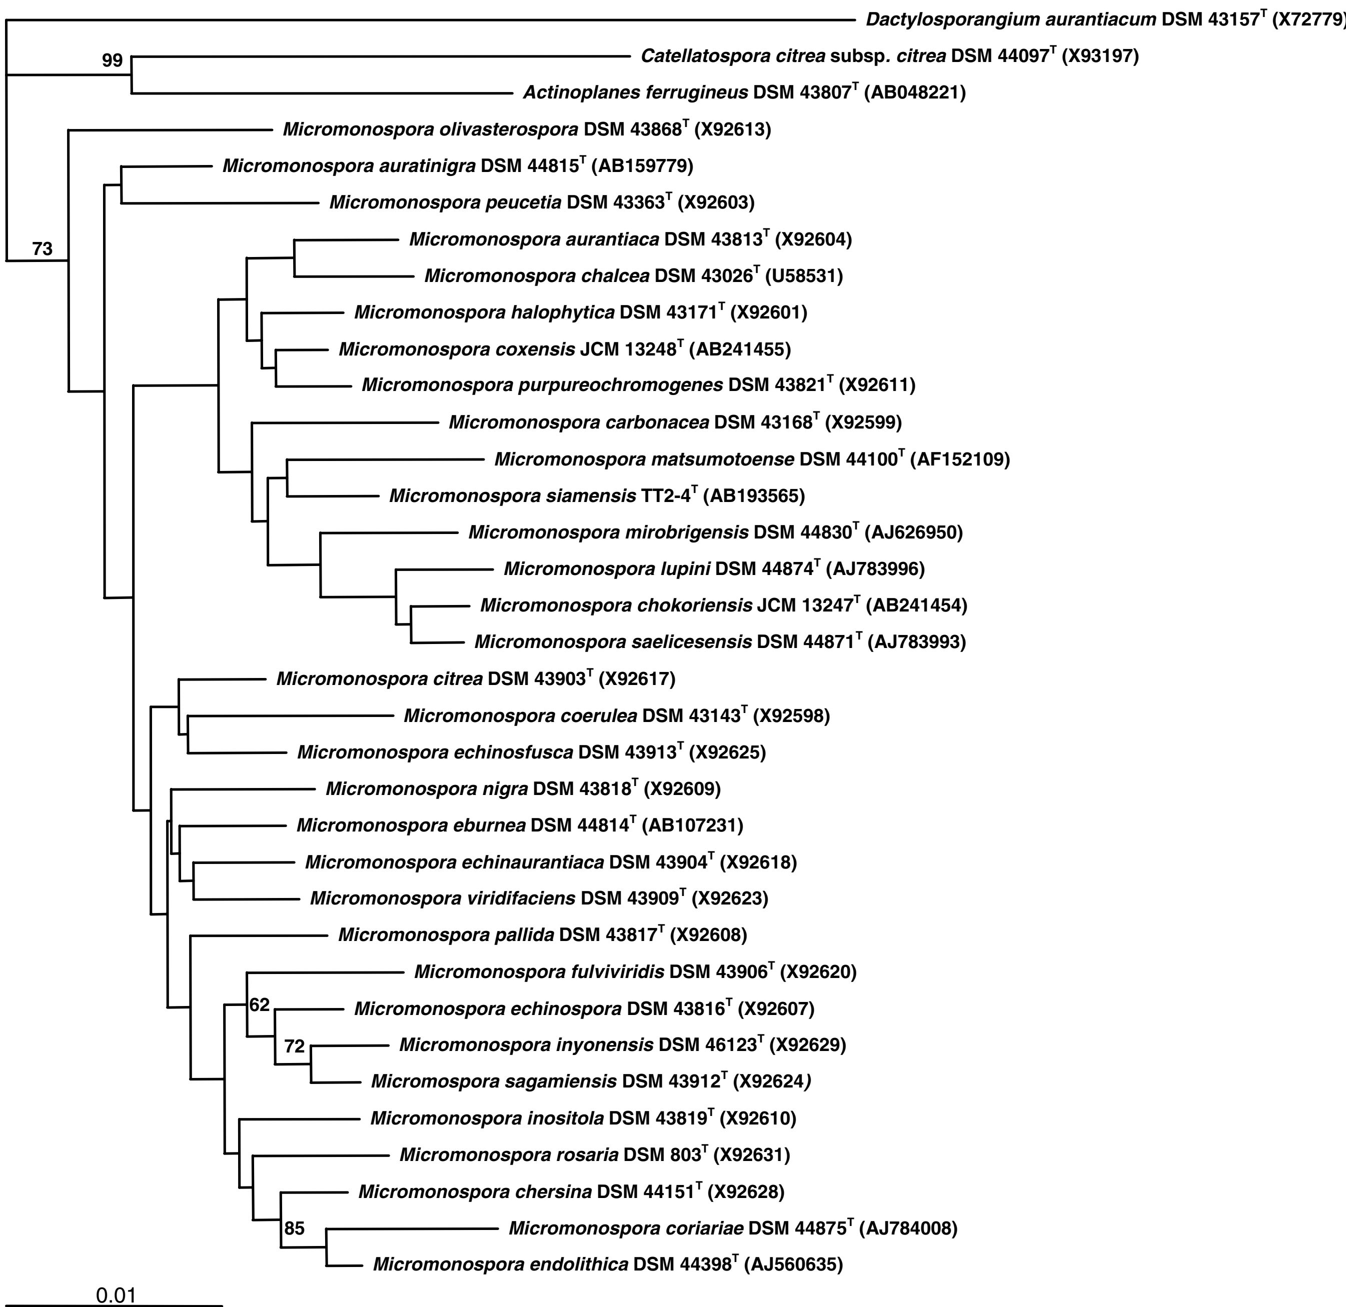

FIGURE 209. Neighbor-joining tree (Saitou and Nei, 1987) based on almost-complete 16S rRNA gene sequences showing relationships between type strains of the genus *Micromonospora*. The tree is based on the Kimura two-parameter method and confidence values of branches were determined by bootstrap analysis (Felsenstein, 1985) based on 1000 replicates. Only values >50% are shown at nodes. Bar = 0.01 substitutions per nucleotide position.

(Johnston and Cross, 1976; Kawamoto et al., 1982; Suárez et al., 1980). Spore viability is only markedly reduced at temperatures above 75°C, as shown in *Micromonospora chalcea* (Suárez et al., 1980). Spores are resistant to desiccation and remain viable in soil or in mud for extended periods (Cross and Attwell, 1974). Heat shock above 70°C induces spore germination (Ensign, 1982; Hoskisson et al., 2000) and dry heat treatments at 120°C clearly select for strains of this genus (Hayakawa et al., 1991b).

Micromonospora spores show some resistance to treatment with different chemical agents, such as acetone (Kawamoto et al., 1982), dimethylformamide, formamide, *tert*-butyl alcohol, and phenol (Hayakawa et al., 1991b). Spore viability is not affected within the pH range 6.0–8.0, but decreases at acidic pH values (Kawamoto et al., 1982). In general, the spore germination process in *Micromonospora* is slower but similar to that observed in other actinomycetes (Kawamoto, 1989).

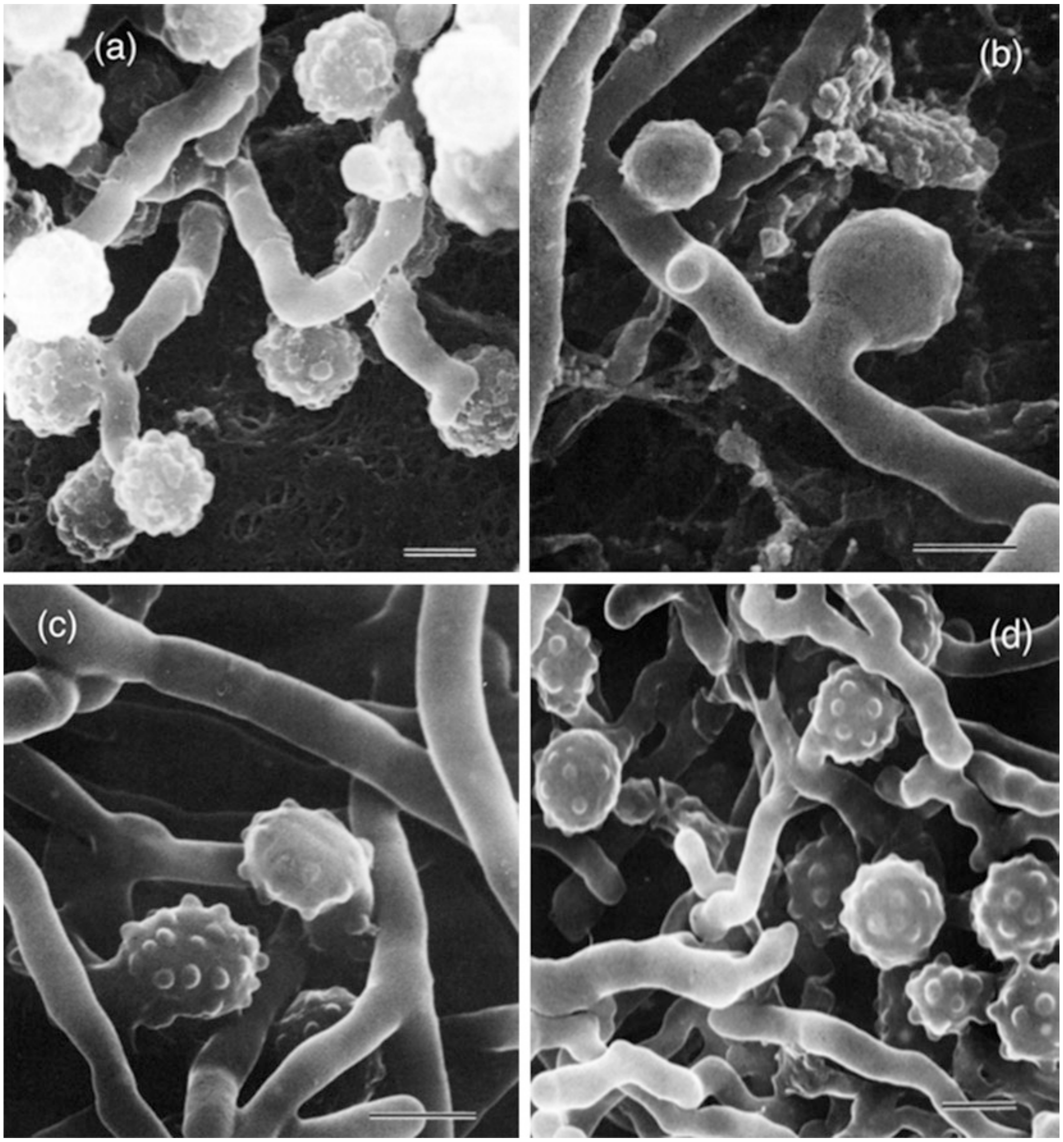

FIGURE 210. Scanning electron micrographs of: (a) *Micromonospora carbonacea* NRRL 2972^T; (b) *Micromonospora chalcea* ATCC 12452^T; (c) *Micromonospora purpureochromogenes* ATCC 27007^T; and (d) *Micromonospora echinospora* NRRL 2985^T. Bar = 0.5 µm.

Cell-wall composition. The genus *Micromonospora* is characterized by a cell-wall type II (Lechevalier and Lechevalier, 1970a, 1970b), a whole-organism sugar pattern D (Lechevalier and Lechevalier, 1970a, 1970b), a phospholipid type PII (Lechevalier et al., 1977), and a fatty acid pattern 3b (Kroppenstedt, 1985). Cell-wall hydrolysates may contain glycine, glutamic acid, diaminopimelic acid (A_2pm), including *meso*- and 3-OH-A_2pm, and D-alanine (Kawamoto et al., 1981). The presence of 3-OH-A_2pm is limited to certain species and its presence/absence divides *Micromonospora* species into two groups (Kawamoto, 1989). The acyl type of the cell-wall muramic acid is glycolyl and there is an almost equimolar ratio of glycolic acid and A_2pm (Kawamoto et al., 1981). Glycine is always present in the first position of the peptide subunit that is attached to *N*-glycolylmuramic acid. However, the peptidoglycan cannot always be hydrolyzed with lysozyme (β-*N*-acetylmuramidase) as observed in *Micromonospora olivasterospora* and *Micromonospora sagamiensis* (Kawamoto et al., 1981) or in strains where protoplasts cannot be effectively obtained (Szvoboda et al., 1980). The cell-wall sugars arabinose and xylose are constituents of the cell wall of most *Micromonospora* species, albeit in variable amounts. Glucose, galactose, mannose, and rhamnose can also be found in whole-organism hydrolysates, although amounts differ from species to species (Kawamoto et al., 1981); galactose, glucose, and rhamnose are found instead of arabinose in certain species (Kroppenstedt et al., 2005a; Trujillo et al., 2005).

Lipids and menaquinone composition. Characteristic phospholipids include diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides (Lechevalier et al., 1977). Dassain et al. (1983) identified the glycolipids, monoglucosyldiglycerides, diglucosyldiglycerides, esters of trehalose, and fatty acids. Predominant

fatty acids are iso- and anteiso-branched components. Fatty acids patterns are of type 3b with saturated and unsaturated fatty acids including $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{17:0}$ 10-methyl, $C_{18:0}$ 10-methyl, $C_{16:0}$ iso, $C_{15:0}$ iso, and $C_{17:0}$ iso acids (Kroppenstedt, 1985). Mycolic acids and cyclic fatty acids are not present. The menaquinone composition of members of the genus *Micromonospora* is complex and heterogeneous; strains can be divided into three groups based on the predominant menaquinone. The two major groups encompass species that have menaquinones with either nine (MK-9) or ten isoprene units (MK-10); the exception, *Micromonospora pallida*, has menaquinones with 12 units (MK-12) (Collins et al., 1984; Hirsch et al., 2004a; Kawamoto, 1989; Kroppenstedt et al., 2005a; Thawai et al., 2004b, 2005a, 2005b; Tomita et al., 1992b; Trujillo et al., 2005).

Growth conditions. The identification of *Micromonospora* species is supported by physiological characteristics, such as growth on special media, carbon utilization profiles, glycosidase activity, nitrate reduction, and NaCl tolerance (Kawamoto, 1989). Fructose, glucose, sucrose, and starch are utilized as sole carbon sources by almost all strains and most strains utilize cellobiose, galactose, mannose, trehalose, and xylose, but little, if any, growth occurs with glycerol, inositol, mannitol, rhamnose, ribose, or salicin. Carbohydrate utilization patterns can be affected by the basal medium and this can account for discrepancies between results reported by different authors (Kawamoto, 1989). *Micromonospora* strains show α- and β-glucosidase, β-galactosidase, and β-*N*-acetylglucosaminidase activities, but variable results are obtained for α-galactosidase, α-mannosidase, and β-xylosidase (Kawamoto, 1989). Inorganic ammonium salts and acidic and basic amino acids are better nitrogen sources than nitrate salts (Kawamoto et al., 1983). NaCl tolerance ranges from 1.5 to 5% (w/v). Micromonosporae do not grow below pH 5.0 or above pH 9.5 and most strains do not grow at 45°C.

Genetics. *Micromonospora* species are defined genomically by having total genomic DNA–DNA reassociation values lower than 70%; this contrasts with their high 16S rRNA similarity values. Indeed, 16S rRNA gene sequences are almost identical with similarities of 99.7–99.9% for members of *Micromonospora* species and subspecies that were later reclassified as synonyms in DNA–DNA hybridization studies (Koch et al., 1996b). These workers also noted that the composition of the different groups of *Micromonospora* species are supported by signature nucleotides between 16S rRNA gene positions 603 and 627 (Koch et al., 1996b). DNA–DNA reassociation studies have confirmed that the genus is overspeciated (Kasai et al., 2000). The protein-encoding gene *gyrB* has been used as an alternative gene to determine the phylogenetic position and relationships of *Micromonospora* type strains given the high consistency found in their 16S rRNA gene sequences (Kasai et al., 2000). The branching patterns in the *gyrB*-based phylogenetic tree of *Micromonospora* type strains representing 14 species were similar to those of the corresponding 16S rRNA-based tree (Kasai et al., 2000).

Genetics, phages, and plasmids. Various lytic and temperate phages, and phages with no characterized infection cycles have been described in *Micromonospora* species (Alexander et al., 2003; Caso et al., 1990; Kikuchi and Perlman, 1977, 1978; Li et al., 2004; Tilley et al., 1990). Plasmids occur frequently, with many of them being cryptic. Numerous host vectors and shuttle vector systems have been developed from *Micromonospora* plasmids and have allowed genetic recombination studies of important biosynthetic gene clusters (Hosted et al., 2005; Inouye et al., 1994; Li et al., 2003; Parag and Goedeke, 1984; Takada et al., 1994; Vukov and Vasiljevic, 1998).

Ecology. *Micromonospora* strains can be isolated easily from soil and aquatic environments, but almost all described type strains have a terrestrial origin. Micromonosporae are very common in alkaline and neutral soils (Jensen, 1930; Vobis, 1992) and although many strains have been shown to be sensitive to acid pH (Kawamoto, 1989), they have also been isolated from acid soils and plant substrates on acidified media (Zenova et al., 2004). *Micromonospora* spores are hydrophilic, highly resistant to heat treatment and to different chemical agents, and can survive for years in the environment (Cross, 1981b).

It was widely accepted for a long time that the principal habitats of micromonosporae were aquatic ecosystems (Cross, 1981a; Goodfellow and Haynes, 1984). *Micromonospora* strains have been isolated extensively from freshwater and marine aquatic environments (Cross, 1981a, 1981b; Goodfellow and Williams, 1983), are frequently present in water samples of streams and rivers (Burman, 1973), and are amongst the predominant actinomycetes in lake sediments and mud samples (Johnston and Cross, 1976). An active role in the degradation of biopolymers in sediments has been proposed given their ability to decompose cellulose, chitin, and xylan (Erikson, 1941; Hunter et al., 1981). Their tolerance to low oxygen tensions suggests that they may grow under the microaerophilic conditions found in alluvial soils, floodplain meadows, and wet soils of river ecosystems (Goodfellow and Williams, 1983; Vobis, 1992; Zenova and Zviagintsev, 2002). *Micromonospora* strains predominate in actinomycete communities isolated from plant litter, lichens, roots, and organic soil horizons (González et al., 2005; Zenova et al., 1994). Their widespread occurrence even in vegetated arid zones has been explained by their ability to degrade biopolymers (Zenova et al., 1994).

Micromonospora strains have been found to be constituents of endophytic actinobacterial populations recovered from plant tissues; they have been described as colonizing roots of *Casuarina* and *Triticum* species (Coombs and Franco, 2003; Valdés et al., 2005). A selective advantage has been suggested for their association with plants given their ability to suppress the fungal pathogens *Pythium* and *Phytophthora* (Coombs and Franco, 2003). An isolate most closely related to "*Micromonospora yulongensis*" (name not validly published) has been described from surface-sterilized wheat root tissue and culture-independent methods have identified clones of endophytic actinobacteria closely related to *Micromonospora endolithica* and *Micromonospora peucetica* in wheat roots suggesting the presence of a large diversity of *Micromonospora* species in plants (Conn and Franco, 2004; Coombs and Franco, 2003). More recently, surface-sterilized legume nodules of *Lupinus angustifolius*, *Pisum sativum*, and *Vicia sativa* have been shown to be extremely rich reservoirs for the isolation of novel *Micromonospora* strains (Trujillo et al., 2006, 2007).

Micromonospora species have been isolated from diverse marine habitats, including coastal areas (Watson and Williams, 1974), salt marshes (Hunter et al., 1981), and deep-sea sediments (Weyland, 1969, 1981). It was widely accepted for many

years that *Micromonospora* spores were washed from soils and accumulated as dormant spores in lake and sea sediments (Cross, 1981a, 1981b; Goodfellow and Haynes, 1984; Johnston and Cross, 1976; Weyland, 1969, 1981). Despite prior evidence suggesting the adaptation of actinomycetes to the marine environment and the existence of an indigenous marine population (Jensen et al., 1991; Magarvey et al., 2004; Mincer et al., 2002; Okami and Okazaki, 1978; Takizawa et al., 1993), it was only recently that active mycelial growth was demonstrated in sand particles (Jensen et al., 2005). In spite of this, many actinomycetes isolated using seawater-based media grow well in media prepared using distilled water.

Secondary metabolism. Micromonosporae, after streptomycetes, are one of the most prolific producers of bioactive secondary metabolites; they produce an extremely large diversity of chemical structures. Bérdy (2005) cited more than 740 *Micromonospora* strains as producers of different bioactive metabolites. They are particularly important producers of aminoglycosides (fortimicins, gentamicins, kanamycin, mannosidostreptomycin, neomycin B, paromamine, sagamicin, sisomicin, and verdamicin), ansamycins (halomicins, rifamycins), anthracyclines (daunorubicin, sibanomicin), anthraquinones (dynemicin), macrolides (antibiotic XK 41-B-2, erythromycins, juvenimicins, megalomycins, rosaramicin, and rustmicin), oligosaccharides (antlermicin and everninomicin), enediyne antitumor antibiotics (calicheamycin), and peptide antibiotics (actinomycin, bottromycin, microsporin, and thiocoraline) (Horan, 1999; Vobis, 1992; Wagman and Weinstein, 1980).

Enrichment and isolation procedures

Micromonosporae are easily isolated from soils and sediments by plating serial dilutions onto suitably nutritionally poor selective media that limit the growth of members of fast-growing bacterial species. The media most commonly used are arginine-glycerol-salts agar (Hunter et al., 1984), arginine-vitamin agar, starch-casein-nitrate agar supplemented with B vitamins (Shearer, 1987), cellulose-asparagine agar (Goodfellow and Haynes, 1984), colloidal chitin agar (Hsu and Lockwood, 1975), humic acid-vitamins agar (Hayakawa and Nonomura, 1987a), Kodoka's cellulose benzoate medium (Sandrak, 1977), and M3 medium (Rowbotham and Cross, 1977); inoculated plates are incubated at 28–30°C for at least 2–3 weeks. The addition of antibiotics such as gentamicin (1–10 µg/ml) (Ivanitskaia et al., 1978), nalidixic acid (20–30 µg/ml), novobiocin (25–50 µg/ml) (Sveshnikova et al., 1976), and tunicamycin (20–50 µg/ml) (Nonomura and Hayakawa, 1988; Wakisaka et al., 1982) to media promote the isolation of *Micromonospora* species. Different pretreatment regimes can also be used such as heating soil suspensions at 70°C for 10–30 min (Rowbotham and Cross, 1977; Sandrak, 1977), and dry heating of soil samples at 120°C for 60 min (Shearer, 1987). The pretreatment of soil suspensions with ammonia then chlorine for 10–30 min (Burman et al., 1969; Willoughby, 1969a) or with 1.5% (w/v) phenol followed by plating onto humic acid-vitamins agar supplemented with nalidixic acid (20 µg/ml) and tunicamycin (20 µg/ml) have been shown to be highly effective isolation methods (Hayakawa et al., 1991b).

The isolation of micromonosporae from plant materials, including roots, requires a preliminary sterilization of the material surface by successive treatments in 99% ethanol, 3.1% NaOCl, and 99% ethanol prior to plating (Coombs and Franco, 2003). Selective media prepared with artificial seawater are used in combination with specific methods to isolate micromonosporae from marine sediments and marine invertebrates. Dilution and heat shock treatments, stamping methods, and enrichments based on the incubation of sediments plated on membrane filters in humid chambers have been effective for the isolation of *Micromonospora* strains from sediments (Magarvey et al., 2004; Mincer et al., 2002). The slow growth of isolates frequently requires extended incubation for up to 10 weeks at lower temperatures (Goodfellow and Haynes, 1984).

Maintenance procedures

Sporulated cultures can be maintained for months on agar slopes or sealed plates at 4°C. Long-term storage can be achieved by lyophilization, by liquid drying, or by maintaining spores or liquid seed cultures in 10–15% glycerol at −80°C.

Differentiation of the genus *Micromonospora* from other genera

The morphological and chemotaxonomic characteristics that distinguish *Micromonospora* from other genera classified in the family *Micromonosporaceae* are given in Table 191. The genus can be differentiated from other members of the family on the basis of cell morphology, chemotaxonomy, and 16S rRNA gene sequence analysis.

Taxonomic comments

The description of *Micromonospora* species began with taxonomic studies on gentamicin-producing strains (Luedemann and Brodsky, 1964). The *Approved Lists of Bacterial Names* (Skerman et al., 1980) included 12 species (*Micromonospora aurantiaca*, *Micromonospora brunnea*, *Micromonospora carbonacea*, *Micromonospora chalcea*, *Micromonospora coerulea*, *Micromonospora echinospora*, *Micromonospora gallica*, *Micromonospora halophytica*, *Micromonospora inositola*, *Micromonospora purpurea*, *Micromonospora purpureochromogenes*, and *Micromonospora rhodorangea*) and seven subspecies as members of the genus *Micromonospora*, though the type strain of *Micromonospora gallica* is not extant (Kawamoto, 1989). *Micromonospora olivasterospora* (Kawamoto et al., 1983), *Micromonospora rosaria* (Horan and Brodsky, 1986b), and *Micromonospora chersina* (Tomita et al., 1992b) were described later and *Catellatospora matsumotoense* was transferred to the genus as *Micromonospora matsumotoense* (Lee et al., 1999).

DNA–DNA hybridization experiments and the study of the intrageneric relationships deduced from 16S rRNA and *gyrB* phylogenetic studies of *Micromonospora* type strains have confirmed the reclassification of many species and subspecies of the genus (Kasai et al., 2000; Koch et al., 1996b). *Micromonospora echinospora* subsp. *pallida* was reclassified as the novel species *Micromonospora pallida*, and the subspecies *Micromonospora halophytica* subsp. *nigra* as *Micromonospora nigra*. DNA–DNA reassociation studies on strains of *Micromonospora* species have confirmed that the taxa *Micromonospora echinospora* subsp. *ferruginea*, *Micromonospora purpurea*, and *Micromonospora rhodorangea* are synonyms of *Micromonospora echinospora* and that *Micromonospora brunnea* is a synonym of *Micromonospora purpureochromogenes* (Kasai et al., 2000; Szabó and Fernandez, 1984). In addition, the division of *Micromonospora carbonacea* into two subspecies, *Micromonospora carbonacea* subsp. *carbonacea* and *Micromonospora carbonacea* subsp. *aurantiaca*, originally established on the basis of the morphology of the spores, is not supported by DNA relatedness data; hence, the subspecies are considered as synonyms

of *Micromonospora carbonacea* (Kasai et al., 2000). The phylogenetic position of the type strain of *Micromonospora aurantiaca* within the genus has been confirmed by 16S rRNA analysis (Kasai et al., 2000), in spite of an early association of this taxon with the genus *Actinoplanes* (Kawamoto, 1989).

Descriptions of 18 novel *Micromonospora* species have been published recently: *Micromonospora auratinigra*, *Micromonospora chokoriensis*, *Micromonospora citrea*, *Micromonospora coriariae*, *Micromonospora coxensis*, *Micromonospora eburnea*, *Micromonospora echinaurantiaca*, *Micromonospora echinofusca*, *Micromonospora endolithica*, *Micromonospora fulviviridis*, *Micromonospora inyonensis*, *Micromonospora lupini*, *Micromonospora mirobrigensis*, *Micromonospora peucetia*, *Micromonospora saelicesensis*, *Micromonospora sagamiensis*, *Micromonospora siamensis*, and *Micromonospora viridifaciens* (Ara and Kudo, 2007b; Hirsch et al., 2004a; Kroppenstedt et al., 2005a; Thawai et al., 2004b, 2005a, 2005b; Trujillo et al., 2005, 2006, 2007).

Since submission of this chapter, the following *Micromonospora* species have been described: *Micromonospora chaiyaphumensis* (Jongrungruangchok et al., 2008b); *Micromonospora krabiensis* (Jongrungruangchok et al., 2008a); *Micromonospora marina* (Tanasupawat et al., 2010); *Micromonospora narathiwatensis* (Thawai et al., 2007); *Micromonospora pattaloongensis* (Thawai et al., 2008); *Micromonospora pisi* (Garcia et al., 2010); *Micromonospora rifamycinica* (Huang et al., 2008); and *Micromonospora tulbaghiae* (Kirby and Meyers, 2010).

Differentiation of species of the genus *Micromonospora*

Characteristics which can be used to differentiate between *Micromonospora* species are shown in Table 192 and Table 193.

Acknowledgements

Many thanks to Dr Oscar Salazar for his contribution to updating the phylogenetic analysis of *Micromonospora* species.

List of species of the genus *Micromonospora*

1. **Micromonospora chalcea** (Foulerton 1905) Ørskov 1923, 156[AL] ("*Streptothrix chalcea*" Foulerton 1905, 1199)

chal′ce.a. L. fem. adj. *chalcea* brazen, of brass.

Raised and folded reddish orange colonies that turn brown, olive-brown to dark-brown with age and eventually black upon sporulation. The substrate mycelium is covered by a moist to dry spore layer; a pale yellow fluorescent diffusible pigment is produced in yeast starch media. Does not form melanin pigments. Spores are produced abundantly on short or long sporophores. Dark brown occasionally sessile, oval to spherical spores (0.7–1.0 µm in diameter) are formed. Phase-contrast microscopy has shown that the spores have smooth surfaces.

Diagnostic carbohydrate utilization pattern is good growth on melibiose, but growth does not occur on mannitol or rhamnose. Grows on arabinose, cellobiose, fructose, glucose, galactose, lactose, levulose, mannose, soluble starch, sucrose, trehalose, and xylose as sole carbon sources, but not on glycerol, inositol, salicin, or ribose. Decomposes cellulose; negative for nitrate reduction; liquefies gelatin and digests milk. Good growth occurs between 27 and 37°C, but does not grow at 45°C. Maximum NaCl tolerance is 5% (w/v). Peptidoglycan contains *meso*-A_2pm; major menaquinones are MK-10(H_4) and MK-10(H_6).

Source: isolated from air, soil, and aquatic environments.

DNA G+C content (mol%): 71.9 (HPLC).

Type strain: ATCC 12452, DSM 43026, NBRC 13503, JCM 3031, NRRL B-2344, VKM Ac-822.

Sequence accession nos: U58531, X92594 (16S rRNA gene); AB014148 (*gyrB*).

2. **Micromonospora aurantiaca** Sveshnikova, Maksimova and Kudrina 1969, 758[AL]

au.ran.ti.a′ca. N.L. fem. adj. *aurantiaca* orange-colored.

Colonies grown on synthetic media produce light yellow, orange, or dark orange mycelium without a spore layer. On organic media, colonies present a pale orange to bright orange pigmentation of the substrate mycelium that turns grayish on sporulation on some media. Does not produce melanin pigments. Spores are formed in clusters, albeit moderately so.

Arabinose, cellobiose, fructose, galactose, melibiose, and xylose are used as sole carbon sources, but not glycerol, lactose, mannitol, rhamnose, ribose, or salicin. Decomposes cellulose; positive for nitrate reduction, milk peptonization, and decomposition of tyrosine; negative for starch hydrolysis.

Source: soil.

DNA G+C content (mol%): 71.6 (HPLC).

Type strain: ATCC 27029, DSM 43813, NBRC 16125, NBRC 16155, JCM 10878, NRRL B-16091, VKM Ac-1936.

Sequence accession nos: X92604 (16S rRNA gene); AB015621 (*gyrB*).

Additional remarks: according to Rule 12b of the *Bacteriological Code* (1990 Revision), Euzéby and Tindall (2004) requested the replacement of the specific epithet "*aurantiaca*" in *Micromonospora aurantiaca* by "*sandarakina*".

3. **Micromonospora auratinigra** corrig. Thawai, Tanasupawat, Itoh, Suwanborirux and Kudo 2004a, 1425[VP] [*Micromonospora aurantionigra* (*sic*)] (Effective publication: Thawai, Tanasupawat, Itoh, Suwanborirux and Kudo 2004b, 13.)

au.ra.ti.ni′gra. L. adj. *auratus -a -um* gold-colored; L. adj. *niger -gra -grum* black; N.L. fem. adj. *auratinigra* gold- and black-colored, referring to the color of colonies.

Colonies are vivid orange on yeast extract-malt extract agar (ISP medium 2) turning to brownish black or black after sporulation; a brown soluble pigment is produced. Aerial mycelium is absent. Does not produce melanin pigments. Single spores are formed on sporophores produced on substrate hyphae. Growth is observed between 20 and 30°C, but not above 40°C. Maximum NaCl concentration for growth is 2% (w/v); pH range for growth is 5–10.

Arabinose, cellobiose, fructose, galactose, glucose, lactose, melibiose, raffinose, ribose, salicin, and xylose are used as sole carbon sources, but not glycerol, mannitol, or

(2005, 2007, 2006); Weinstein et al. (1968, 1970). nd, Not determined; v, variable response; w, weak response.

rhamnose. Positive for starch hydrolysis and gelatin liquefaction; weakly positive for milk peptonization; negative for nitrate reduction and for decomposition of adenine, hypoxanthine, tyrosine, and xanthine. Hydrogen sulfide is not produced.

Cell wall contains glutamic acid, glycine, alanine, and *meso*-A_2pm and 3-OH-A_2pm. Arabinose and xylose are the characteristic whole-organism sugars, but galactose, glucose, mannose, and ribose are also present. The phospholipid profile contains diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. Predominant menaquinones are MK-10(H_4), MK-9(H_4), and MK-10(H_6); the major fatty acids include $C_{15:0}$ iso and $C_{16:0}$ iso with small amounts of $C_{17:0}$ iso, $C_{17:0}$ anteiso, and $C_{15:0}$ anteiso. Does not contain mycolic acids. DNA–DNA relatedness with other *Micromonospora* type strains ranges between 32 and 53%.

Source: isolated from soil collected in a peat swamp forest, Thailand.

DNA G+C content (mol%): 72.8 (HPLC).

Type strain: TT1-11, JCM 12357, PCU 239, DSM 44815, TISTR 1532.

Sequence accession no. (16S rRNA gene): AB159779.

4. **Micromonospora carbonacea** Luedemann and Brodsky 1965, 51[AL]

car.bo.na′ce.a. L. n. *carbo -onis* coal, charcoal; L. suff. *-aceus* suffix of various meanings, but signifying in general made of or belonging to; N.L. fem. adj. *carbonacea* charcoal-like (referring to color of spores).

Colonies are raised, folded, and initially orange, but turn brown to black on sporulation. Spores are generally abundant. Characteristic blackish sporulating peripheral sectors are formed. Spore layer is moist or dry, but not viscid. Spores are oval to spherical (0.7–1.0 µm in diameter), and smooth-walled by light microscopy. Sporulation is observed in liquid media as sparsely dispersed clumps of mycelium, which consist mostly of unbranched, long, loosely woven, fine mycelial strands. Spores remain firmly attached to the sympodial type of sporophore, and are only free in older cultures. The mycelium does not degenerate into polymorphic bodies. Fair to good growth occurs on Czapek's sucrose agar supplemented with 0.1% $CaCO_3$. Melanin pigments are not produced. Good growth occurs between 27 and 37°C, but does not grow at 45°C.

Arabinose, cellobiose, fructose, glucose, galactose, lactose, levulose, mannose, melibiose, soluble starch, sucrose, trehalose, and xylose are used as sole carbon sources, but not mannitol or rhamnose. Poor growth is observed on arabinose, dulcitol, glycerol, inositol, raffinose, ribose, salicin, sorbose, and sorbitol. Gelatin is liquefied. Milk is digested. Positive for nitrate reduction, hydrolysis of tyrosine, and oxidase reaction. Tolerates salt up to 3% (w/v).

Major fatty acids are $C_{15:0}$ iso and $C_{17:1}$ ω8 and the predominant menaquinone is MK-9(H_4). Produces antibiotics of the everninomicin complex.

Source: isolated from a soil sample collected from Olean, New York.

DNA G+C content (mol%): 73.3 (HPLC).

Type strain: ATCC 27114, DSM 43168, NBRC 14108, JCM 3139, NRRL 2972.

Sequence accession nos: X92599 (16S rRNA gene); AB014147 (*gyrB*).

Additional remarks: in the original description, poor growth was reported on raffinose and salicin, but these sugars are utilized in a chemically defined agar medium (Kawamoto, 1989). *Micromonospora carbonacea* subsp. *carbonacea* Luedemann and Brodsky 1965[AL] and *Micromonospora carbonacea* subsp. *aurantiaca* Luedemann and Brodsky 1965[AL] are synonyms of *Micromonospora carbonacea* Luedemann and Brodsky 1965, 51[AL] (Kasai et al., 2000).

5. **Micromonospora chersina** Tomita, Hoshino, Ohkusa, Tsuno and Miyaki 1992a, 656[VP] (Effective publication: Tomita, Hoshino, Ohkusa, Tsuno and Miyaki 1992b, 25.)

cher.si′na. Gr. adj. *khersinos* living in dry land; N.L. fem. adj. *chersina* referring to the savanna vegetation from which this organism was isolated.

Light orange to yellow colonies turning light olive gray or black upon sporulation. Fluorescent yellow diffusible pigment produced on Czapek's sucrose-nitrate agar and inorganic salts-starch agar (ISP medium 4). Melanin pigments are not produced. Single spherical spores (1.2–1.8 µm) are sessile or borne on short or long monopodial sporophores developed from well-branched substrate hyphae (0.5 µm diameter). The spore surface carries short blunt spines. Short sterile aerial hyphae occasionally developed on some media. Moderate growth occurs on inorganic salts starch and yeast-malt extract agars, but poor growth occurs on many media, including Czapek's agar, and glycerol-asparagine and tyrosine agars. Grows between 18 and 49°C, and optimally between 37 and 44°C. pH range for growth is 5.5–10.5. Maximum NaCl tolerance is 3% (w/v).

Arabinose, cellobiose, fructose, galactose, glucose, mannose, melibiose, sucrose, trehalose, and xylose are used as sole carbon sources, but not arabinose, inositol, glycerol, mannitol, rhamnose, or ribose. Utilization of raffinose is variable depending on the medium. Positive for gelatin liquefaction and starch hydrolysis. Nitrate reduction is variable depending on the medium. Negative for tyrosinase activity. Positive for α- and β-glucosidases, but negative for α-mannosidase and β-xylosidase.

Cell wall contains *meso*-A_2pm and glycine. Whole-organism sugars include glucose and mannose, and traces of arabinose and xylose. Predominant menaquinones are MK-9(H_4), MK-9(H_6), MK-10(H_4), and MK-10(H_6). Major phospholipids are phosphatidylinositol and phosphatidylethanolamine. Produces antitumor antibiotic dynemicin.

Source: isolated from an Indian soil.

DNA G+C content (mol%): 72.9 (HPLC).

Type strain: M956-1, ATCC 53710, DSM 44151, NBRC 15963, JCM 9459.

Sequence accession nos: X92628 (16S rRNA gene); AB015622 (*gyrB*).

6. **Micromonospora chokoriensis** Ara and Kudo 2007, 1372[VP] (Effective publication: Ara and Kudo 2007b, 35.)

cho.ko.ri.en′sis. N.L. fem. adj. *chokoriensis* of or pertaining to Chokoria, Bangladesh, the origin of the soil from which the type strain was isolated

Golden brown to dark brown colonies are formed on yeast extract-starch agar without soluble pigments. Melanin pigments are not produced. Well-developed branched substrate mycelium bears single sessile spores. Spores are spherical with a rough to nodular spore surface. Grows at pH 5–9, at 20–37°C, and in 3% NaCl.

Arabinose, fructose, galactose, glucose, lactose, maltose, mannose, α-melibiose, raffinose, salicin, sucrose, trehalose, and xylose are used as sole carbon sources, but not adonitol, erythritol, fructose, glycerol, rhamnose, *myo*-inositol, or mannitol. Ribose is weakly utilized.

Cell wall contains *meso*-A_2pm. Whole-organism sugars include arabinose, galactose, glucose, mannose, ribose, and xylose. Contains diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides as major polar lipids. Major fatty acids are $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$ iso, and $C_{15:0}$ anteiso. The predominant menaquinone is MK-10(H_4); minor amounts of MK-10(H_6), MK-9(H_4), and MK-9(H_6) are formed.

Source: isolated from sandy soil in forest-side waterfall.

DNA G+C content (mol%): 71 (HPLC).

Type strain: 2-19(6), JCM 13247.

Sequence accession no. (16S rRNA gene): AB241454.

7. **Micromonospora citrea** Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005b, 1743[VP] (Effective publication: Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005a, 333.)

ci′tre.a. L. fem. adj. *citrea* of or pertaining to the citrus-tree.

Colonies are pastel orange on yeast-malt extract agar (ISP medium 2), pastel yellow on inorganic salts-starch agar (ISP medium 4), and yellow orange on peptone-yeast extract-iron agar (ISP medium 6). A yellow orange soluble pigment is formed on peptone-yeast extract-iron agar. Aerial mycelium is absent. Single spores are formed on substrate mycelium.

Arabinose, glucose, and sucrose are used as sole carbon sources, but not fructose, inositol, mannitol, raffinose, rhamnose, or xylose. Positive for alkaline phosphatase, *N*-acetyl-β-glucosaminidase, esterase, α-and β-galactosidases, α-glucosidase, and acid phosphatase, but negative for α-fucosidase, β-glucosidase, β-glucuronidase, lipase, and α-mannosidase.

Peptidoglycan contains *meso*-A_2pm. Whole-organism diagnostic sugars are glucose and xylose. Major menaquinone is MK-9(H_4); phosphatidylethanolamine is the diagnostic phospholipid. Major fatty acids are $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:0}$ 10-methyl.

Source: isolated from lake mud, China.

DNA G+C content (mol%): not determined.

Type strain: DSM 43903, ATCC 35571, JCM 3256, NBRC 14025, NRRL B-16101.

Sequence accession no. (16S rRNA gene): X92617.

8. **Micromonospora coerulea** Jensen 1932, 177[AL]

coe.ru′le.a. L. fem. adj. *coerulea* dark blue, dark green.

Slow-growing colonies that require 3–5 weeks to develop. Pale-yellow-orange colonies turn yellow-green then dark blue-green to greenish black with age. pH-sensitive soluble pigment is produced. Spherical spores (0.8–1.5 µm in diameter) are borne on short or lateral sporophores. Mycelium fragmentation is observed rarely in old liquid cultures. Good growth occurs between 24 and 37°C.

Fructose, galactose, and lactose are used as sole carbon sources, but poor growth is seen on arabinose and arabinose. Starch is hydrolyzed.

Source: isolated from soil from Mt Haleakala, Maui Island, Hawaii.

DNA G+C content (mol%): 71.7 (HPLC).

Type strain: ATCC 27008, DSM 43143, NBRC 13504, JCM 3175, VKM Ac-661.

Sequence accession nos: X92598 (16S rRNA gene); AB014151 (*gyrB*).

9. **Micromonospora coriariae** Trujillo, Kroppenstedt, Schumann, Carro and Martínez-Molina 2006, 2384[VP]

co.ri.a.ri′a.e. N.L. gen. n. *coriariae* of *Coriaria*, pertaining to the isolation of the type strain from root nodules of *Coriaria myrtifolia*.

Raised, folded, intensively orange colonies turn darker with age, does not form diffusible pigments. Abundant growth on Bennett's SA1 and yeast extract-malt extract (ISP medium 2) agars. Single spores form at the tips of well-developed substrate hyphae. Optimum growth is at 28°C. Grows at pH 7–9, does not grow below pH 6.5.

Alanine, arabinose, arginine, cellobiose, fructose, gluconate, glucose, histidine, mannose, melibiose, pyruvate, raffinose, rhamnose, salicin, serine, starch, trehalose, and xylose are used as sole carbon sources, but not ascorbic acid, galactose, glutaric acid, lysine, melezitose, proline, propionic acid, sorbitol, sorbose, sucrose, tyrosine, valine, or xylitol. Positive for acid and alkaline phosphatases, esterases, α- and β-galactosidases, α- and β-glucosidases, and *N*-acetyl-β-glucosaminidase, but not for α-chymotrypsin, β-glucuronidase, or α-mannosidase. Oxidase- and catalase-positive. Degrades arbutin, casein, esculin, gelatin, starch, and Tween 80, but not tyrosine, urea, or Tween 20.

Whole-organism hydrolysates contain *meso*-A_2pm, and arabinose, glucose, mannose, ribose, and, xylose as characteristic sugars. Fatty acid profile is characterized by significant amounts of $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$, and $C_{17:0}$ 10-methyl. Major menaquinone is MK-10(H_4), with minor amounts of MK-10(H_6) and MK-9(H_4).

Source: the type strain was isolated from root nodules of *Coriaria myrtifolia*.

DNA G+C content (mol%): 70.2 (T_m).

Type strain: NAR01, DSM 44875, LMG 23557.

Sequence accession no. (16S rRNA gene): AJ784008.

10. **Micromonospora coxensis** Ara and Kudo 2007, 1372[VP] (Effective publication: Ara and Kudo 2007b, 36.)

cox.en′sis. N.L. fem. adj. *coxensis* pertaining to Cox's Bazaar, Bangladesh, the origin of the soil from which the type strain was isolated.

Colonies on yeast extract-starch agar are light brown to cinnamon brown without diffusible pigment. Melanin pigments are not produced. Well-developed substrate mycelium is formed with spherical single spores borne directly on substrate hyphae. Spore surface is nodular to warty. Grows at pH 5–9, at 15–37°C, and in 3% (w/v) NaCl.

Adonitol (weak), arabinose, fructose, galactose, glycerol, lactose, mannose, maltose, α-melibiose, raffinose, rhamnose, ribose, salicin, sucrose, trehalose, and xylose are used as sole carbon sources, but not erythritol, *myo*-inositol, or mannitol.

Whole-organism hydrolysates contain *meso*-A_2pm, and arabinose, galactose, glucose, mannose, rhamnose, ribose, and xylose as characteristic sugars. Fatty acid profile is characterized by significant amounts of $C_{17:0}$, $C_{17:1}$ iso, $C_{15:0}$ iso, $C_{17:0}$ anteiso, and $C_{16:1}$ iso. Major menaquinones are MK-10(H_6) and MK-10(H_8), with minor amounts of MK-10(H_4), MK-9(H_4), MK-9(H_6), and MK-9(H_8).

Source: isolated from sandy soil next to a forest-side waterfall.

DNA G+C content (mol%): 73 (HPLC).

Type strain: 2-30-b(28), JCM 13248, MTCC 8093.

Sequence accession no. (16S rRNA gene): AB241455.

11. **Micromonospora eburnea** Thawai, Tanasupawat, Itoh, Suwanborirux, Suzuki and Kudo 2005b, 55[VP]

e.bur′ne.a. L. fem. adj. *eburnea* of ivory, white as ivory, referring to the color of colonies.

Well-developed and branched substrate mycelium. Colonies have a characteristic yellowish white or dull orange color depending on the media. They turn grayish black upon sporulation on yeast extract-malt extract agar (ISP medium 2); a pale yellow soluble pigment is produced on this medium and on oatmeal (ISP medium 3) and nutrient agars. Nonmotile single spores (0.45 µm in diameter)

are borne on substrate hyphae. Aerial mycelium is not produced. Optimal temperature for growth is 25–30°C, does not grow above 45°C. Maximum NaCl concentration tolerated for growth is 4% (w/v).

Cellobiose, glucose, glycerol, lactose, melibiose, raffinose, rhamnose, salicin, and xylose are used as sole carbon sources, but not arabinose, fructose, or ribose. Positive for milk peptonization, starch hydrolysis, and nitrate reduction.

Cell-wall hydrolysates contain alanine, glycine, glutamic acid, and *meso*-A_2pm. Muramic acid is glycolated. Arabinose and xylose are the characteristic whole-organism sugars. Whole-organism hydrolysates contain galactose, glucose, mannose, and ribose. The characteristic phospholipids are phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides. Predominant menaquinones are MK-9(H_4), MK-10(H_4), and MK-9(H_6). Major fatty acids include $C_{15:0}$ iso, $C_{16.0}$, $C_{17:0}$ iso, $C_{15:0}$ anteiso, $C_{17:0}$, and $C_{17:0}$ anteiso. Mycolic acids are absent.

Source: isolated from a peat swamp forest soil in southern Thailand.

DNA G+C content (mol%): 71.5 (HPLC).

Type strain: LK2-10, DSM 44814, JCM 12345, PCU 238, TISTR 1531.

Sequence accession no. (16S rRNA gene): AB107231.

12. **Micromonospora echinaurantiaca** Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005b, 1743[VP] (Effective publication: Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005a, 333.)

e.chin.au.ran.ti.a′ca. Gr. n. *echinos* hedgehog, sea-urchin, N.L. fem. adj. *aurantiaca* orange-colored; N.L. fem. adj. *echinaurantiaca* spiny and orange-colored.

Orange-colored colonies. Aerial mycelium is not formed. Pigment of substrate mycelium ranges from bright orange on inorganic salts-starch agar (ISP medium 4), peptone-yeast extract-iron agar (ISP medium 6), and yeast extract-malt extract agar (ISP medium 2) to deep orange on oatmeal agar (ISP medium 3). Soluble pigments are not produced.

Arabinose, fructose, glucose, mannitol, sucrose, and raffinose are used as sole carbon sources, but not inositol, rhamnose, or xylose. Positive for alkaline phosphatase, *N*-acetyl-β-glucosaminidase, esterase, α-glucosidase, α- and β-galactosidase, and phosphatase acid, but not for β-glucosidase, β-glucuronidase, lipase, α-mannosidase, or α-fucosidase.

Peptidoglycan contains *meso*-A_2pm. Whole-organism diagnostic sugars are glucose and rhamnose. Major menaquinone is MK-9(H_4). Phosphatidylethanolamine is the diagnostic phospholipid. Major fatty acids include $C_{15:0}$ iso, $C_{16.0}$, and $C_{17:0}$ iso.

Source: isolated from a Chinese soil.

DNA G+C content (mol%): not determined.

Type strain: DSM 43904, ATCC 35572, JCM 3257, NBRC 14022, NRRL B-16102.

Sequence accession no. (16S rRNA gene): X92618.

13. **Micromonospora echinofusca** Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005b, 1743[VP] (Effective publication: Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005a, 333.)

e.chi.no.fus′ca. Gr. n. *echinos* hedgehog, sea-urchin; L. fem. adj. *fusca* brown-colored, N.L. fem. adj. *echinofusca* spiny and brown-colored.

Colonies are orange-colored ranging from deep brownish-orange on inorganic-salts-starch agar (ISP medium 4), and glucose-asparagine agar (ISP medium 5), to pastel orange on oatmeal agar (ISP medium 3), tyrosine agar (ISP medium 7), and yeast extract-malt extract agar (ISP medium 2). Aerial mycelium is absent. Poor growth occurs on peptone-yeast extract-iron agar (ISP medium 6). Soluble pigments are not formed.

Fructose, glucose, and sucrose are used as sole carbon sources, but not arabinose, inositol, mannitol, raffinose, rhamnose, or xylose. Positive for *N*-acetyl-β-glucosaminidase, alkaline phosphatase, α- and β-galactosidases, α- and β-glucosidases, and acid phosphatase, but not for α-fucosidase, glucuronidase, lipase, or α-mannosidase.

Peptidoglycan contains *meso*-A_2pm. Whole-organism diagnostic sugars are glucose and xylose. Major menaquinone is MK-9(H_4). Phosphatidylethanolamine is the diagnostic phospholipid. Major fatty acids are $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:1}$ ω8*c*.

Source: isolated from excrement of a chukar at Beijing Zoological Garden, China.

DNA G+C content (mol%): not determined.

Type strain: DSM 43913, JCM 3327, NBRC 14267.

Sequence accession no. (16S rRNA gene): X92625.

14. **Micromonospora echinospora** Luedemann and Brodsky 1964, 121[AL] emend. Kasai, Tamura and Harayama 2000, 131

e.chi.no.spo′ra. Gr. n. *echinos* hedgehog, sea-urchin; Gr. n. *spora* seed and in biology a spore; N.L. fem. n. *echinospora* spiny spore.

Colonies are orange-brown, maroon to dark purple and folded. Maroon to dark-purple pigments are pH-sensitive (red in the acid range and blue-green and precipitable in the basic range). Black spore layer is waxy to dry. Does not form melanin pigments. Sporulation is moderate, requiring 2–3 weeks for completion. Occasionally forms a sterile aerial mycelium in the form of a gray bloom. Spores are spherical (1.0–1.5 µm) and rough walled under phase-contrast microscopy. Sporophores are single or in small clusters on the same hyphae. Grows between 27 and 37°C, but not at 45°C.

Arabinose, cellobiose, glucose, mannose, sucrose, trehalose, soluble starch, and xylose are used as sole carbon sources, but not glycerol, inositol, raffinose, sorbitol, or salicin. Poor to fair growth occurs on galactose, lactose, and levulose. Diagnostic carbohydrate utilization pattern: good growth on rhamnose; poor growth on melibiose, mannitol, and ribose. Slow decomposition of cellulose. Gelatin is weakly liquefied. Milk is weakly digested.

Most strains produce antibiotics of the gentamicin complex.

Source: isolated from a soil sample collected from Jamesville, New York.

DNA G+C content (mol%): 71.7 (HPLC).

Type strain: ATCC 15837, DSM 43816, NBRC 13149, JCM 3073, NRRL 2985, VKM Ac-669.

Sequence accession nos: X92607 (16S rRNA gene); AB014154 (*gyrB*).

Additional remarks: earlier heterotypic synonyms are *Micromonospora rhodorangea* Wagman et al. 1974, *Micromonospora echinospora* subsp. *ferruginea* Luedemann and Brodsky 1964, and *Micromonospora purpurea* Luedemann and Brodsky 1964 (Skerman et al., 1980).

15. **Micromonospora endolithica** Hirsch, Mevs, Kroppenstedt, Schumann and Stackebrandt 2004b, 631[VP] (Effective publication: Hirsch, Mevs, Kroppenstedt, Schumann and Stackebrandt 2004a, 172.)

en.do.li′thi.ca. L. prep. *endo* in, within; Gr. n. *lithos* stone; L. suff. *-icus -a –um*, suffix used in adjectives with the sense of belonging to; N.L. fem. adj. *endolithica* (growing) within stone.

Orange, folded colonies that turn grayish-black, olive, or black upon sporulation. Soluble pigments are not produced. Vegetative hyphae (0.5–1.0 µm in diameter) often produce terminal "lemon-shaped" bodies. Spores (0.8–1.1 µm) are produced singly on short hyphae side branches and have short warty surfaces. Temperature range for growth is 8–39°C, with an optimal temperature of 27–29°C. Tolerates up to 7% salt, but optimum for growth is 2%.

Arabinose, cellobiose, fructose, galactose, glucose, lactose, maltose, mannitol (weak), mannose, melibiose, raffinose (weak), sucrose, trehalose, and xylose are used as sole carbon sources, but not *N*-acetylglucosamine, citrate, dextrin, inositol, oxalate, rhamnose, ribose, sorbitol, or sorbose. Catalase- and cytochrome oxidase-positive. Degrades adenine, casein, gelatin, starch, tyrosine, and xanthine, but not cellulose, chitin, or xylan. Hydrolyzes esculin.

Cell-wall amino acids include alanine, glycine, glutamic acid, and *meso*-A_2pm, and whole-organism sugars are arabinose, galactose, rhamnose, ribose, and xylose. Characteristic cell-wall sugars are arabinose and xylose. The characteristic phospholipids are phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol. Predominant menaquinones are MK-10(H_4) and MK-10(H_6). Major fatty acids include $C_{16:0}$ iso, $C_{17:1}$ ω8*c*, $C_{17:1}$ iso ω9*c*, and $C_{15:0}$ iso; $C_{18:0}$ 10-methyl is also present. Sensitive to 50 µg/ml lysozyme.

Source: isolated from sandstone in Antarctica.

DNA G+C content (mol%): 70.0 (T_m).

Type strain: AA-459, DSM 44398, JCM 12677, NRRL B-24248.

Sequence accession no. (16S rRNA gene): AJ560635.

16. **Micromonospora fulviviridis** Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005b, 1743[VP] (Effective publication: Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005a, 335.)

ful.vi.vi′ri.dis. L. adj. *fulvus* tawny, brown; L. adj. *viridis* green; N.L. fem. adj. *fulviviridis* brown-green.

Salmon orange to salmon pink colonies are formed on inorganic salts-starch (ISP medium 4), oatmeal (ISP medium 3), and yeast extract-malt extract (ISP medium 2) agars. Pastel yellow substrate mycelium is formed on glycerol-asparagine (ISP medium 5) and peptone-yeast extract (ISP medium 6) agars. Soluble pigments are not formed.

Arabinose, fructose, glucose, mannitol, raffinose, and sucrose are used as sole carbon sources, but not inositol, rhamnose, or xylose. Positive for alkaline phosphatase, α- and β-galactosidases, α- and β-glucosidases, and acid phosphatase, but not for *N*-acetyl-β-glucosaminidase, α-fucosidase, β-glucuronidase, or α-mannosidase.

Peptidoglycan contains *meso*-A_2pm. Whole-organism diagnostic sugars are glucose and xylose. Major menaquinone is MK-9(H_4). Phosphatidylethanolamine is the diagnostic phospholipid. Major fatty acids are $C_{15:0}$ iso, $C_{16:0}$, and $C_{17:0}$ iso.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: DSM 43906, ATCC 35574, JCM 3259, NRRL B-6104.

Sequence accession no. (16S rRNA gene): X92620.

17. **Micromonospora halophytica** Weinstein, Luedemann, Oden and Wagman 1968, 436[AL]

ha.lo.phy′ti.ca. N.L. fem. adj. *halophytica* growing under the influence of seawater.

Forms folded orange colonies that turn orange-brown with age. Sporulation is abundant, especially in older colonies. Light reddish brown diffusible pigment is produced in media containing galactose, lactose, levulose, mannose, raffinose, or trehalose. Melanin pigments are not produced. Grows between 18 and 40°C, but not at 50°C. Good growth within pH range 6.8–7.8. Spores are produced randomly along branching mycelium on short or long sporophores, but are occasionally sessile. Abundant dark colored spores occur in older cultures. Spores are spherical to ellipsoidal (up to 1.2 µm in diameter).

Arabinose, fructose, galactose, glucose, lactose, levulose, mannose, melibiose, raffinose, starch, sucrose, trehalose, and xylose are used as sole carbon sources. Poor growth occurs on adonitol, cellulose, rhamnose, inositol, mannitol, ribose, and sorbitol. Hydrolyzes starch, decomposes cellulose, reduces nitrate, liquefies gelatin, and digests milk. Produces antibiotics of the halomicin antibiotic complex.

Source: isolated from a salt pool in Syracuse, New York.

DNA G+C content (mol%): 72.5 (HPLC).

Type strain: ATCC 27596, DSM 43171, NBRC 14112, JCM 3125, NRRL 2998.

Sequence accession nos: X92601 (16S rRNA gene); AB014157 (*gyrB*).

18. **Micromonospora inositola** Kawamoto, Okachi, Kato, Yamamoto, Takahashi, Takasawa and Nara 1974, 495[AL]

i.no.si′to.la. N.L. fem. adj. *inositola* intended to mean that the bacterium is able to utilize inositol.

Folded, bright orange to orange colonies are formed on Bennett's, nutrient, and potato agars. Soluble pigments are not produced. Does not form a spore layer. Poor growth occurs on glucose-asparagine, inorganic starch, and oatmeal agars. Poor sporulation occurs on most media. Spores are oval to spherical (0.8–1.0 µm in diameter) and borne on short sporophores. Grows between 25 and 40°C and at pH 5.5–8.5.

Cellobiose, fructose, galactose, glucose, inositol (weak), lactose, mannose, raffinose, and xylose are used as sole carbon sources, but not arabinose, glycerol, mannitol, rhamnose, ribose, salicin, or sorbitol. Liquefies gelatin. Milk is slightly coagulated, but not peptonized. Negative for nitrate reduction. Cellulose is slightly decomposed. Starch is hydrolyzed. Produces antibiotics of the macrolide XK-41 complex.

Source: isolated from a soil sample from Hokkaido, Japan.

DNA G+C content (mol%): 71.4 (HPLC).

Type strain: ATCC 21773, DSM 43819, JCM 6239, NRRL B-16095.

Sequence accession nos: X92610 (16S rRNA gene); AB014158 (*gyrB*).

19. **Micromonospora inyonensis** Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005b, 1743[VP] (Effective publication: Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005a, 337.)

in.yo.nen′sis. N.L. fem. adj. *inyonensis* of or pertaining to Inyo County, California.

Viscid to poorly plicate colonies with fair to poor growth of substrate mycelium. Aerial mycelium is not formed. Substrate mycelium ranges from copper brown on inorganic salts-starch agar (ISP medium 4), to red-green on oatmeal agar (ISP medium 3), yellow on peptone-yeast extract-iron (medium ISP 6) and tyrosine (ISP medium 7), and yellow-olive on yeast extract-malt extract agar (ISP medium 2). Soluble brown yellow pigment is produced on ISP medium 6. Sparse growth occurs on glycerol-asparagine agar (ISP medium 5). Long branched mycelium is formed that is regular and nonseptate and with a mean diameter of 0.5 µm. Ovoid to spherical spores (1.0–1.5 µm in diameter) are rough walled and occasionally borne singly on sporophores.

Poor utilization of arabinose, fructose, glucose, inositol, mannitol, rhamnose, raffinose, sucrose, and xylose is observed. Positive for alkaline phosphatase, esterase, *N*-acetyl-β-glucosaminidase, α- and β-glucosidases, and acid phosphatase, but not for α-fucosidase, lipase, α- or β-galactosidase, β-glucuronidase, or α-mannosidase.

Peptidoglycan contains *meso*-A_2pm. Whole-organism diagnostic sugars are arabinose, glucose, and xylose. Major menaquinone is MK-9(H_4). Phosphatidylethanolamine is the diagnostic phospholipid. Major fatty acids are $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:1}$ iso. Produces the aminoglycoside sisomicin (also known as rickamicin or antibiotic 6640).

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: DSM 46123, JCM 3188, ATCC 27600, NBRC 13156, NRRL 3292.

Sequence accession no. (16S rRNA gene): X92629.

20. **Micromonospora lupini** Trujillo, Kroppenstedt, Fernández-Molinero, Schumann and Martínez-Molina 2007, 2803[VP]

lu′pi.ni. L. gen. n. *lupini* of a lupin, referring to the isolation of the first strains from *Lupinus angustifolius*.

Light orange, folded, raised colonies without diffusible pigments are formed on yeast extract-malt extract agar. Produces well-developed branched hyphae (0.3–0.6 µm in diameter) with smooth-surfaced spores produced at hyphal tips. Grows at 20–37°C. Good growth occurs in 1% (w/v) NaCl, but growth is variable in 2% (w/v) NaCl.

Alanine, cellobiose, galactose, maltose, mannose, melibiose, raffinose, and trehalose are assimilated as carbon sources, but not arginine, histidine, lysine, proline, rhamnose, serine, sorbitol sorbose, tyrosine, valine, or xylitol. Catalase- and oxidase-positive. Nitrate is not reduced. Degrades arbutin, casein, esculin, gelatin, starch, and xylan, but not tyrosine. Positive for alkaline phosphatase, esterases and lipases, α- and β-galactosidases, α- and β-glucosidases, and *N*-acetyl-β-glucosaminidase, but not for urease, or β-glucuronidase.

Whole-organism hydrolysates contain *meso*-A_2pm and arabinose, glucose, mannose, rhamnose, and xylose as characteristic sugars. Diagnostic phospholipid is diphosphatidylethanolamine. Major fatty acids are $C_{16:0}$ iso and $C_{15:0}$ iso. Predominant menaquinone is MK-10(H_4). One of the strains of this species produces the antitumoral lupinamicins A and B.

Source: isolated from root nodules of *Lupinus angustifolius*.

DNA G+C content (mol%): 70.9 (T_m).

Type strain: Lupac 14N, DSM 44874, LMG 24055.

Sequence accession no. (16S rRNA gene): AJ783996.

21. **Micromonospora matsumotoense** (Asano, Masunaga and Kawamoto 1989a) Lee, Goodfellow and Hah 2000a, 3[VP] (Effective publication: Lee, Goodfellow and Hah 1999, 353.) (*Catellatospora matsumotoense* Asano, Masunaga and Kawamoto 1989a, 313)

mat.su.mo.to.en′se. L. deriv. *matsumotoense* (*sic*) of Matsumoto Nagago, Japan, the location of the soil sample from which the type strain was isolated.

Orange colonies are formed on oatmeal and yeast extract-malt extract agars and yellow colonies are formed on glucose-yeast extract and nutrient agars. A reddish-brown soluble pigment is produced on oatmeal agar. Does not require thiamine for growth. Grows in the presence of 2% (w/v) NaCl, but not in 3% (w/v) NaCl.

L-Arabinose, cellobiose, fructose, glucose, galactose, lactose, maltose, mannose, raffinose, ribose, starch, sucrose, trehalose, and xylose are used as sole carbon sources, but not adonitol, D-arabinose, dextran, gluconate, glycerol, mannitol, melezitose, melibiose, rhamnose, salicin, sorbitol, sorbose, or xylitol. Decomposes casein, elastin, gelatin, and starch. Resistant to neomycin (5 µg/ml), novobiocin (50 µg/ml), tetracycline (20 µg/ml), and vancomycin (20 µg/ml).

Cell walls contain *meso*- and 3-OH-A_2pm. Muramic acid is glycolated. Diagnostic cell-wall sugars are arabinose, galactose, 3-*O*-methylrhamnose, and xylose. Major menaquinones are MK-10(H_4), MK-10(H_6), and MK-10(H_8). Diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylglycerol are the predominant polar lipids. Major fatty acids include $C_{16:0}$ iso, $C_{18:1}$, $C_{17:1}$, $C_{16:1}$ iso, and $C_{15:0}$ iso.

Source: isolated from soil.

DNA G+C content (mol%): 71.0 (HPLC).

Type strain: 6393-C, ATCC 49364, CIP 106812, DSM 44100, NBRC 14550, JCM 9104, NRRL B-16490, VKM Ac-2009, MSNU 22003.

Sequence accession no. (16S rRNA gene): AF152109.

22. **Micromonospora mirobrigensis** Trujillo, Fernández-Molinero, Velázquez, Kroppenstedt, Schumann, Mateos and Martínez-Molina 2005, 879[VP]

mi.ro.bri.gen′sis. N.L. fem. adj. *mirobrigensis* of or belonging to Mirobriga, the region in Spain where the type strain was isolated.

Small, raised, and folded colonies. Colonies grow slowly on Bennett's, glucose-yeast extract, and nutrient agars, and are 2–3 mm in diameter after incubation for 2 weeks on SA1 medium. Initially, colonies are orange, but turn brownish black with age and upon sporulation. Produces a well developed substrate mycelium with single warty spores. Grows between 20–37°C, with an optimal temperature of 28°C, but does not grow at 45°C. Grows at pH 7.0 and tolerates NaCl up to 3% (w/v).

Arabinose, cellobiose, galactose, glucose, maltose, mannose, raffinose, sucrose, and trehalose are used as sole carbon sources, but not citrate, malate, mannitol, melezitose, rhamnose, sorbitol, sorbose, or xylitol. Hydrolyzes arbutin and esculin. Degrades casein, gelatin, starch, and xylan. Nitrate is not reduced. Shows resistance to ampicillin (2 μg). Positive for acid phosphatase, alkaline phosphatase, esterase lipase, α- and β-galactosidases, β-glucuronidase, α- and β-glucosidases, and *N*-acetyl-β-glucosaminidase.

Cell wall contains *meso*-A_2pm. Whole-organism sugars are galactose, glucose, mannose, and xylose. Major fatty acids are $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$ iso, and $C_{17:0}$ anteiso. Predominant menaquinones are MK-10(H_4) and MK-10(H_6). Major phospholipids are diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol.

Source: isolated from a water sample taken from a pond in the region of Mirobriga, Ciudad Rodrigo, Spain.

DNA G+C content (mol%): 68.6 (T_m).

Type strain: WA201, DSM 44830, LMG 22229.

Sequence accession no. (16S rRNA gene): AJ626950.

23. **Micromonospora nigra** (Weinstein, Luedemann, Oden and Wagman 1968) Kasai, Tamura and Harayama 2000, 131[VP] (*Micromonospora halophytica* subsp. *nigra* Weinstein, Luedemann, Oden and Wagman 1968, 437; Kawamoto 1989, 2446)

ni′gra. L. fem. adj. *nigra* black.

Orange colonies turn olive-brown to black upon sporulation. Diffusible pigments are not produced. A black spore layer is observed on media containing fructose, galactose, lactose, raffinose, or trehalose. Melanin pigments are not produced. Grows between 18 and 40°C, but not at 50°C.

Adonitol (weak), arabinose, cellulose (weak), fructose, galactose, lactose, salicin, and raffinose are used as sole carbon sources, but not glycerol, mannitol, or rhamnose. Starch is hydrolyzed, cellulose is decomposed, and nitrate is reduced. Gelatin liquefaction and milk digestion are variable. Produces antibiotics of the halomycin complex.

Source: isolated from a salt pool in Syracuse, New York.

DNA G+C content (mol%): 71.7 (HPLC).

Type strain: ATCC 33088, DSM 43818, NBRC 16103, JCM 8973, NCIMB 2225, NRRL 3097.

Sequence accession nos: X92609 (16S rRNA gene); AB014156 (*gyrB*).

24. **Micromonospora olivasterospora** Kawamoto, Yamamoto and Nara 1983, 110[VP]

o.li.va.ste.ro.spo′ra. L. n. *oliva* an olive; Gr. n. *aster* a star; Gr. n. *spora* a seed and in biology a spore; N.L. fem. n. *olivasterospora* olive-colored spore that looks like a star.

Light brown to dark yellow colonies that become covered with an olive to dark green waxy layer of spores with age. Olive-green soluble, non-pH-sensitive pigments are formed on oatmeal and yeast extract-malt extract agars. Good growth occurs on most organic media. Melanin pigments are not formed. Well-developed branched and septate substrate hyphae (0.5 μm diameter) are formed. Spores are oval to spherical (approx 1.0 μm diameter), and rough-surfaced as seen by phase-contrast microscopy. Spores are borne on short sporophores or sessile, occurring randomly or in clusters. Terminally or intercalary chlamydospore-like swellings are sometimes present. Grows at 28–38°C and pH 6.8–7.8.

Fructose, galactose, glycerol, mannose, maltose, ribose, starch, sucrose, trehalose, and xylose are used as sole carbon sources, but not arabinose, dulcitol, inositol, lactose, mannitol, raffinose, melezitose, α-melibiose, rhamnose, salicin, sorbitol, or sorbose. NH_4NO_3, $(NH_4)_2SO_4$, NH_4Cl, arginine, aspartic acid, glutamic acid, histidine, and serine are used as sole nitrogen sources. Starch is hydrolyzed. Skim milk is peptonized, but not coagulated. Weak decomposition of cellulose. Positive for α- and β-glucosidases, and *N*-acetyl-β-glucosaminidase, but not for α-fucosidase, α- or β-galactosidases, or α-mannosidase.

Cell walls contain D-alanine, 3-OH-A_2pm, glycine, and glutamic acid. Arabinose, glucose, and xylose are the predominant whole-organism sugars. Major polar lipids are diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. Major fatty acids are $C_{15:0}$ iso and $C_{16:0}$ iso. Produces antibiotics of the fortimicin complex.

Source: isolated from a soil sample from Hiroshima, Japan.

DNA G+C content (mol%): 71.9 (HPLC).

Type strain: MK-70, ATCC 21819, DSM 43868, NBRC 14304, JCM 7348, NRRL 8178, VKM Ac-1317.

Sequence accession nos: X92613 (16S rRNA gene); AB014159 (*gyrB*).

25. **Micromonospora pallida** (Luedemann and Brodsky 1964) Kasai, Tamura and Harayama 2000, 131^VP (*Micromonospora echinospora* subsp. *pallida* Luedemann and Brodsky 1964, 116)

pal′li.da. L. fem. adj. *pallida* pale.

Light ivory to light melon-yellow colonies, which turn brown to black upon sporulation. Does not produce purple mycelial pigments, or melanin pigments. Spores are spherical, dark brown to black. Sporophores are solitary or in small clusters.

Arabinose, cellobiose, glucose, levulose, mannose, soluble starch, sucrose, trehalose, and xylose are used as sole carbon sources. Good growth occurs on rhamnose, whereas slight growth is found on ribose with abundant sporulation. Poor growth occurs on salicin. Growth on and decomposition of cellulose is slow. Positive for nitrate reduction, gelatin liquefaction, and milk digestion. Good growth is observed at 27–37°C.

Possesses a different menaquinone (MK-12) to other *Micromonospora* species. Produces antibiotics of the gentamicin complex.

Source: isolated from soil collected in Jamesville, New York.

DNA G+C content (mol%): 71.1 (HPLC).

Type strain: ATCC 15838, DSM 43817, NBRC 16070, JCM 3133, NRRL 2996.

Sequence accession nos: X92608 (16S rRNA gene); AB014153 (*gyrB*).

26. **Micromonospora peucetia** Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005b, 1743^VP (Effective publication: Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005a, 337.)

peu.ce′ti.a. L. fem. adj. *peucetia* Peucetian, of Peucetia, Latin name of landscape in Apulia (Puglia), Southern Italy.

Bottle green colonies are formed on inorganic salts-starch agar (ISP medium 4), pine green colonies are formed on glycerol-asparagine (ISP medium 5) and tyrosine agars (ISP medium 7), pale green to beige red colonies are formed on oatmeal agar (ISP medium 3), deep orange colonies are formed on yeast extract-malt extract agar (ISP medium 2), and chrome green colonies are formed on peptone-yeast extract-iron agar (ISP medium 6). Aerial hyphae are absent. Single spores are produced on substrate mycelium. Soluble pigments are not formed.

Fructose, glucose, and sucrose are used as sole carbon sources. Positive for alkaline phosphatase, *N*-acetyl-β-glucosaminidase, esterase (C4), α-glucosidase, and acid phosphatase, but not for α-fucosidase, α- or β-galactosidases, lipase, β-glucosidase, β-glucuronidase, or α-mannosidase.

Peptidoglycan contains *meso*-A_2pm. Whole-organism diagnostic sugars are arabinose, glucose, and xylose. Major menaquinone is MK-9(H_4). Phosphatidylethanolamine is the diagnostic phospholipid. Major fatty acids are $C_{15:0}$ iso, $C_{16:0}$, and $C_{17:1}$ ω8.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: DSM 43363, JCM 12820.

Sequence accession no. (16S rRNA gene): X92603.

27. **Micromonospora purpureochromogenes** (Waksman and Curtis 1916) Luedemann 1971, 244^VP ("*Actinomyces purpureochromogenes*" Waksman and Curtis 1916, 113; *Micromonospora fusca* Jensen 1932, 173; *Micromonospora brunnea* Sveshnikova, Maksimova and Kudrina 1969, 762)

pur.pur.e.o.chro.mo′ge.nes. L. adj. *purpureus* purple colored; Gr. n. *chroma* color; Gr. v. *gennaio* to produce; N.L. part. adj. *purpureochromogenes* producing purple color (relating to the color of the diffusible pigment).

Dark brown colonies are formed on yeast extract-glucose agar after 21 days; a dark brown, diffusible, and water-soluble pigment is produced in most media. Very slow growth is seen on Czapek's sucrose agar. Spores (0.8–1.0 µm in diameter) are formed singly or in clusters. A monopodial branching system of sporulating hyphae is found, best observed at the periphery of colonies. Apparent dichotomous branching of sporulating hyphae is observed. Fragmentation of mycelium occurs in liquid cultures. Grows at 26–37°C, but not at 45°C.

Fructose, galactose, glucose, glycerol, lactose, levulose, melibiose, raffinose, sucrose, and xylose are used as sole carbon sources. Poor growth occurs on D- and L-arabinose. Milk is poorly peptonized. Limited hydrolysis of casein occurs and nitrate reduction is variable.

Source: isolated from adobe soil in California.

DNA G+C content (mol%): 73 (HPLC).

Type strain: ATCC 27007, IMRU 3343, ATCC 27334, DSM 43821, NBRC 13324, JCM 3156, NRRL B-2101, NRRL B-16094, VKM Ac-937.

Sequence accession nos: X92611 (16S rRNA gene); AB014161 (*gyrB*).

28. **Micromonospora rosaria** (*ex* Wagman, Waltz, Marquez, Murawski, Oden, Testa and Weinstein 1972) Horan and Brodsky 1986b, 478^VP ("*Micromonospora rosaria*" Wagman, Waltz, Marquez, Murawski, Oden, Testa and Weinstein 1972, 641)

ro.sa′ri.a. L. fem. adj. *rosaria* of roses, rose-. The epithet refers to the wine red diffusible pigment produced by the strain.

Raised, folded colonies are formed on most media with orange brown to purple black vegetative mycelial pigments. Produces characteristic wine red diffusible pigment on most media. Short, sterile aerial hyphae produce a gray white bloom in some media. Single, warty spores (1.5–1.8 µm) are formed on short sporophores or are sessile. Good growth occurs on most rich organic media. Good growth is found at 35–40°C; grows poorly at 42°C.

D- and L-Arabinose, fructose, galactose (weak), glucose, lactose, maltose, mannose, mannitol, rhamnose, ribose, sucrose, trehalose, and xylose are used as sole carbon sources, but not adonitol, dulcitol, glycerol, melibiose, melezitose, or raffinose. Degrades chitin, casein, starch, gelatin, tyrosine, and xylan. Hydrolyzes esculin. Nitrate reduction is negative.

Sensitive to acid. Resistant to clindamycin, erythromycin, everninomicin, gentamicin, lincomycin, novobiocin, penicillin G, and sisomicin, at concentrations of 50 µg/ml, but is sensitive to aminoglycosides, rifamycin, and tetracycline at this concentration.

Whole-organism hydrolysates contain *meso-* and 3-OH-A_2pm. Arabinose, galactose, and xylose are the characteristic sugars. Produces the macrolide antibiotic rosaramicin.

Source: isolated from soil.

DNA G+C content (mol%): 72.9 (HPLC).

Type strain: SCC 957, 67694, NRRL 3718, ATCC 29337, NBRC 13697, DSM 803, JCM 3159.

Sequence accession nos: X92631 (16S rRNA gene); AB014163 (*gyrB*).

29. **Micromonospora saelicesensis** Trujillo, Kroppenstedt, Fernández-Molinero, Schumann and Martínez-Molina 2007, 801[VP]

sa.e.li.ces.en′sis. N.L. fem. adj. *saelicesensis* of or pertaining to Saelices, the place where the plants from which the first strains were isolated were collected.

Orange colonies are formed on yeast extract-malt extract agar (ISP medium 2). Orange-brown to brown diffusible pigments are produced on oatmeal agar (ISP medium 3). Well-developed branched hyphae (0.3–0.6 µm diameter) are observed with smooth-surfaced spores formed at the tips of hyphae. Good growth is seen at 20–37°C. Grows in the presence of 2% (w/v) NaCl.

Arabinose, cellobiose, galactose, glutarate, histidine, inositol, maltose, mannose, melibiose, and raffinose are used as sole carbon sources, but not alanine, arginine, gluconate, lysine, proline, rhamnose, serine, sorbitol sorbose, sucrose, trehalose, valine, or xylitol. Catalase-positive and oxidase-variable. Nitrate is not reduced. Degrades arbutin, casein, gelatin, and xylan; starch degradation is variable. Esculin is hydrolyzed. Positive for acid and alkaline phosphatases, esterases and lipases, α- and β-galactosidase, α- and β-glucosidases, and *N*-acetyl-β-glucosaminidase, but not for β-glucuronidase or urease.

Whole-organism hydrolysates contain *meso*-A_2pm, and arabinose, glucose, mannose, ribose, rhamnose, and xylose as characteristic sugars. Diagnostic phospholipid is diphosphatidylethanolamine. Major fatty acids are $C_{15:0}$ iso, $C_{16.0}$, and $C_{17:1}$ ω8. Predominant menaquinone is MK-10(H_4).

Source: isolated from root nodules of *Lupinus angustifolius.*

DNA G+C content (mol%): 71.6 (T_m).

Type strain: Lupac 09, DSM 44871, LMG 24056.

Sequence accession no. (16S rRNA gene): AJ783993.

30. **Micromonospora sagamiensis** Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005b, 1743[VP] (Effective publication: Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005a, 338.)

sa.ga.mi.en′sis. N.L. fem. adj. *sagamiensis* of or belonging to Sagami Bay.

Salmon pink colonies are formed on inorganic salts-starch (ISP medium 4) oatmeal agar (ISP medium 3) and tyrosine agar (ISP medium 7), red colonies are formed on glycerol-asparagine agar (ISP medium 5), and pastel coral red colonies are formed on yeast extract-malt extract agar (ISP medium 2). Does not grow on peptone-yeast extract-iron agar (ISP medium 6). Aerial mycelium is not formed. Diffusible pigments are not produced. Oval or spherical spores with rough surfaces are produced singly on the substrate mycelium. Grows optimally at 30–40°C; optimum pH for growth is between 7.0 and 8.0.

Galactose, glucose, levulose, sucrose, raffinose (weak), and xylose are used as sole carbon sources, but not arabinose, glycerol, lactose, inositol, mannitol, or rhamnose. Positive for starch hydrolysis, nitrate reduction, and milk coagulation. Cellulose decomposition is weak. Positive for alkaline phosphatase, α- and β-galactosidases, α- and β-glucosidases, *N*-acetyl-β-glucosaminidase, and acid phosphatase, but not for α-fucosidase, β-glucuronidase, lipase, or α-mannosidase.

Peptidoglycan contains *meso*-A_2pm. Whole-organism diagnostic sugars are glucose and xylose. Major menaquinone is MK-9(H_4). Phosphatidylethanolamine is the diagnostic phospholipid. Major fatty acids are $C_{15:0}$ iso, $C_{16.0}$, $C_{17:1}$ iso, and $C_{17:0}$.

Produces sagamicin (XK62-2) and antibiotics of the gentamicin C complex.

Source: isolated from forest soil, Japan.

DNA G+C content (mol%): not determined.

Type strain: MK-65, DSM 43912, JCM 3310, ATCC 21826, NRRL 11334.

Sequence accession no. (16S rRNA gene): X92624.

31. **Micromonospora siamensis** Thawai, Tanasupawat, Itoh, Suwanborirux and Kudo 2006b, 2[VP] (Effective publication: Thawai, Tanasupawat, Itoh, Suwanborirux and Kudo 2005a, 233.)

si.am.en′sis. N.L. fem. adj. *siamensis* of or pertaining to Siam, the old name for Thailand, the origin of the soil from which the type strain was isolated.

Forms vivid orange colonies that turn brownish black upon sporulation, and a pale yellow soluble pigment on yeast extract-malt extract agar (ISP medium 2). Aerial mycelium is absent. Melanin pigments are not formed. Develops abundant branched substrate hyphae which carry single spores. Spores are nonmotile and smooth-surfaced. Grows optimally at 25–30°C, but not above 40°C. Tolerates up to 5% (w/v) NaCl.

L-Arabinose, cellobiose, fructose (weak), galactose, glucose, lactose, melibiose, raffinose, rhamnose, salicin, and xylose are used as sole carbon sources, but not glycerol, mannitol, or ribose. Positive for milk peptonization, starch hydrolysis, and gelatin liquefaction, but negative for nitrate reduction and H_2S production.

Peptidoglycan contains *meso*-A_2pm. Whole-organism diagnostic sugars are arabinose and xylose. Predominant menaquinones are MK-10(H_4) and MK-10(H_6). Diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides are the major polar lipids. Rich in $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$ anteiso, and $C_{17:0}$ fatty acids.

Source: isolated from a peat swamp forest soil, Thailand.

DNA G+C content (mol%): 73.0 (HPLC).

Type strain: TT2-4, JCM 12769, PCU 266, TISTR 1554.

Sequence accession no. (16S rRNA gene): AB193565.

32. **Micromonospora viridifaciens** Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005b, 1744[VP] (Effective publication: Kroppenstedt, Mayilraj, Wink, Kallow, Schumann, Secondini and Stackebrandt 2005a, 338.)

vi.ri.di.fa′ci.ens. L. adj. *viridis* green; L. part. adj. *faciens* making, N.L. part. adj. *viridifaciens* green making.

Beige red colonies are formed on oatmeal agar (ISP medium 3), yellow colonies are formed on peptone-yeast extract-iron agar (ISP medium 6) and yellow to brown are formed colonies on yeast extract-malt extract-iron agar (ISP medium 2). Sparse growth is seen on inorganic salts-starch (ISP medium 4), glycerol-asparagine agar (ISP medium 5), and tyrosine agar (ISP medium 7).

Aerial mycelium is absent. Soluble pigments, including melanin, are not produced. Spores with smooth surfaces are formed singly on the substrate mycelium. Good growth occurs between 28 and 45°C.

Good utilization of ribose and starch is observed, but poorly utilizes arabinose, fructose, glucose, inositol, mannitol, rhamnose, raffinose, and sucrose. Positive for liquefaction of gelatin, and milk coagulation and peptonization, but negative for nitrate reduction and tyrosine degradation. Positive for alkaline phosphatase, α-glucosidase, and acid phosphatase; negative for α-fucosidase, lipase, *N*-acetyl-β-glucosaminidase, α- and β-galactosidase, β-glucosidase, β-glucuronidase, and α-mannosidase.

Peptidoglycan contains *meso*-A_2pm. Whole-organism diagnostic sugars are glucose, rhamnose, and xylose. Major menaquinone is MK-9(H_4). Phosphatidylethanolamine is the diagnostic phospholipid. Major fatty acids are $C_{15:0}$ iso and $C_{17:0}$ 10-methyl. Produces antibiotic 37505.

Source: isolated from soil sample, Japan.

DNA G+C content (mol%): not determined.

Type strain: DSM 43909, JCM 3267, ATCC 31146.

Sequence accession no. (16S rRNA gene): X92623.

Species *incertae sedis*

1. **Micromonospora gallica** (Erikson 1935; Waksman 1961) Kawamoto 1989

gal′li.ca. L. fem adj. *gallica* of or belong to the Gauls.

This species was included in the *Approved Lists of Bacterial Names* (Skerman et al., 1980), but the type strain NCTC 4582[T] is not extant (Kawamoto, 1989).

Genus II. **Actinocatenispora** Thawai, Tanasupawat, Itoh and Kudo 2006a, 1792[VP]

The Editorial Board

Ac.ti.no.ca.te.ni.spo′ra. Gr. n. *aktis -inos* ray; L. n. *catena* chain; Gr. n. *spora* seed and in biology a spore; N.L. fem. n. *Actinocatenispora* spore chain-producing ray (fungus).

Gram-stain-positive. Nonmotile. **Aerobic**. **Sporeforming** branching substrate hyphae; mycelia are yellow to vivid orange in color. Aerial hyphae or vegetative mycelium bear spore chains consisting of more than 10 spores. Cylindrical spores (0.3–0.4 × 0.5–1.0 µm) have a smooth surface. Cell wall contains glutamic acid, glycine, alanine, and *meso*-diaminopimelic acid. The *N*-acyl group of the cell-wall muramic acid is glycolyl. Characteristic whole-cell sugars are arabinose and xylose. Possess phospholipid pattern type II; cellular phospholipids are phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, phosphatidylglycerol and unidentified ninhydrin-negative phospholipids. The predominant fatty acids are iso- and anteiso-methyl branched acids. Major menaquinone is MK-9(H_4). Mycolic acids are not detected.

DNA G+C content (mol%): 72.0–74.3.

Type species: **Actinocatenispora thailandica** Thawai, Tanasupawat, Itoh and Kudo 2006a, 1793[VP].

Further descriptive information

Phylogenetic analysis of the 16S rRNA gene positions the genus within the family *Micromonosporaceae*. The closest phylogenetic neighbor is *Phytohabitans suffuscus* (93.4%, accession no. AB490769) (Inahashi et al., 2010). So far, all the described species have all been isolated from soil. Environmental clones with high 16S rRNA gene sequence similarity have been detected in cellulosic waste from a simulated low-level-radioactive-waste site (99.2 %, accession no. GQ263629 and 99.0%, accession no. GQ263525). Environmental isolates identified as *Micromonospora* sp. and *Solwaraspora* sp. but with high 16S rRNA gene sequence similarity to *Actinocatenispora* have been cultivated from marine sediments (94% accession no. DQ448714 and ~93% accession nos AY552766–AY552773, respectively) (Gontang et al., 2007; Magarvey et al., 2004).

Enrichment and isolation procedures

Actinocatenispora thailandica strain TT2-10[T] was isolated from peat swamp forest soil in Pattaloong Province, Thailand. Samples were taken from the soil surface were cultivated on starch-casein nitrate agar for 21 d at 30°C. Isolated colonies were purified on yeast extract-malt extract agar (ISP medium no. 2) and maintained on the same medium as a working culture (Thawai et al., 2004b), and the pure culture was kept at 4–10°C on yeast extract-malt extract agar (ISP 2 medium) slants.

Maintenance procedures

Strains are maintained yeast extract-malt extract agar (ISP medium no. 2) or in 20% (v/v) glycerol at −20 °C or −70°C.

Differentiation of the genus *Actinocatenispora* from closely related genera

Spore motility and true aerial mycelium production differentiates *Actinocatenispora* from other genera of the family *Micromonosporaceae*, except for *Longispora*. *Actinocatenispora* can be differentiated from *Longispora* by differences in the menaquinone and fatty acid composition.

List of species of the genus *Actinocatenispora*

1. **Actinocatenispora thailandica** Thawai, Tanasupawat, Itoh and Kudo 2006a, 1793[VP]

thai.lan′di.ca. N.L. fem. adj. *thailandica* of or belonging to Thailand, where the type strain was isolated.

White aerial mycelia are formed on oatmeal-nitrate agar. Soluble yellow pigment present on oatmeal agar. Temperature range for growth 25–30°C, does not grow above 40°C. Does not grow below pH 4.5, maximum NaCl tolerance is 7%. Major menaquinones are MK-9(H_4) and MK-9(H_6); MK-9(H_2) and MK-9(H_8) are also produced. Whole-cell sugars are galactose, xylose, arabinose, glucose, mannose, and ribose. Utilizes D-glucose, D-mannitol, D-melibiose, D-raffinose, glycerol, *myo*-inositol, salicin, and cellobiose. Does not utilize D-ribose, L-rhamnose, lactose, D-galactose, L-arabinose or D-fructose. Reduces nitrate, weakly positive for peptonization of milk and gelatin liquefaction. Does not hydrolyze starch. Melanin and H_2S are not produced. The major cellular fatty acid components are $C_{16:0}$ iso (26%), $C_{17:0}$ anteiso (19%), $C_{15:0}$ iso (20%) and $C_{17:0}$ iso (11%).

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 72.0 (HPLC).

Type strain: TT2-10, JCM 12343, PCU 235, DSM 44816.

Sequence accession no. (16S rRNA gene): AB107233.

2. **Actinocatenispora rupis** Seo and Lee 2009, 3082[VP]

ru′pis. L. gen. n. *rupis* of a cliff, referring to the site from which the type strain was isolated.

Vegetative mycelium is well developed and pale to strong yellow in color. Hyphal swellings are observed on the tips of the vegetative mycelium. Growth temperature optimum is 37°C, range is 25–42°C; and pH optimum is 5.1–9.1, range is 5.1–12.1; NaCl tolerance up to 4%. Degrades DNA, elastin, esculin, casein, Tween 80 and chitin, but not cellulose, starch, hypoxanthine, tyrosine, urea or xanthine. Catalase- and oxidase-negative. Utilizes D-arabinose, dextran, D-galactose, lactose, maltose, D-mannose, methyl α-D-glucoside, sucrose, adonitol, *meso*-erythritol, D-sorbitol and citrate as sole carbon sources. Does not utilize inulin, melezitose, methyl α-D-mannoside, salicin, L-sorbose, dulcitol, D-xylitol, acetate, benzoate, formate, malate, succinate or tartrate. Does not reduce nitrate to nitrite. Major menaquinones are MK-9(H_4), MK-9(H_6) and MK-9(H_8). The whole-cell sugars are glucose, rhamnose, ribose, arabinose and xylose. The diagnostic polar lipids are phosphatidylethanolamine, phosphatidylinositol and phosphatidylglycerol. The predominant fatty acids are $C_{16:0}$ iso (39%), $C_{17:0}$ anteiso (15%) and $C_{16:1}$ iso (13%).

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 74.3 (HPLC).

Type strain: CS5-AC17, DSM 45178, NRRL B-24660.

Sequence accession no. (16S rRNA gene): AM980986.

3. **Actinocatenispora sera** Matsumoto, Takahashi, Fukumoto and Ōmura 2007, 2653[VP]

se′ra. L. fem. adj. *sera* late.

Growth temperature optimum is 18–25°C, range is 13–37°C. Growth occurs at pH 6–9. No growth at 5% NaCl. Melanoid pigments are not produced. Negative for the liquefaction of gelatin. Hydrolyzes starch. Positive for coagulation and peptonization of milk. Reduces nitrate. Utilizes adonitol, D-glucose, L-rhamnose, xylitol and D-xylose. Does not utilize L-arabinose, D-cellobiose, D-fructose, glycerol, *myo*-inositol, maltose, D-mannose, D-mannitol, melibiose, raffinose, D-ribose, trehalose and sucrose. Cellulose is not decomposed. Predominant cellular fatty acids are $C_{17:0}$ anteiso (25%), $C_{16:0}$ iso (22%), $C_{17:0}$ iso (16%) and $C_{15:0}$ iso (14%).

Isolated from soil in Niigata Prefecture, Japan.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 72.0 (HPLC).

Type strain: KV-744, NRRL B-24477, NBRC 101916.

Sequence accession no. (16S rRNA gene): AB263096.

Genus III. **Actinoplanes** Couch 1950, 89[AL] emend. Stackebrandt and Kroppenstedt 1987, 112

Gernot Vobis, Jenny Schäfer and Peter Kämpfer

Ac.ti.no.pla′nes. Gr. n. *aktis aktinos* ray, beam; Gr. masc. n. *planes* a wanderer, roamer; N.L. masc. n. *Actinoplanes* literally, a ray wanderer (intended to signify an actinomycete with swimming spores).

Substrate mycelium is developed on various agar media. Hyphae are 0.2–1.2 µm in diameter, branched, and septated; fragmentation is very rare. Gram-stain-positive, although parts may be Gram-stain-negative. Non-acid-fast. Aerial mycelium is absent or scanty.

Sporangia are produced on the surface of the substrate, sessile on the agar or detached on short sporangiophores. In many cases, they are formed at the tip of so-called palisade hyphae. **The shape of the sporangia varies from spherical, subspherical to irregular** (mean diameter 7.0–16.0 µm), **or cylindrical, bell-shaped, lobate, or digitate** (mean dimensions: 5.0–12.0 µm wide and 8.0–20.0 µm long). Numerous spores are produced within the sporangium, arranged in coiled, parallel, or irregular chains. **Sporangiospores are globose, subglobose, oval** (mean diameter 1.1–1.6 µm), **oblong** (mean 0.8 × 1.6 µm) or **rod-shaped** (mean 0.8 × 3.0 µm); **motile by a polarly inserted tuft of flagella**.

Grows under aerobic conditions. Colonies on various complex agar media are flat, elevated, or convoluted with a smooth, wrinkled, or ridged surface. The characteristic color of substrate mycelium is orange; by loss or additional formation of pigments, nearly all modifications occur from ivory,

pale yellow to red, violet, green, brown and black. Most strains do not require organic growth factors. Chemo-organotrophic, mesophilic, in some cases moderately psychrophilic or thermotolerant. Grows well between 20 and 28°C.

The peptidoglycan of the cell wall contains glycine, *meso*-diaminopimelic acid and/or hydroxy-diaminopimelic acid. The diagnostic sugar of whole-cell hydrolysates is xylose; galactose and/or arabinose are also present. Phosphatidylethanolamine is the predominant phospholipid. Major menaquinone is MK-9(H_4). Iso/anteiso-branched and monounsaturated fatty acids and/or *cis*-9,10-octadecanoic acid (oleic acid) are the predominant fatty acids.

DNA G+C content (mol%): 69.0–73.0 (T_m).

Type species: **Actinoplanes philippinensis** Couch 1950, 89^{AL}.

Further descriptive information

Phylogeny. A phylogenetic study based on 16S rRNA gene sequence analysis assigned the genus *Actinoplanes* to the family *Micromonosporaceae*. This has been confirmed by other 16S rRNA gene sequence studies of this genus (Stackebrandt and Kroppenstedt, 1987; Stackebrandt et al., 1997; Tamura and Hatano, 2001). The taxon currently encompasses 28 species with validly published names. Representatives of species with validly published names show a high similarity in the 16S rRNA *Actinoplanes* gene tree (Figure 211), with the exception of *Actinoplanes globisporus*. Similarity values of the different species within the genus *Actinoplanes* range between 95.0 and 100%. The 16S rRNA gene sequence of *Actinoplanes globisporus* differs by 3.1–5.0% from those of other species of the genus *Actinoplanes* (similarity values between the sequences of *Actinoplanes globisporus* and those of other species of the genus *Actinoplanes* range from 95.0 to 96.9%).

Similarity values between *Actinoplanes* and the other genera within the family *Micromonosporaceae* (based on the type species) range from 97.7 to 94.4%. Based on distance calculations of the type species of the different genera, the nearest relatives are the genera *Spirilliplanes* (97.0%), *Polymorphospora* (96.9%), and *Micromonospora* (96.8%).

Cell morphology. Strains of *Actinoplanes* produce substrate mycelium on solid agar media. Substrate hyphae are fine, 0.2–1.0 µm in diameter, branched, and septated. Fragmentation is very rare, e.g. observable in *Actinoplanes couchii*, developing substrate mycelium that fragments in irregular rod-shaped cells when cultured on DSMZ medium 65 (Kämpfer et al., 2007). Strains may be morphogenetically characterized by specialized, vertically orientated hyphae directly under the surface of agar media (Couch, 1963). They are two to three times thicker than the usual hyphae and strongly arranged in parallel positions. In general, these so called palisade hyphae are identical to sporangiophores (Figure 213A), first described from the species *Actinoplanes philippinensis* (Couch, 1950).

The development of aerial mycelium in the genus *Actinoplanes* is not frequent and is observed only in some species, e.g. *Actinoplanes couchii*, *Actinoplanes ferrugineus*, *Actinoplanes liguriensis*,

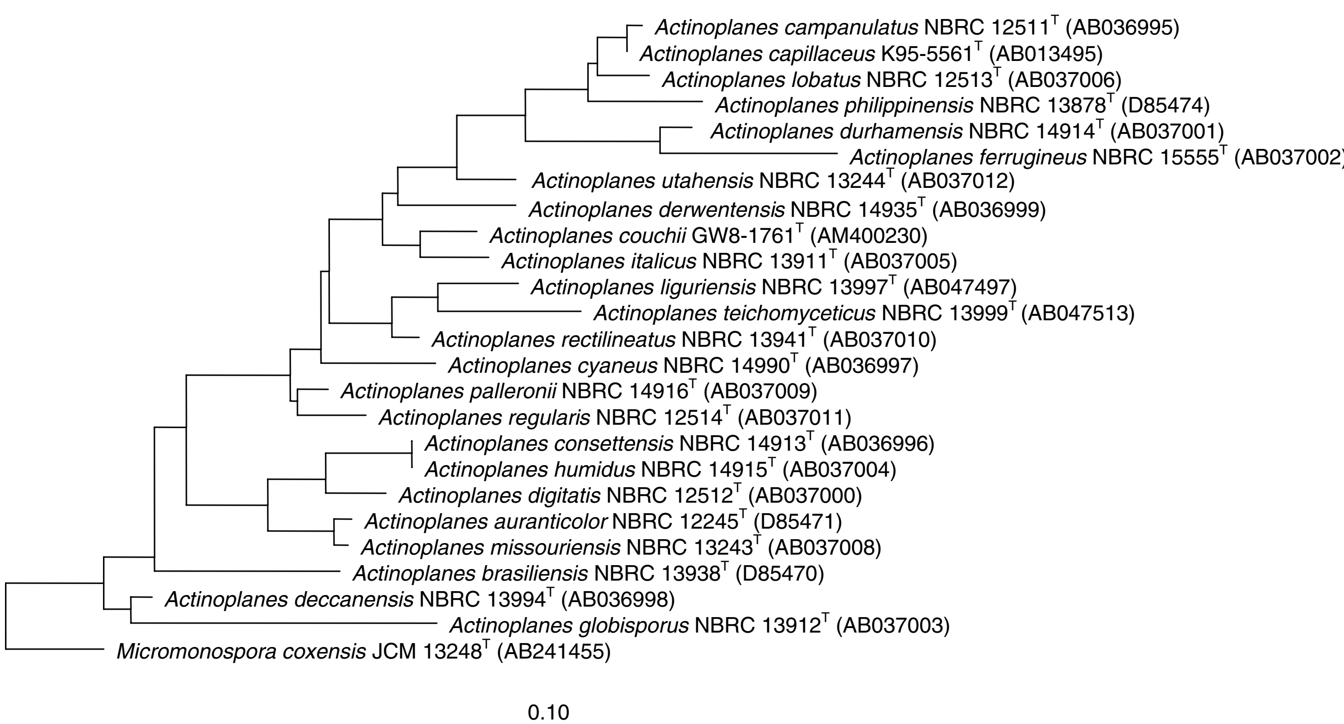

FIGURE 211. Phylogenetic analysis of *Actinoplanes* species based on 16S rRNA gene sequences available from EMBL (accession numbers are given in parentheses). Multiple alignment, distances (distance options according to the Kimura-2 model; Kimura, 1980) and clustering with the neighbor-joining method were performed by using the software packages MEGA (Molecular Evolutionary Genetics Analysis) version 4 (Tamura et al., 2007). Bootstrap values based on 1000 replications are given as percentages at the branching points. *Micromonospora coxensis* was used as an outgroup.

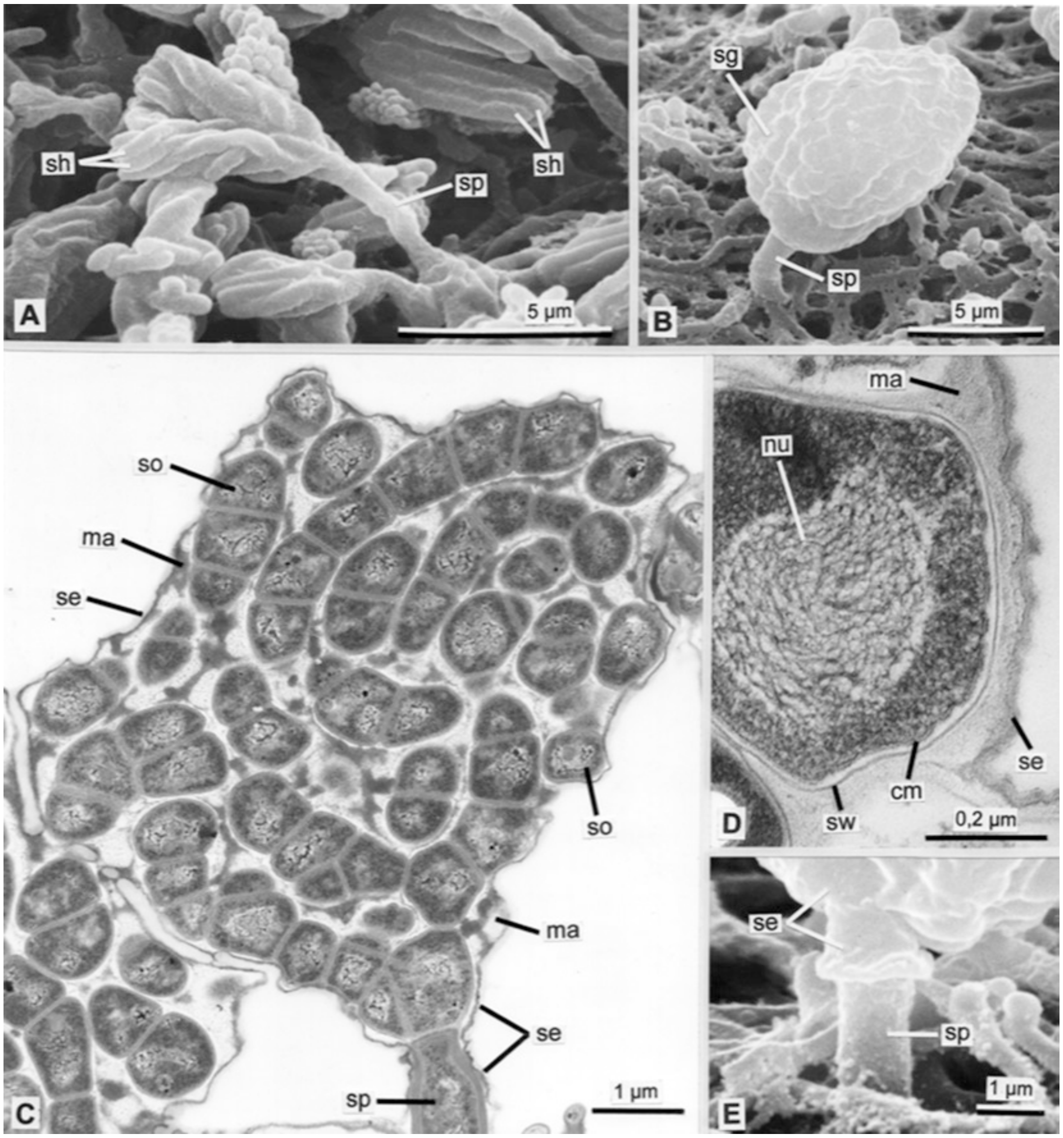

FIGURE 212. Multispored sporangia of *Actinoplanes*. A, "*Ampullariella*"-type with rows of sporogenous hyphae orientated in parallel (strain MB-VE 1144, SEM); B, subglobose sporangium developed on substrate mycelium (strain MB-SE 50, SEM); C, longitudinal section of a sporangium containing spores in chains (strain MB-SE 50, TEM); D, spore on the inner side of a thin, "membranous" sporangial envelope (strain ATCC 21983, TEM); E, sporangiophore in transition between humid substrate and air-exposed sporangium (strain MB-SE 50, SEM). Abbreviations: SEM, scanning electron microscope; TEM, transmission electron microscope; ma, intrasporangial matrix; se, sporangial envelope; sg, sporangium; sh, sporogenous hypha; so, spore; sp, sporangiophore; sw, spore wall.

Actinoplanes rectilineatus, and *Actinoplanes teichomyceticus*, if cultured on special media. In general, this kind of aerial mycelium is named rudimentary or sterile because it does not reach the dimensions of typical aerial mycelium and its hyphae are not involved in any production of sporangia or spores. Aerial mycelium is white and imparts to the colonies a powdery appearance (Lechevalier and Lechevalier, 1975; Parenti et al., 1978).

Sporangia are the characteristic reproductive structures of *Actinoplanes*, which are developed by substrate mycelium (Figure 212A, B, E). The sporangiophores are either more or less undifferentiated hyphae or palisade hyphae. They transgress the aqueous surroundings of the substrate. Once air-exposed, sporangia are additionally covered by a hydrophobic sheath, which passes over without interruption into the sporangial envelope (Figure 212C, E). The single steps of sporangial development are described elsewhere (Lechevalier and Holbert, 1965; Lechevalier et al., 1966; Vobis, 1997; Vobis and Kothe, 1985): inside the sporangial envelope, sporogenous hyphae are septated into spore-shaped segments, which are rounded off into individual spores (Figure 212C). In most species, the spore chains are arranged in coils or, in the case of the former "*Ampullariella*" strains, in parallel rows. Evidently, the external form of a sporangium depends on the internal arrangement of the sporogenous hyphae/spore chains (Figure 212A,

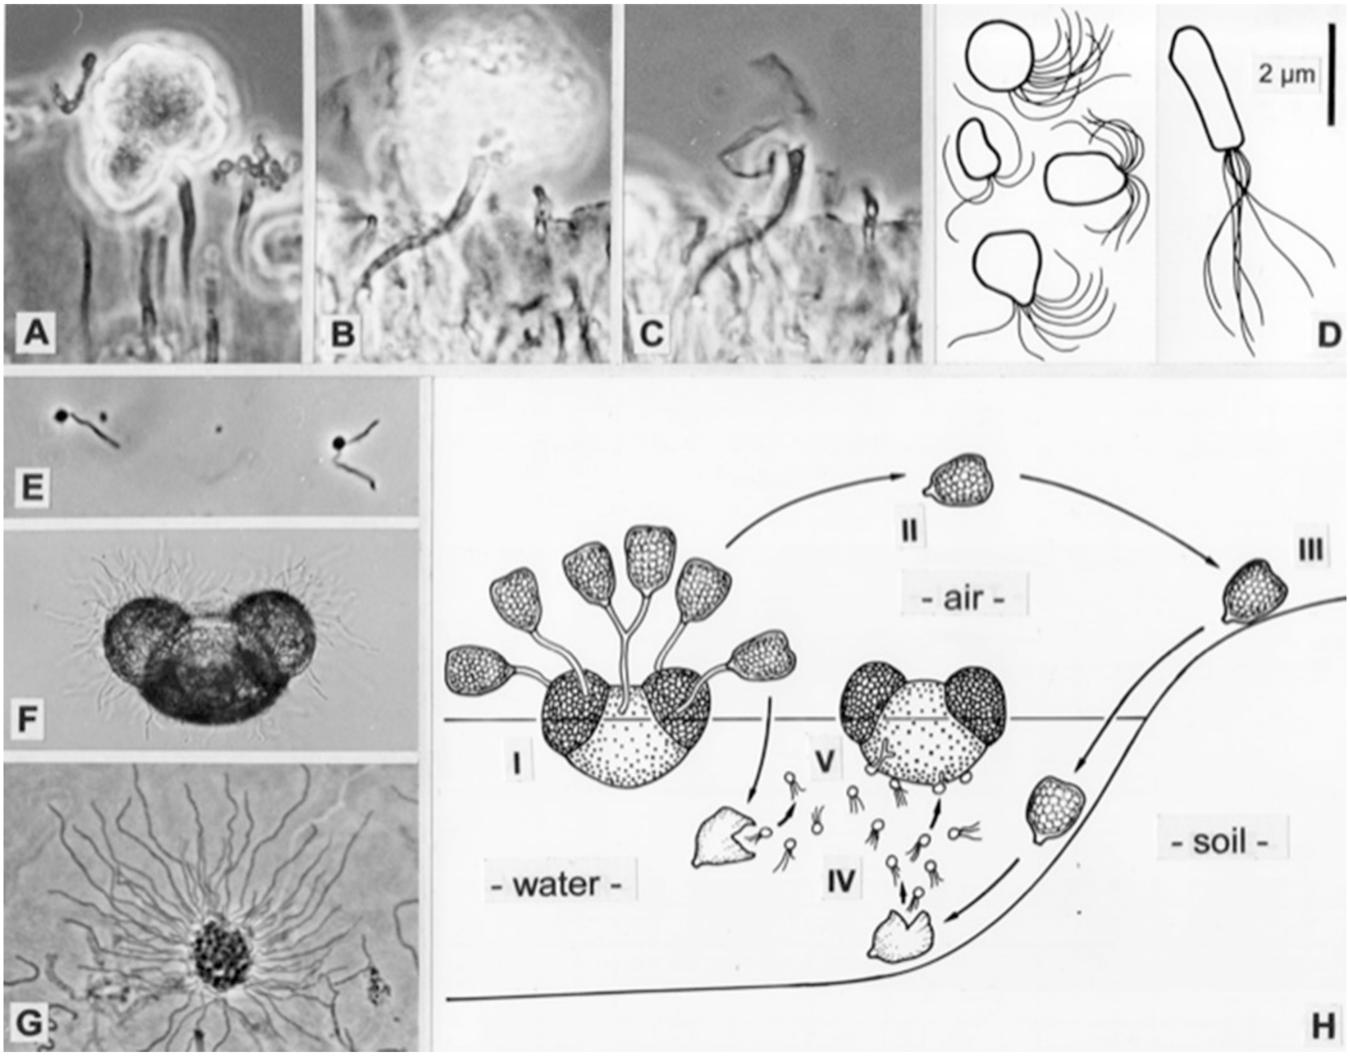

FIGURE 213. Release of sporangiospores (A, B, C), and aero-aquatic life cycle of *Actinoplanes* (H). A, Sporangium originated on palisade hypha, submersed in water; B, burst sporangium and swarming spores; C, left empty sporangial envelope; D, sporangiospores with a polarly inserted tuft of flagella, varying in size and shape; E, germinating spores; F, growth of mycelium on a pollen grain of *Pinus* sp.; G, germinated sporangium, developing new mycelium. H (I) Floating pollen grain with mycelium and sporangia; (II) dispersal of sporangia by air; (III) dry-resistant sporangia on soil; (IV) flagellated sporangiospores are released in water; (V) new substrate is colonized by germinating spores. Note: A, B, C, E, F, G (strain MB-SE 165; light microscope, phase-contrast; for dimensions compare Figure 212).

B). Very rarely, chains orientated in spirals can be observed (G. Vobis, unpublished). The surface of the sporangial envelope is generally smooth (Figure 212A–D). External ornamentation is described only for *Actinoplanes capillaceus*, including four invalidly proposed species of "*Ampullariella*" (Matsumoto et al., 2000; Miyadoh et al., 1997; Seino, 1983). In all these cases, the sporangia are covered with hair-like structures, resembling the hairy spores of *Streptomyces*.

The polysporous sporangia vary in shape and size (Vobis, 1997). In most species, the sporangia are spherical (globose), subspherical (subglobose), oval to irregular, occasionally wider than they are long, and rarely lobed. The smallest sporangia have a diameter of 4 μm, with the biggest being 25 μm (mean diameter of about 11 μm). As an extreme exception, a strain with sporangia of 47 μm in diameter has been observed (Vobis, 1992). The former "*Ampullariella*" species, including *Actinoplanes capillaceus* and *Actinoplanes rectilineatus*, have sporangial shapes from cylindrical or bottle-shaped to bell-shaped and digitate, frequently lobed and papillate (Vobis and Kothe, 1989). Extremely small sporangia may be found in *Actinoplanes digitatis* (3 μm wide and 6 μm long), and the biggest are found in *Actinoplanes regularis* (14 × 30 μm). Typical sporangia with parallel spore chains have a mean size of 5–12 × 8–20 μm.

The spores produced within the sporangia have a smooth surface and are actively motile by flagella (zoospores or planospores). With regard to their shape, they can be subdivided into two categories (Figure 213D). The typical globose spores vary from spherical (globose), subspherical (subglobose), to oval with a mean diameter of 1.35 μm (range: 0.8–2.0 μm). The sporangiospores of the former "*Ampullariella*" species are

distinct rod-shaped or bacilliform, four times longer than they are wide, with a mean width of 0.75 µm and mean length of 3.0 µm (range: from 0.5 × 2.0 µm to 1.0 × 4.0 µm). Oblong spores are twice as long as they are wide and are generally described as short rod-shaped; with a mean width of 0.8 µm and a mean length of 1.63 µm (range: from 0.5 × 1.0 µm to 1.2 × 2.3 µm), they may belong to the last category. Variations in the shape of spores of one strain (e.g. globose, subglobose, oval) are explained by slight distance deviations during the segmentation process of the branched sporogenous hyphae.

The motility of the spores is caused by means of a tuft of flagella, inserted at the apical end (Figure 213D). This polytrichous type of flagellation was first documented by light microscopy in *Actinoplanes philippinensis* (Couch, 1950) and confirmed by electron microscopy preparations in other species and strains (Bland, 1970; Hanton, 1968; Karwowski et al., 1988; Lechevalier and Holbert, 1965; Miyadoh et al., 1997; Palleroni, 1979; Schäfer, 1973). In *Actinoplanes rectilineatus*, the number of flagella ranges from 17 to 40; their bases are hooked (Lechevalier and Lechevalier, 1975). In general, the tuft is formed by less flagella. They are 2–6 µm in length (Couch and Bland, 1974b). The rod-shaped spores with their polar tuft of flagella can be named lophotrichous (Schäfer, 1973) and they are well documented in *Actinoplanes regularis* (Kane, 1966), *Actinoplanes campanulatus* (Higgins et al., 1967), and *Actinoplanes capillaceus* (Matsumoto et al., 2000). The number of flagella on these species ranges from 1 to 12 (Higgins et al., 1967) and they are 3.5–6.0 µm in length (Couch and Bland, 1974b). Peritrichous flagellation has also been reported occasionally, both in spherical spores (Ruan et al., 1976; Willoughby, 1968) and in rod-shaped spores (Ruan and Zhang, 1974). Nonomura et al. (1979) observed polar (lophotrichous and amphitrichous) and peritrichous flagella arrangement in 12 "*Ampullariella*" isolates. The flagella are up to 19.0 µm in length (mean of 6–12 µm).

Besides the characteristic sporangia producing zoospores, formation of nonmotile spores (conidia) may also occur. The conidiophores develop in a similar manner to the sporangia, but in the absence of the sporangial envelope, the sporogenous (conidiogenous) hyphae appear as brushlike bunches (Willoughby, 1966). Conidiophores originate at the margin of the colonies of *Actinoplanes regularis* (Couch, 1963). In "*Actinoplanes arizonaensis*", conidiogenous hyphae occur as digitate hyphae on the surface of the colony (Karwowski et al., 1988). They are interpreted as abortive sporangia. *Actinoplanes campanulatus* develops microconidia and *Actinoplanes lobatus* develops oval conidia in moniliform arrangement, which are produced by substrate mycelium (Couch, 1963). Microconidia are also formed in the substrate mycelium of *Actinoplanes auranticolor* (Hanton, 1968) and chlamydospores are formed in *Actinoplanes globisporus* (Thiemann, 1967).

Cell-wall composition. The peptidoglycan of the cell wall contains glycine and *meso-* and/or hydroxy-diaminopimelic acid, according to wall chemotype II of Lechevalier and Lechevalier (1970a). It has been demonstrated that the acyl groups of the muramyl residue in the cell-wall peptidoglycan are of the glucolyl type (Uchida and Seino, 1997).

The principal wall sugars are arabinose, galactose, glucose, mannose, and xylose. The latter is the diagnostic sugar of whole-cell hydrolysates (Tamura and Hatano, 2001). The presence of xylose and arabinose corresponds to the whole-cell sugar pattern type D of Lechevalier and Lechevalier (1970a). Galactose was not detected in *Actinoplanes regularis*, *Actinoplanes campanulatus*, or *Actinoplanes digitatis* (Stackebrandt and Kroppenstedt, 1987).

The polar lipid profile is characterized by the presence of phosphatidylethanolamine as diagnostic phospholipid and the absence of phosphatidylcholine and amino-containing phosphoglycolipid, corresponding to phospholipid type PII of Lechevalier et al. (1981, 1977). Many species also contain phosphatidylinositol, phosphatidylinositol mannoside, and phosphatidylglycerol (Table 194). The type strain of *Actinoplanes regularis* is of particular note as it lacks phosphatidylethanolamine (Stackebrandt and Kroppenstedt, 1987). The whole polar lipid composition may also contain a highly hydrophilic glycolipid and further unknown or uncharacterized lipids and glycolipids (Goodfellow et al., 1990b; Kämpfer et al., 2007).

Fatty acids. *Actinoplanes* species contain complex mixtures of straight-chain, branched-chain, and unsaturated fatty acids and the proportions of these vary considerably between the strains (Ara et al., 2010; Goodfellow et al., 1990b; Sun et al., 2009). Characteristic fatty acid patterns for *Actinoplanes* species include major amounts of iso/anteiso branched- and monosaturated fatty acids, as well as *cis*-9,10-octadecanoic acid (oleic acid, n-$C_{18:1}$), 14-methylpentadecanoic ($C_{16:0}$ iso), and 14-methylhexadecanoic ($C_{17:0}$ anteiso) acids (Ara et al., 2010; Kämpfer et al., 2007; Matsumoto et al., 2000; Stackebrandt and Kroppenstedt, 1987; Sun et al., 2009; Wink et al., 2006).

The predominant saturated straight-chain fatty acids of the *Actinoplanes* species are penta- ($C_{15:0}$), hexa- ($C_{16:0}$), and heptadecanoic ($C_{17:0}$) acids. Major saturated branched fatty acids are 13-methyltetradecanoic ($C_{15:0}$ iso) and 14-methylpentadecanoic ($C_{16:0}$ iso), as well as 12-methyltetradecanoic ($C_{15:0}$ anteiso) and 14-methylhexadecanoic ($C_{17:0}$ anteiso) acids.

The predominant components of the unsaturated fatty acids are *cis*-9-heptadecenoic acid ($C_{17:1}$ ω9*c*) and *cis*-9-octadecenoic acid ($C_{18:1}$ ω9*c*, oleic acid). However, some differences have been detected by Kämpfer et al. (2007), where only *cis*-8-heptadecenoic acid ($C_{17:1}$ ω8*c*) instead of *cis*-9-heptadecenoic acid were detected in the analyzed strains, e.g. *Actinoplanes philippinensis*, *Actinoplanes couchii*, *Actinoplanes italicus*, and *Actinoplanes rectilineatus*. Minor amounts of tetra- and octadecanoic ($C_{14:0}$, $C_{18:0}$) acids, as well as 15-methylhexadecanoic- ($C_{17:0}$ iso) and *cis*-9-hexadecenoic acid ($C_{16:1}$ ω9*c*) have been found in most species. In a few cases, 12-methyltridecanoic acid ($C_{14:0}$ iso), 10-methylheptadecanoic acid ($C_{17:0}$ 10-methyl), and *cis*-9,14-methylhexadecenoic ($C_{17:1}$ iso ω9*c*) acids (Ara et al., 2010; Kämpfer et al., 2007; Sun et al., 2009) were detected in *Actinoplanes* species.

No fatty acid data are available for *Actinoplanes cyaneus* and *Actinoplanes digitatis*. Most analyses of the fatty acid components have been made according to Sasser (1990); fatty acid analyses described by Goodfellow et al. (1990b) were done according to Miwa et al. (1960). The distribution of cellular fatty acids amongst *Actinoplanes* species is summarized in Table 194.

Actinoplanes species contain tetrahydrogenated menaquinones with nine isoprene units [MK-9(H_4)] as predominant isoprenologue, with moderate amounts of MK-9(H_2) and MK-9(H_6) (Goodfellow et al., 1990b; Stackebrandt and Kroppenstedt, 1987). Minor proportions of MK-9(H_8) can also be found (Goodfellow et al., 1990b; Kämpfer et al., 2007). Tetrahydrogenated menaquinones with 10 side chains [MK-10(H_4)] may occur additionally as characteristic components of the quinone

[r]Occurs in spirals (G. Vobis, unpublished observation).

system (Kroppenstedt, 1985; Wink et al., 2006), but usually in minor amounts (Matsumoto et al., 2000; Stackebrandt and Kroppenstedt, 1987). Smaller amounts of MK-10(H_2) and traces of MK-10(H_6) are characteristic for *Actinoplanes couchii* (Kämpfer et al., 2007). The additional presence of MK-7(H_4, H_6, H_8) and MK-8(H_2, H_4, H_6, H_8) can be observed in some species, where they may occur in minor amounts (Goodfellow et al., 1990b). The distribution patterns of polar lipids and menaquinones for the species are given in Table 194.

Colonial characteristics. *Actinoplanes* strains grow well on various complex media, forming compact colonies up to about 3 cm in diameter after 4–6 weeks of incubation. They are characteristically elevated and convoluted, and frequently have protuberances in the center. The marginal areas can be ridged or flat. The colonies can be divided into sectors. Their consistency is generally hard, but may occasionally be soft, especially for "*Ampullariella*" strains. Colonies can be covered with a slight glittering whitish bloom if abundant sporangia are produced on the surface of the substrate mycelium. Aerial mycelium is rarely developed and generally only in a rudimentary state, giving the colonies a whitish gray surface layer.

Colonies are usually brightly colored, with orange being the basic color component. Szaniszlo (1968) has identified spectrophotometrically the orange pigment of various strains as being associated with carotenoids. Besides all shades of orange, a great variety of additional colors exists, depending on the individual strains: cream to yellow, brown, rusty brown, red, purple, violet, green, or black (Palleroni, 1989; Parenti and Coronelli, 1979; Vobis, 1987). Segments with different colors may even occur in a single colony (Vobis, 1992). Palleroni (1989) reported a red pigment analyzed from two strains of *Actinoplanes* that had the structure of an anthraquinone derivative. Methanolic extracts of *Actinoplanes ferrugineus* lack a characteristic carotenoid spectrum (Palleroni, 1979).

Soluble pigments are also produced in several species, ranging from yellowish, greenish, and auburn to dark brown (Couch, 1963). "*Ampullariella violaceochromogenes*" produces a violet to dark purple soluble pigment on various agar media (Nonomura et al., 1979). A cherry red pigment is the distinctive mark of *Actinoplanes italicus*, although this red pigment is not produced and substrate mycelium appears deep orange on exposure to light during growth (Beretta, 1973). The soluble blue pigment of *Actinoplanes cyaneus* has been shown to belong to the celocomycin-actinorodine group (Terekhova et al., 1977). Melanoid pigments are produced in *Actinoplanes digitatis* (Couch, 1963).

Production of secondary metabolites. *Actinoplanes* strains have shown a high capacity to produce antibiotics and other useful secondary metabolites. First reviews revealed about 20 antibiotics (Palleroni, 1983; Parenti and Coronelli, 1979). The number increased to more than 120, covering a wide range of chemical diversity including peptides, glycopeptides, anthracyclines, nucleosides, polyenes, and quinones (Okami and Hotta, 1988; Vobis, 1992). The amino acid derivatives are predominant and some are of clinical relevance (Lazzarini et al., 2000), e.g. teicoplanin, a glycopeptide from *Actinoplanes teichomyceticus* ATCC 31121^T (Bardone et al., 1978), actaplanin, a glycopeptide from *Actinoplanes missouriensis* ATCC 23342 (Debono et al., 1984), and ramoplanin, a glycolipodepsidpeptide from *Actinoplanes* sp. ATCC 33076 (Ciabatti and Cavalleri, 1989). Further examples of other interesting antibiotics are the friulimicins, lipopetides from "*Actinoplanes friuliensis*" DSM 7358 (Aretz et al., 2000), purpuromycin, a naphthoquinone from "*Actinoplanes ianthinogenes*" ATCC 21884 (Coronelli et al., 1974), the chloride-containing lipiarmycin from *Actinoplanes deccanensis* ATCC 21983^T (Parenti et al., 1975), and actagardine, an oligopeptide from *Actinoplanes liguriensis* ATCC 31048^T (Parenti et al., 1976; Vértesy et al., 1999). The list of "Practically used Antibiotics and Their Related Substances" (Sezaki and Miyadoh, 2001) also includes acarbose, a pseudotetrasaccharide produced by *Actinoplanes* sp. SE-50 (Truscheit et al., 1981), a very effective inhibitor of α-glucosidase, successfully applied in cases of diabetes mellitus (Creutzfeld, 1988).

Life cycle. The life cycle of *Actinoplanes* is characterized by an alternation between terrestrial and aquatic habitats (Figure 213H) (Vobis, 1987, 1992). The growth of vegetative mycelium on plant or animal debris or other adequate substrates (Figure 213F) culminates in the differentiation into sporangia (Figure 213H, I), which are generally produced on the surface of the substrate, directly in contact with the air (Bland and Couch, 1981). The sporangia can easily lose their connection to the degenerating mycelium and are disseminated as diaspores by the wind (Figure 213H, II), or by soil fauna such as mites, collembola, or arthropods. The sporangial envelope and the intrasporangial matrix hold together the mass of spores and shield the thin-walled spores (Figure 212C, D) from mechanical and physiological stress. The sporangia withstand prolonged desiccation (Figure 213H, III) and survive for many years (Makkar and Cross, 1982).

The sporangial envelope is usually hydrophobic. It can be rehydrated by sufficient moisture, e.g. during periods of fog or rain, and flagellated spores are released from the sporangia. Under laboratory conditions (Figure 213A, B, C), this process takes 10–60 min (Higgins, 1967; Vobis, 1987). The process can be facilitated by the addition of wetting agents like Tween 80 (Higgins, 1967). During immersion in water, the spores swell, becoming more clearly visible within the sporangium. In general, spores show motility inside the sporangium before they are released by disruption of the sporangial envelope (Lechevalier and Holbert, 1965). As Higgins (1967) has shown, both swelling and motility of the spores contribute to their release, thus contradicting the suggestion made by Couch (1963) that this may be a consequence of the swelling of the intersporal material. Of the two factors, swelling of the spores is the more important, as sometimes sporangium dehiscence gives nonmotile spores (Palleroni, 1989). In some instances, motility begins after spore release. Spores of *Actinoplanes brasiliensis* retain their motility in water or in diluted buffers for more than 1 d at room temperature (Palleroni, 1983). In baiting experiments simulating a natural aquatic microhabitat, pollen or other natural substrates are exposed to the surface of water. The zoospores, once released from the submerged sporangia, are able to swim to the surface (Figure 213H, IV), attach to the natural substrates, germinate (Figure 213E, H, V), and colonize them within several days (Figure 213F) (Couch, 1963; Vobis, 1987). This may be a result of aerotactic and chemotactic behavior of the spores (Cross, 1986). Although the chemotactic response is used effectively in the isolation method of Palleroni (1980), up to now the exact physiological explanation is not known. If the liquid contains nutrients, germination may ensue after a few hours and

the emergence of the filamentous stage completes the cycle of morphogenetic changes (Palleroni, 1989).

The state of swarming sporangiospores (Cross, 1986) may be skipped over during the life cycle. In nearly all cases, under culture conditions, it is possible to induce the spores to germinate, if they are still enclosed within the sporangia. Exposed on the surface of agar media, the spores germinate synchronously, and can develop directly into new mycelium (Figure 213G) (Vobis, 1987).

Metabolism and physiology. *Actinoplanes* strains are aerobic and mesophilic, growing between 10 and 35°C, with an optimal growth temperature of about 23–28°C. Some species, e.g. *Actinoplanes deccanensis*, show moderate thermotolerance, growing at a maximum temperature of 45°C (Parenti and Coronelli, 1979). No growth occurs at 50°C (Kothe, 1987; Parenti et al., 1978). The minimum growth temperature observed for many species is 4°C (Goodfellow et al., 1990b).

Species of *Actinoplanes* can be characterized as neutrophilic micro-organisms, growing well at pH 6.0–8.0. Goodfellow et al. (1990b) could not register growth at either pH 5.6 and lower or at pH 9.0 and higher for 13 species cultivated on modified Bennett's agar. In contrast, Kothe (1987) observed growth in acid conditions at pH 4.0 for four species and in alkaline conditions at pH 10.0 for nine species grown on yeast extract-starch agar (Table 195). These differences can probably be explained by the use of the two distinct agar media, perhaps having diverse buffer effects.

Strains of *Actinoplanes* can be cultured on most complex media generally used for actinomycetes, including various ISP media (Wink et al., 2006). Further recommendations and/or recipes of media suitable for isolation, vegetative growth, sporulation, and many kinds of physiological tests are given by Goodfellow et al. (1990b), Palleroni (1989), and Vobis (1992).

Isolates of *Actinoplanes* are able to grow on chemically defined agar media prepared with inorganic salts and a single compound as the sole source of carbon. In general, the test method follows the recommendations of Shirling and Gottlieb (1966) using about ten organic compounds (Schäfer, 1973; Thiemann et al., 1969; Wink et al., 2006). Other authors used different basal media and/or amplified the number of tested carbohydrates (Goodfellow et al., 1990b; Kämpfer et al., 2007; Kothe, 1987; Palleroni, 1989). D-Glucose and, to a lesser extent, L-arabinose, D-mannose, and maltose are used as carbon sources by all species (Table 195).

As typical saprophytic inhabitants of soil, *Actinoplanes* strains are able to degrade organic compounds (Table 195). Casein, chitin, gelatin, DNA, RNA, and lecithin are decomposed by most species, as well as starch as a representative polymer of plant origin. Pectin is decomposed by many species. Different results are reported for cellulose degradation. Goodfellow et al. (1990b) found that none of the 55 strains investigated were able to break down cellulose, whereas tests of Schäfer (1973) and Solans and Vobis (2003) presented positive results for 21 strains. Hemicellulose can be degraded and lignocellulose is used as a preferred substrate by various strains (Solans and Vobis, 2003). The compound guanine and the polymer keratin, both of typical animal origin, are not degraded. Further enzymic activities have been studied recently (Wink et al., 2006), specifically hydrolysis of chromogenic substances (Kämpfer et al., 2007) (Table 195).

Studies on other physiological features, including the ability to grow in media supplemented with sodium chloride, have been tested for 15 species with different results (Table 195): concentrations of up to 2.0% (w/v) were tolerated by six species; *Actinoplanes campanulatus* and one strain of *Actinoplanes palleronii* could grow at 3.0% (w/v) NaCl (Goodfellow et al., 1990b); and a concentration of 5% (w/v) sodium chloride was not tolerated by eight species including *Actinoplanes campanulatus* (Kothe, 1987).

Many species have been tested by Goodfellow et al. (1990b) for their capacity to grow in the presence of various other organic and inorganic chemical compounds at different concentrations, as well as their resistance to several antibiotics (Table 194). Aside from well-studied antibiotics produced by *Actinoplanes*, antimicrobial activities against *Aspergillus niger* and *Candida albicans*, as representatives of eukaryotic microorganisms, and against Gram-stain-negative and Gram-stain-positive bacteria have been carried out to characterize various species (Goodfellow et al., 1990b; Wink et al., 2006) (Table 194). Further biochemical tests like reduction of nitrate, production of urease and hydrogen sulfide, and coagulation and peptonization of milk are additional useful taxonomic markers (Table 195).

The production of sporangia occurs preferably on certain agar media, depending on the strain. In general, starch-casein and a minimal agar medium with certain carbon sources promotes sporangia formation (Palleroni, 1989). Humic acid and fulvic acid are possible factors to stimulate sporangiogenesis (Willoughby et al., 1968; Willoughby and Baker, 1969), as well as tea infusion (Parenti et al., 1978). Good results have been obtained when sections of mycelia, originally grown on nutrient-rich complex media, were transferred onto nutrient-poor media like artificial soil agar (Vobis, 1992; Vobis and Kothe, 1985).

The motile sporangiospores of *Actinoplanes* are, in general, vigorous swimmers, moving in a straight line. They interrupt the movement for moments, tumbling and "re-arranging" their flagella, and continue to swim in a different direction (Palleroni, 1983). Couch and Koch (1962) have observed that 1% Casamino acid induces the motility of sporangiospores of an "*Ampullariella*" strain that is a rather poor swimmer and that L-arginine hydrochloride (6 mM) and urea (0.01 M) greatly increase the motility. In spore-releasing studies on *Actinoplanes rectilineatus*, Higgins (1967) could demonstrate that flagellation and motility decreased in old spores, but motility can be regained if glucose is supplied as exogenous carbon source, which must be applied within 180 min of the initial wetting. The addition of amino acids or phosphate buffer permitted flagellation, but not motility. Deflagellation/reflagellation experiments indicated that functional flagella can be regenerated only in the presence of both amino acids and glucose. Inoperative flagella were formed in the presence of inhibitors of nucleic acid synthesis, such as 6-azauracil, but inhibitors of protein synthesis, such as chloramphenicol, did not interfere with reflagellation. Inhibitors such as sodium *p*-chlormercuribenzoate, sodium iodoacetate, 2-iodoacetamide, sodium azide, and 2,4-dinitrophenol inhibit the formation of flagella and also immobilized fully motile spores (Higgins, 1967). Carbonylcyanide-*m*-chlorophenylhydrazone, which is effective against oxidative phosphorylation, has the same physiological effect (Palleroni, 1983).

The zoospores of *Actinoplanes* exhibit chemotactic properties. In *Actinoplanes brasiliensis*, Palleroni (1976) found bromide and chloride ions acting as attractants at a relatively high concentration (0.1 M). Addition of methionine stimulated this chemotactic effect, suggesting that protein methylation may be involved (Palleroni, 1983). Spores of *Actinoplanes missouriensis* were attracted by fungal conidia and sclerotia and to their respective exudates (Arora, 1986). Phototactic effects have not been observed, but an apparent microaerophilic behavior was seen in *Actinoplanes brasiliensis* (Palleroni, 1976).

Sporangiospores of *Actinoplanes brasiliensis* are able to germinate in a minimal medium with glucose as sole carbon source. The germination rate is nearly 100% (Palleroni, 1989). In contrast, *Actinoplanes rectilineatus* gave a much lower proportion of spores able to germinate under minimal conditions and normal levels of germination depended on the addition of amino acids. Germination could be inhibited by chloramphenicol and actinomycin D and, even though it was stimulated by 6-azauracil, this compound inhibited further growth (Higgins, 1967).

Ecology. While studying the distribution and abundance of *Actinoplanes* in soils of Japan, Nonomura and Takagi (1977) introduced the convenient term "actinoplanetes", which was accepted for further ecological investigations (Makkar and Cross, 1982). In a more extended sense, the name "Actinoplanetes" was used for a long time for a suprageneric group within actinomycete systematics (Goodfellow, 1989) until the genera belonging to it could be harbored in the well-defined taxon *Micromonosporaceae* (Goodfellow et al., 1990b). Now, the term actinoplanetes can be used again in its original meaning, characterizing an ecological group of actinomycetes.

Actinoplanetes are widely distributed in soil throughout the world (Couch, 1963; Parenti and Coronelli, 1979; Schäfer, 1973). Strains of *Actinoplanes* occur in all types of soil, in arid desert areas (Couch, 1957; Garrity et al., 1996; Makkar and Cross, 1982), in sand dune systems close to seashores (Palleroni, 1976), and in subtropical and tropical regions. In a large-scale investigation of the distribution of the actinoplanetes in soil in Japan, Nonomura and Takagi (1977) demonstrated a correlation between their abundance, the type of soil, its pH value, and the content of organic matter. Relatively few actinoplanetes occurred in soils with pH 4.0–5.0 and abundant organic matter content. Their number increased with lower humus content and a pH value between 6.4 and 7.2. Soils with a permanent high content of water (e.g. paddy rice fields) have no advantage compared with cultivated fields, which are dry for longer periods.

Strains of *Actinoplanes* can also colonize plant or animal debris (Cross, 1981b; Makkar and Cross, 1982). A frequent drying and wetting of the substrates increases their occurrence. Favored habitats are edges of ponds, drainage ditches, and barnyards (Shearer, 1987). Sediments of rivers are also a good source for the isolation of *Actinoplanes* strains (Goodfellow et al., 1990b). They occur frequently on twigs submerged in streams (Willoughby, 1971), muddy dead leaves that are caught and dried on branches of overhanging trees (Cross, 1981b), and on allochthonous leaf litter cast up on the shores of lakes (Willoughby, 1969b). In general, the sporangiate actinoplanetes can be considered as normal inhabitants of soil and leaf litter (Cross, 1981b), although they can also be isolated directly from lake or river water (Willoughby, 1969a, 1971).

After 20 years of experience, Couch (1963) concluded that about 66% of the soil samples collected from all over the world contain sporangiate actinomycetes. This is in accordance with the observations of Schäfer (1973), who isolated *Actinoplanes* strains from 56% of soil samples investigated. Similar results were also obtained from geographically limited regions like Japan (strains isolated from 75% samples; Nonomura and Takagi, 1977) or Argentina (strains isolated from 65% samples; Vobis, 1987).

The function of actinoplanetes in soil ecosystems is poorly known. With a behavior of typical saprophytic micro-organisms, abilities to degrade any kind of biological material may be possible. Chitin has been used as a carbon source for the isolation of strains by Makkar and Cross (1982). However, chitin degradation seems to be extremely slow and the greatest advantage using chitin media is the inhibition/decrease in growth of other micro-organisms (Willoughby, 1968). Degradation tests using chitin from insects and fungi gave negative results (Schäfer, 1973), which is in contrast to the positive results of Goodfellow et al. (1990b), using the basal medium of Gordon (1967) supplemented with 0.5% (w/v) chitin.

Because *Actinoplanes* strains exhibit good growth on xylose and arabinose, it is conceivable that they play a role in decomposing pentosans of plant origin (Parenti and Coronelli, 1979). It was assumed that strains of *Actinoplanes* cannot decompose cellulose, with the exception of *Actinoplanes brasiliensis* (Palleroni, 1989; Parenti and Coronelli, 1979), but recently, a study of saprophytic actinomycete strains associated with the root system of the actinorhizal plant *Ochetophila* (*Discaria*) *trinervis*, revealed that all 27 isolated *Actinoplanes* strains can degrade starch, cellulose, and pectin. Furthermore, a third of them were also able to decompose hemicellulose and/or colonized preferably thin sections of dead wood (Solans and Vobis, 2003). It could be demonstrated in plant growth assays that one of the most active *Actinoplanes* strains, BCRU-ME 3, promotes *Frankia* symbiosis of *Ochetophila trinervis* as well as *Sinorhizobium meliloti*/*Medicago sativa* symbiosis (Solans, 2007; Solans et al., 2009). This helper effect could be increased by coinoculations with strains of *Streptomyces* and *Micromonospora*, respectively, which were isolated from the rhizosphere of the same host plant (Solans, 2007). The actinomycetes involved produce phytohormones, which seem to play an important role in those interactions with higher plants (Solans, 2008). Presumably, single strains of *Actinoplanes* have a multiple function in terrestrial ecosystems, as shown in this example.

Enrichment and isolation procedures

All isolation methods stated below, with exception of the incubation technique, are based on the knowledge of morphological or physiological properties of the organisms. Three main aspects of their life cycle are utilized: the sporangia are dry-resistant survival units that can release motile spores when sufficiently wet and the spores are attracted by organic or inorganic chemical substances. It is recommended that freshly collected samples are dried at about 35°C. Well enclosed in a glass vessel or even a plastic bag, the air-dried probes are suitable for later investigations and can be stored for a long time, preferably at 4°C (Makkar and Cross, 1982; Nonomura and Takagi, 1977).

Baiting technique. The baiting technique is the traditional isolation method, which was originally designed to isolate water

molds and chytrids, but led to the discovery of actinomycetes with motile spores (Couch, 1949, 1950).

About 1 g soil is placed in a small sterilized Petri dish (3 or 4 cm in diameter), which is then covered with sterile water. After cautiously stirring, the particles settle to the bottom. Natural baits are placed singly or in combination on the surface of the water: e.g. pollen of *Pinus*, *Liquidambar*, or *Sparganium*, boiled *Paspalum* grass leaves or other material of biological origin (Bland and Couch, 1981; Couch, 1949, 1954; Makkar and Cross, 1982; Schäfer, 1973). A ring of Parafilm can be used to ensure the baits do not stick to the wall of the Petri dish (Hayakawa, 2003). Pollen grains of *Pinus* are the most recommended baits (Hayakawa, 2003; Palleroni, 1989). The baits must be presterilized, depending on their consistency, either chemically with ethanol or propylene dioxide or by autoclaving (Gaertner, 1955; Makkar and Cross, 1982; Schäfer, 1973). The enrichment cultures with floating baits are stored undisturbed at room temperature for several days or weeks. The water level can be regulated by addition of sterile distilled water. The examination for actinoplanetes is carried out with a dissecting microscope, preferably with ×100 magnification and horizontal lighting (Bland and Couch, 1981). Typical sporangia of *Actinoplanes* are recognizable as glistening beads on the air-exposed sides of the baits. Such baits are then removed carefully from the water and transferred to a 3% agar plate (Bland and Couch, 1981). Individual sporangia can be separated from the bait and rolled several centimeters over the surface of agar, using a micromanipulator or a thin-pointed tungsten needle, which has a tip curved like a hockey stick (Vobis, 1992). In this way, contaminants are removed from the sporangial surface. Cleaned sporangia are transferred onto a Petri dish with suitable agar media such as Czapek sucrose or peptone Czapek agars (Bland and Couch, 1981), half-concentrated Casamino acids-peptone Czapek agar (Schäfer, 1973), or Emerson's yeast extract-starch agar (Vobis, 1992). The colonies originating from the individual sporangia are visible to the naked eye after 1–4 weeks.

Makkar and Cross (1982) designed a special apparatus to apply an additional enrichment step. The colonized baits are transferred onto a Nucleopore polycarbonate membrane filter, washed with distilled water, and immediately dried at 28°C for 7 d. If this sporangia-containing material is resuspended and incubated in water, the fluid is highly enriched with motile spores, and is used for spreading onto agar plates.

Hayakawa et al. (1991c) enhanced the effect of releasing the spores by desiccating the sporangia-bearing baits for 2 h at 30°C in a mixture of fine soil particles and silica gel. These specially treated baits were then immersed in water and portions of the liquid, now enriched with zoospores, were plated on humic acid-vitamin agar.

Another convenient variation consists of making a wet mount with the colonized pollen grains in a drop of water on a slide and following the spore liberation microscopically. When this occurs, the liquid, enriched with swimming spores, can be used as an inoculum for isolation (Palleroni, 1989).

Dehydration-rehydration technique. This technique utilizes the ability of the sporangia to withstand desiccation and to release motile spores when they are subsequently in contact with water. Besides soil samples, it is also applicable to leaf litter, decaying plant material from aquatic habitats, organic debris, etc. (Makkar and Cross, 1982).

Samples are dried at 28–30°C for 7 d. For rehydration, 0.5 g soil or corresponding substrate is mixed with 50 ml sterile tap water in a 150 ml beaker or Erlenmeyer flask, which is covered with sterile aluminum foil (Shearer, 1987; Vettermann and Prauser, 1979). The suspension is incubated at 20–30°C for about 1 h. During the first 30 min, the vessel can be shaken at irregular intervals. After that, the particles should be permitted to settle. From the supernatant, 0.5–1.0 ml is removed with a sterile Pasteur pipette and spread onto agar plates (Shearer, 1987). If necessary, dilutions can be prepared from the inoculation suspension (Makkar and Cross, 1982). Soil extract agar or colloidal chitin agar containing cycloheximide and nystatin (Makkar and Cross, 1982), oatmeal-soil extract agar, or starch-casein-sulfate agar (Shearer, 1987) have been used in combination with this technique. Plates are incubated at 28°C for 2–4 weeks.

Rehydration and centrifugation method. Hayakawa et al. (2000) described an enrichment method incorporating differential centrifugation. Samples are rehydrated with 10 mM phosphate buffer containing 10% soil extract at 30°C for 90 min. The liquid enriched with zoospores is centrifuged at 1500 × *g* for 20 min. Portions of the supernatant are then plated on humic acid-vitamin agar supplemented with nalidixic acid and trimethoprim. The centrifugation procedure specifically eliminates strains of *Streptomyces* and other nonmotile actinomycetes (Hayakawa, 2003).

Chemotactic method. Investigations of the chemotactic behavior of the sporangiospores of *Actinoplanes brasiliensis* demonstrated, among other things, that they are attracted by chloride ions (Palleroni, 1976). This fact induced the same author to develop a new, very effective, and time-saving isolation method (Palleroni, 1980).

The essential tool of this technique is the isolation chamber, a sterilizable plastic block (80 × 40 × 12 mm) with two cylindrical wells (9 mm deep and 24 mm in diameter) with centers 32 mm apart. The wells are connected by a channel that is 2 mm wide and 3 mm deep (Palleroni, 1980).

The soil sample (1 g) is divided equally between the two compartments. Sterile water is added nearly to the rim. After incubation for approximately 1 h at 30°C, spores are released from the sporangia and move freely in the water. A sterile 1 µl glass capillary about 32 mm long, filled with 0.01 M phosphate buffer (pH 7.0), containing 0.01 M KCl as chemoattractant (Palleroni, 1980), is placed in the channel. Buffer and attractants may vary: phosphate buffer (5–10 mM, pH 6.8) and KCI (2 mM) (Palleroni, 1989), or colloidine (100 mM) (Hayakawa, 2003). The capillary must be submerged about 1 mm below the surface of the liquid. One hour after immersion of the capillary, sufficient spores are attracted and trapped in the lumen of the capillary, which is then removed and washed from the outside with sterile water. The contents of the capillary are blown into 1 ml sterile water or buffer. Portions of the spore suspension are taken with a sterile pipette and spread onto agar plates. The plates are then incubated at 28°C. Starch casein-sulfate agar is recommended as the isolation medium by Palleroni (1980) and humic acid-vitamin agar is recommended by Hayakawa (2003). Although colonies can be selected after 4 d, slowly growing actinoplanetes may only be detectable after 3 weeks.

Moist incubation procedure. This method is suitable for the direct detection of actinoplanetes on natural substrates.

Although the ability to produce motile spores obviously plays no role, *Actinoplanes* strains can be readily enriched. Willoughby (1968) emphasized the importance of selecting materials, such as plant residues found on the shores of lakes and streams, that are alternatively wetted and dried as the level of water rises and falls.

Portions of decaying leaves or other biological substrates, freshly collected from the field, are washed with sterile water to remove adhering detritus. They are placed in Petri dishes, the bottoms of which have been covered with moist filter paper or layers of cellulose before autoclaving. The Petri dishes, acting as humid chambers, are sealed and incubated for about 4 weeks at 25°C. Examination by both dissecting and light microscopy is necessary to identify the sporangia of the actinoplanetes (Willoughby, 1969b). The isolation media recommended by Willoughby (1968) include starch-casein agar and chitin agar.

Maintenance procedures

The traditional method for maintaining *Actinoplanes* strains is lyophilization. The experiments of Miller and Couch (1959) show that both the mycelium and the sporangia can survive the freeze-drying process. As pointed out by Palleroni (1989), actinoplanetes do not differ from other actinomycetes in their conservation requirements. Good results are also obtained by freezing concentrated spore suspensions in liquid media or in dilute phosphate buffer with 5% (v/v) glycerol and storing them at −20°C or in liquid nitrogen.

Differentiation of the genus *Actinoplanes* from other related genera and taxonomic comments

With the discovery of *Actinoplanes* strains, Couch (1949) demonstrated for the first time the existence of actinomycetes having a motile phase during their life cycle, represented by flagellated spores produced within sporangia. In addition, he confirmed the close affinity to the genus *Micromonospora*, correlated by colonial characters like production of substrate mycelium and absence of aerial mycelium (Couch, 1950). During the following decades, newly described or formerly known sporangia-forming genera with or without motility were classified either closer or more distantly related to *Actinoplanes* (Bland and Couch, 1981; Goodfellow and Cross, 1984; Palleroni, 1989; Vobis, 1989b). Considering chemotaxonomic properties, DNA pairing experiments, rRNA cistron similarity, and 16S rRNA oligonucleotide cataloging, the genera *Ampullariella* and *Amorphosporangium* were combined in a redefined genus *Actinoplanes* (Stackebrandt and Kroppenstedt, 1987). Supported by chemotaxonomic and numerical taxonomic studies, as well as 16S rRNA gene sequence-based phylogenetic clustering, other sporangiate genera were separated from the "*Micromonospora–Actinoplanes*–complex" and classified within other families (Goodfellow et al., 1990b; Miyadoh et al., 1997, 2001; Stackebrandt et al., 1997). This was the case for the genera *Acrocarpospora*, *Cryptosporangium*, *Kutzneria*, *Planobispora*, *Planomonospora*, *Planotetraspora*, *Sphaerisporangium*, *Spirillospora*, *Streptoalloteichus*, and *Streptosporangium*, and the genera with multilocular sporangia, *Dermatophilus*, *Frankia*, and *Geodermatophilus*.

The genera *Actinoplanes* and *Micromonospora* form the central part of the well-established family *Micromonosporaceae* (Goodfellow et al., 1990b), which can be distinguished from other suprageneric groups by 16S rRNA gene sequence similarity (Koch et al., 1996a). Each genus of the family *Micromonosporaceae* is characterized by distinctive morphological and/or chemotaxonomic features (Ara et al., 2008b). The morphological heterogeneity of spore-producing structures allows differentiation of the genus *Actinoplanes* from the other genera. Members of the *Micromonospora*, *Salinospora*, and *Verrucosispora* can be clearly separated morphologically by forming single, nonmotile spores on substrate hyphae. Species of *Actinocatenispora*, *Asanoa*, *Catellatospora*, *Catenuloplanes*, *Longispora*, *Polymorphospora*, and *Spirilliplanes* produce spores in chains on the surface of the substrate mycelium. The spores of *Catenuloplanes* and *Spirilliplanes* are motile, a feature in common with *Actinoplanes*, but they are not developed within sporangia. Morphologically more related may be the group comprising the genera *Couchioplanes*, *Krasilnikovia*, and *Pseudosporangium*, which form spore chains within pseudosporangium-like structures or pseudosporangia on substrate mycelium; spores are motile in the case of *Couchioplanes*, but not in *Pseudosporangium* or *Krasilnikovia*.

The genera *Dactylosporangium*, *Luedemannella*, *Pilimelia*, *Planosporangium*, and *Virgisporangium* appear morphologically much more related to *Actinoplanes* because they all develop real sporangia on the surface of the substrate mycelium. *Luedemanella* can be distinguished by the production of nonmotile sporangiospores. The genera *Dactylosporangium*, *Planosporangium*, and *Virgisporangium* form finger-like or rod-shaped, oligospore sporangia, with 2–6 or more motile spores per sporangium in a single row. *Pilimelia* is a genus characterized by multispored sporangia and motile sporangiospores, features in common with *Actinoplanes*. The spores of most *Actinoplanes* species are spherical, but in the case of the former "*Ampullariella*" species, they are also rod-like as in *Pilimelia* species. The distinguishing properties are the size of spores and the type of flagellation: the rod-like spores of *Actinoplanes* are 0.5–1.0 × 2.0–4.0 µm and have a polarly inserted tuft of flagella; and the rod-like spores of *Pilimelia* are 0.3–0.7 × 0.7–1.5 µm with a lateral tuft of flagella. Based on the type of flagellation, the mode of movement is completely different. The rod-like spores of *Actinoplanes* rotate around their longitudinal axis, whereas those of *Pilimelia* rotate around the lateral axis (Vobis, 1992).

Differentiation of species of the genus *Actinoplanes*

Morphological characters are easy to recognize, but the strains have to be cultured onto suitable agar media and investigated microscopically at the right time, e.g. on M3 agar of Rowbotham and Cross (1977), supplemented with 0.1% (w/v) fructose, after incubation for 14 d at 25°C (Goodfellow et al., 1990b). The artificial soil agar of Henssen and Schäfer (1971) is also recommended (Vobis, 1992). Sporangia are the joint characteristic structures, which can be used to limit groups of species or even species. The spores produced within spherical sporangia have in general a globose shape and are arranged in coiled chains. The observation "irregular arrangement" depends possibly on an advanced process of maturity. All species with globose spores belong to *Actinoplanes* in the original concept of Couch (1963). Sporangia shapes other than spherical are characterized by spore chains orientated in parallel and rod-like spores, which are characteristic for the former "*Ampullariella*" species (Vobis and Kothe, 1989). Within this group, *Actinoplanes capillaceus* stands out, with a hairy ornamentation on the surface of the sporangia, and *Actinoplanes rectilineatus*, with globose spores.

Another useful morphological marker is the presence of aerial mycelium, which is well developed in two species, *Actinoplanes rectilineatus* and *Actinoplanes regularis*, and observed in a rudimentary form in *Actinoplanes couchii*, *Actinoplanes ferrugineus*, and *Actinoplanes liguriensis* (Table 194). None of the other species produce aerial mycelium. Fragmentation of substrate mycelium is described only in *Actinoplanes couchii* (Kämpfer et al., 2007) and *Actinoplanes philippinensis* (Couch and Bland, 1974b).

In many cases, the different colors of the substrate mycelium maybe useful for the separation of species. Physiological conditions like the type of agar medium or the age of cultures are factors that can influence exact determinations. Additionally, zonal divisions of the colonies like radial sectors or central and marginal areas may cause differences. Using modified Bennett's agar, Goodfellow et al. (1990b) assigned a total of 163 isolates to eight color groups. In Table 194, the spectrum of colors of substrate mycelium is restricted to six main colors. Their combinations permit specification of a characteristic color for each species. The color white also comprises the variations ivory, creamish, or pale; yellow also represents buff, tawny, amber, and ochre. Orange is the most frequent color, with all shades like apricot or orange-red. Orange may lead to the variations of red, brick-like, cherry, coral, pink, scarlet, cinnabar, purple, and mahogany. The color brown includes cinnamon, chestnut, rufous or rusty. Black may be interpreted as a very dense concentration of many colors.

The soluble pigments are considered by Goodfellow et al. (1990b) as a character of possible diagnostic value to define *Actinoplanes* clusters at the 83% similarity level (S_{SM}). Because the production and/or the color variations depend on the culture media, RNA agar was recommended. The soluble pigments may influence the basic orange color of the substrate mycelium and then, in the case of overproduction, are diffused into the substrate (Parenti and Coronelli, 1979). In Table 194, the most common pigments are compiled for each species; e.g. the rare blue soluble pigment allows a rapid diagnosis for the species *Actinoplanes cyaneus*. Brown pigments are formed by many strains; however, it is not known if these pigments are melanoid. The production of melanin, regarded as a constant physiological feature for *Streptomyces* strains (Shirling and Gottlieb, 1966), is also used as a taxonomic character for *Actinoplanes* species. Nevertheless, Goodfellow et al. (1990b) could not obtain reproducible results. Additionally, Kothe (1987) demonstrated by absorption spectra that the type strains of *Actinoplanes philippinensis* and *Actinoplanes brasiliensis* characterized as melanin-negative organisms show the same peaks at 275 nm and 345 nm like in *Actinoplanes utahensis*, a typically melanin-positive species (Table 195). The feature of melanin production seems to have no diagnostic value.

The assimilation of different organic compounds as sole sources of carbon is used as a diagnostic feature to recognize species. A total of 86 compounds is listed in Table 195, some of which have a differentiating value (Goodfellow et al., 1990b; Kämpfer et al., 2007; Palleroni, 1989; Wink et al., 2006). However, more than 70% of the tests have not been determined. Enzymic activities, including degradation and hydrolysis of organic compounds, can be used to differentiate *Actinoplanes* species, but the list is also incomplete for many species (Table 195). Other physiological properties like pH and sodium chloride tolerances (Table 195), growth in the presence of organic and inorganic substances, and resistance to various antibiotics (Table 194) supply further diagnostic data. Tests for antimicrobial activities against micro-organisms may also be integrated into the large list of diagnostic characters (Table 194).

Among the chemotaxonomic features, the fatty acid profiles, menaquinone components, and polar lipid patterns show sufficient quantitative differences, which could be used in particular cases for separating species of *Actinoplanes* (Table 194).

Many species are described only on the basis of their corresponding type strain. In this case, the species description is identical with the characterization of a single strain in all phylogenetic and phenotypic aspects. The studies of Goodfellow et al. (1990b), Kothe (1987), Matsumoto et al. (2000), and Schäfer (1973) have shown that not all features that are characteristic for one strain have diagnostic value to differentiate between species, but allow intraspecific variations. In this sense, the concept of many species of the genus *Actinoplanes* seems to be still ill-defined (Palleroni, 1989).

List of species of the genus *Actinoplanes*

The following list is based upon J.P. Euzéby's "List of Prokaryotic names with Standing in Nomenclature – Genus *Actinoplanes*" (http://www.bacterio.cict.fr/a/actinoplanes.html).

1. **Actinoplanes philippinensis** Couch 1950, 89[AL]

phi.lip.pi.nen′sis. N.L. masc. adj. *philippinensis* of or pertaining to the Philippines.

Sporangia are spherical to subspherical, 8.8–25.0 µm in diameter (most are about 16 µm thick), produced on the surface of substrate mycelium by palisade hyphae. Spores are arranged in coils within the sporangia, globose, 1.0–1.2 µm in diameter, motile with a tuft of flagella. Substrate hyphae are 0.5–1.5 µm wide, branched, and sparingly septate. Conidia may be developed under certain circumstances.

Growth on Czapek agar is moderate; colonies are flat, or slightly elevated, light buff to tawny, occasionally changing to purplish brown with age. Hyphae in the upper layer are arranged in palisades with abundant production of sporangia. On peptone Czapek agar, growth is very good, surface of the colonies with concentric rings and radial grooves, formation of sporangia is very rare. Hyphae may fragment into spheres and rods. Color is apricot-orange to orange-chrome. Vigorous growth is observed on potato glucose agar, with the color at first near apricot-orange, then mahogany red, chestnut, or cinnamon-rufous. On nutrient agar, colonies are flat, slightly elevated in the center, color orange to cinnamon-rufous. A dark brown soluble pigment is produced on potato glucose and glycerine Czapek agars.

Produces macrocyclic lactone antibiotics.

Source: the type strain was isolated from rice paddy soil (the Philippines).

DNA G+C content (mol%): 72.1 (Bd).

Type strain: ATCC 12427, CBS 107.58, DSM 43019, NBRC 13878, HAMBI 1927, JCM 3001, NRRL 2506, RIA 468, UNCC P-15, VKM Ac-842.

Sequence accession no. (16S rRNA gene): D85474.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes sichuanensis* 03-723^{T}, 99.0%; *Actinoplanes capillaceus* NBRC 16408^{T}, 98.9%; *Actinoplanes campanulatus* NBRC 12511^{T}, 98.9%.

2. **Actinoplanes auranticolor** (Couch 1963) Stackebrandt and Kroppenstedt 1988, 328^{VP} (Effective publication: Stackebrandt and Kroppenstedt 1987, 113.) (*Amorphosporangium auranticolor* Couch 1963, 65)

au.ran′ti.co.lor. N.L. n. *aurantium* a bitter orange; L. n. *color* tint, hue; N.L. adj. *auranticolor* orange colored.

Sporangia are very irregular in shape, multilobed, 6.0–25.0 μm wide and 8.0–15.0 μm long. Spore chains are irregularly arranged within the sporangium. Sporangiophores may be branched. Spores are short rod-shaped, 0.5–0.7 × 1.0–1.5 μm. The original description by Couch (1963) considers the spores to be nonmotile, but Kane Hanton (1968) later reported motility by means of polar flagella. Nonmotile microconidia may be produced on tyrosine medium.

Growth on Czapek agar is very good and colonies are frequently elevated and convoluted with slippery surfaces and apricot-orange in color; colonies are scarlet on peptone Czapek agar. Good growth is also seen on oatmeal agar and on casein media, but poor growth is observed on tyrosine media. In all cases, colony colors are various shades of orange. A diffusible dark pigment is formed in tyrosine media whereas, in other media, a yellow diffusible pigment may be observed.

Source: the type strain and a further strain were isolated from soil collected from meadows (Nevada, USA).

DNA G+C content (mol%): 72 (T_m).

Type strain: ATCC 15330, DSM 43031, NBRC 12245, HAMBI 1975, JCM 3038, NRRL B-3343, UNCC 253, VKM Ac-648.

Sequence accession no. (16S rRNA gene): D85471.

Additional comments: the type strain shows highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes missouriensis* NBRC 13243^{T}, 99.8%; *Actinoplanes cosettensis* NBRC 14913^{T}, 98.7%; *Actinoplanes digitatis* NBRC 12512^{T}, 98.7%; *Actinoplanes humidus* NBRC 14915^{T}, 98.7%.

3. **Actinoplanes brasiliensis** Thiemann, Beretta, Coronelli and Pagani 1969, 119^{AL}

bra.si.li.en′sis. N.L. masc. adj. *brasiliensis* of or pertaining to Brazil.

Sporangia are produced abundantly on soil extract agar, calcium malate agar, and starch-casein agar. They are umbraculiformis (umbrella shaped) to irregular or very occasionally globose, with very wrinkled surfaces, measuring at their widest from 3.5 to 11.5 μm. Spores vary from subspherical (1.2 μm) to rod-shaped (1.2 μm in width and 1.7–2.3 μm in length).

Good growth occurs on skim milk, glucose asparagine, and potato agars. Growth varies from very good to moderate on different ISP media (Shirling and Gottlieb, 1966). Colonies have smooth to wrinkled surfaces and vary in color from light pink, orange rose, and orange to deep orange. No aerial mycelium is produced.

Produces the acidic antibiotic A/672.

Source: the type strain was isolated from a soil sample (State Bahia, Brazil).

DNA G+C content (mol%): 70.5 (HPLC).

Type strain: ATCC 25844, DSM 43805, NBRC 13938, JCM 3196, NRRL B-16714, VKM Ac-1320.

Sequence accession no. (16S rRNA gene): D85470.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes deccanensis* NBRC 13994^{T}, 98.2%; *Actinoplanes digitatis* NBRC 12512^{T}, 98.0%.

4. **Actinoplanes campanulatus** (Couch 1963) Stackebrandt and Kroppenstedt 1988, 328^{VP} (Effective publication: Stackebrandt and Kroppenstedt 1987, 113.) ["*Ampullaria campanulata*" Couch 1963, 59; *Ampullariella campanulata* (Couch 1963) Couch 1964, 29]

cam.pa.nu.la′tus. N.L. dim. n. *campanella* small bell; L. masc. suff. *-atus* suffix denoting provided with; N.L. masc. adj. *campanulatus* bell-shaped.

Sporangia are characteristically bell shaped, frequently lobed or irregular, sometimes pyriform or cylindrical, and 5.0–15.0 × 6.0–12.0 μm. They often have a papillate appearance at the proximal end because the spore chains are of unequal length. Spore chains are arranged in parallel rows within the sporangia. The spores are rod-shaped (0.5–1.0 × 2.0–4.0 μm) and motile by a polarly inserted tuft of flagella.

Good growth occurs on Czapek, peptone Czapek, and casein agars and moderate growth occurs on tyrosine agar. Colonies are elevated and convoluted with ridged areas at the margin. The color of the substrate mycelium is coral-red, coral-pink, orange, brown, or black. Soluble yellowish, greenish, and brownish pigments may be produced on various media. Formation of sporangia occurs on Czapek agar. D-Mannitol is utilized by the type strain; inositol and raffinose are not utilized. Gelatin is not liquefied.

The iso- and anteiso- fatty acids are unsaturated.

Source: the type strain was isolated from soil (Douglas, Kansas, USA). Three further isolates were from Chapel Hill, North Carolina, USA, and four were from soils collected in Tahiti (Couch, 1963). Additionally, 17 strains were isolated from soil by D. Schäfer (Marburg, Germany) originating from: Kenya (2), Ceylon (4), Corsica (1), Mexico (2), Austria (1), Taiwan (1), Germany (1), South Africa (1), Italy (1), USA (2), and Turkey (1) (Kothe, 1987).

DNA G+C content (mol%): 71 (T_m).

Type strain: ATCC 15348, CBS 190.64, DSM 43148, NBRC 12511, JCM 3059, NRRL B-3344, UNCC 65, VKM Ac-1319.

Sequence accession no. (16S rRNA gene): AB036995.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes capillaceus* K95-5561^{T}, 99.9%; *Actinoplanes lobatus* NBRC 12513^{T}, 99.3%.

5. **Actinoplanes capillaceus** Matsumoto, Takahashi, Kudo, Seino, Iwai and Ōmura 2001, 793[VP] (Effective publication: Matsumoto, Takahashi, Kudo, Seino, Iwai and Ōmura 2000, 114.)

ca.pil.la′ce.us. L. masc. adj. *capillaceus* capillary, hairlike, referring to the hairy surface of the sporangium.

Sporangia are produced by substrate hyphae on short sporangiophores and are bell-shaped (5.0–10.0 × 5.0–15.0 μm). The surface of the sporangia is covered with short hair-like elements. Spores are oblong in shape (0.7–0.8 × 2.0–3.0 μm) and motile by means of a polar tuft of flagella.

Good growth occurs on inorganic salts-starch agar; colonies are brick-red in color. Colonies on yeast extract-starch agar are pink to yellow colored. No soluble or melanoid pigments are produced. No growth occurs in the presence of 3% (w/v) NaCl. Sensitive to streptomycin (50 μg/ml), but resistant to novobiocin (20 μg/ml).

Source: two strains, including the type strain, were isolated from a soil sample collected in Sayama City, Saitama Prefecture, Japan. Regarding the subjective synonym species, further three strains were isolated from soil (China) (Jiang and Ruan, 1982; Juan and Zhang, 1974).

DNA G+C content (mol%): 71.4 (HPLC).

Type strain: DSM 44859, NBRC 16408, JCM 10268, K95-5561, NBRC 16408.

Sequence accession no. (16S rRNA gene): AB013495.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes campanulatus*, NBRC 12511[T], 99.9%; *Actinoplanes lobatus*, NBRC 12513[T], 99.2%. Subjective synonyms (*sensu* Matsumoto et al., 2000) are: "*Ampullariella cylindrica*" Jiang and Ruan 1982 (type strains: JCM 3329, NBRC 14264); "*Ampullariella pekinesis*" Juan (Ruan) and Zhang 1974 (type strains: JCM 3174, NBRC 13662, DSM 46148); and "*Ampullariella pilifera*" Jiang and Ruan 1982 (type strains: JCM 3330, NBRC 14265).

6. **Actinoplanes consettensis** Goodfellow, Stanton, Simpson and Minnikin 1990a, 320[VP] (Effective publication: Goodfellow, Stanton, Simpson and Minnikin 1990b, 33.)

con.set.ten′sis. N.L. masc. adj. *consettensis* of or belonging to Consett, UK, a town near the site where the organism was isolated.

Sporangia are globose; spores are motile and arranged irregularly within sporangia.

Abundant growth occurs on modified Bennett's agar, developing light to yellow-brown substrate mycelium. Degrades arbutin, casein, DNA, elastin, lecithin, starch, and RNA. Adonitol, L-arabinose, dextrin, D-fructose, D-galactose, D-glucose, D-lactose, maltose, D-mannitol, D-mannose, methyl β-D-glucoside, raffinose, L-rhamnose, and D-xylose are utilized as sole carbon sources, but not cellobiose, erythritol, *myo*-inositol, methyl α-D-glucoside, D-ribose, catechol, *m*-, *o*- or *p*-hydroxybenzoic acid, syringaldehyde, or vanillin. Nitrate is not reduced and urea is not hydrolyzed. Tolerant to a number of antibiotics and chemical inhibitors. Grows between 4 and 30°C.

The peptidoglycan of the cell wall contains *meso*- and hydroxy-diaminopimelic acid. The principal wall sugars are arabinose, galactose, glucose, mannose, and xylose. The organism contains complex mixtures of straight- and branched-chain fatty acids, with hexadecanoic and 12-methyltetradecanoic acids predominating. Tetrahydrogenated menaquinones with nine isoprene units are the predominant isoprenologue, and major amounts of phosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol are present.

Source: the type strain and five further strains were isolated from sediments of the River Derwent at Allensford, County Durham, UK.

DNA G+C content (mol%): not known.

Type strain: ATCC 49799, DSM 43942, NBRC 14913, LA 97, NCIB (now NCIMB) 20027, NRRL B-16688.

Sequence accession no. (16S rRNA gene): AB036996.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes humidus* NBRC 14915[T], 100%; *Actinoplanes digitatis* NBRC 12512[T], 98.8%.

7. **Actinoplanes couchii** Kämpfer, Huber, Thummes, Grün-Wollny and Busse 2007, 722[VP]

cou′chi.i. N.L. gen. masc. n. *couchii* of Couch, named after J.N. Couch (1896–1986), who proposed the genus name *Actinoplanes* in 1950.

Sporangia are globose to oval. A rudimentary sterile aerial mycelium is formed. Substrate hyphae fragment easily in irregular rod-shaped cells.

Good growth occurs on nutrient agar and DSMZ medium 65 at 25–30°C. Color of the substrate mycelium is yellow-orange to orange-red. A red to brown soluble pigment develops on DSMZ medium 65. Starch, xylan, tyrosine, casein, hypoxanthine, adenine, and xanthine are degraded.

The quinone system consists of MK-9(H_4) (75%) as the predominant compound, with moderate amounts of MK-9(H_6) (11%), minor amounts of MK-9(H_2) (4%), MK-9(H_8) (2%), and MK-10(H_2) (2%), and traces of MK-10(H_6) (<0.1%). The polar lipid profile contains the major compounds diphosphatidylglycerol and phosphatidylethanolamine, but lacks phosphatidylcholine and aminoglycolipids. Additionally, moderate amounts of phosphatidylinositol, two unknown phospholipids, a highly hydrophilic glycolipid, and a polar lipid are detectable and traces of a single phosphatidylinositol mannoside are present.

Source: the type strain was isolated from soil close to the Marmore waterfalls, Terni, Italy.

DNA G+C content (mol%): not known.

Type strain: CIP 109316, DSM 45050, GW8-1761.

Sequence accession no. (16S rRNA gene): AM400230.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes italicus* NBRC 13911[T], 99.2%; *Actinoplanes rectilineatus* NBRC 13941[T], 98.9%.

8. **Actinoplanes cyaneus** Terekhova, Sadikova and Preobrazhenskaya 1987, 179[VP] (Effective publication: Terekhova, Sadikova and Preobrazhenskaya 1977, 1059.)

cy.a.ne′us. L. masc. adj. *cyaneus* dark blue.

Spherical sporangia with diameters of 30–60 μm are formed by substrate mycelium, sporangiospores are globose

(1.2–1.4 µm) and motile. Aerial mycelium is not developed. On synthetic media, a soluble blue pigment is produced, belonging to the chemical group of celicomycin-actinorodine.

Source: the type strain was isolated from soil (Siberia, Russia).

DNA G+C content (mol%): not known.

Type strain: DSM 46137, NBRC 14990, INA 1569, JCM 9082, VKM Ac-1095.

Sequence accession no. (16S rRNA gene): AB036997.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes rectilineatus* NBRC 13941^{T}, 98.4%; *Actinoplanes italicus* NBRC 13911^{T}, 98.3%.

9. **Actinoplanes deccanensis** Parenti, Pagani and Beretta 1975, 248^{AL}

dec.ca.nen′sis. N.L. masc. adj. *deccanensis* of or pertaining to the Indian locality of Decca.

Sporangia are globose, small with irregular surfaces (4.0–7.0 µm in diameter), produced on hyphae of substrate mycelium, especially when grown on soil extract agar. Spores are subspherical, 1.0 × 1.5 µm in diameter, and motile. Soil extract agar promotes formation of sporangia. Hyphae of substrate mycelium are branched and about 1.0 µm in diameter. Aerial mycelium is not formed.

Growth is abundant on ISP agar media 2, 4, and 7 (Shirling and Gottlieb, 1966), and on other media like oatmeal, potato, Hickey–Tresner, Bennett's, or skim milk agars. Surfaces of the colonies are wrinkled, crusty, or rough. Color varies from light amber, light orange, light orange pinkish to orange. No growth on calcium malate agar. On tyrosine agar, a brown diffusible pigment is produced. Thermotolerant, grows between 26 and 42°C.

Produces the antibiotic lipiarmycin.

Source: the type strain was isolated from soil (Decca, India).

DNA G+C content (mol%): 72.0 (HPLC).

Type strain: A/10655, ATCC 21983, DSM 43806, NBRC 13994, JCM 3247, NRRL B-16715.

Sequence accession no. (16S rRNA gene): AB036998.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes missouriensis* NBRC 13243^{T}, 98.5%; *Actinoplanes digitatis* NBRC 12512^{T}, 98.3%.

10. **Actinoplanes derwentensis** Goodfellow, Stanton, Simpson and Minnikin 1990a, 320^{VP} (Effective publication: Goodfellow, Stanton, Simpson and Minnikin 1990b, 33.)

der.wen.ten′sis. N.L. masc. adj. *derwentensis* of or pertaining to The Derwent, a river in County Durham, England, from which the organism was isolated.

Globose sporangia are readily produced; spores are motile and arranged irregularly within sporangia.

Color of substrate mycelium is orange to dark orange on modified Bennett's agar. Degrades arbutin, casein, chitin, DNA, elastin, lecithin, RNA, and starch; utilizes adonitol, L-arabinose, dextrin, D-fructose, D-galactose, D-glucose, *myo*-inositol, D-lactose, maltose, D-mannitol, D-mannose, methyl β-D-glucoside, D-xylose, and sodium fumarate as sole carbon sources but not methyl α-D-glucoside, D-ribose, catechol, coumarin, *m*-, *o*- or *p*-hydroxybenzoic acid, syringaldehyde, syringic acid, or vanillin. Grows between 4 and 30°C.

The peptidoglycan of the cell walls contains *meso*- and hydroxy-diaminopimelic acid. The principal wall sugars are arabinose, galactose, glucose, mannose, and xylose. The organism contains complex mixtures of straight- and branched-chain fatty acids, with hexadecanoic, 14-methylpentadecanoic, and 14-methylhexadecanoic acids predominating. Tetrahydrogenated menaquinones with nine isoprene units are the predominant isoprenologue, and major amounts of diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol are present.

Source: the type strain and seven further strains were isolated from sediments of the River Derwent, Allensford, Durham, UK.

DNA G+C content (mol%): not known.

Type strain: ATCC 49798, DSM 43941, NBRC 14935, JCM 7556, LA 107, NCIB (now NCIMB) 12875, NRRL B-16692.

Sequence accession no. (16S rRNA gene): AB036999.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes couchii* GW8-1761^{T}, 98.6%; *Actinoplanes rectilineatus* NBRC 13941^{T}, 98.5%; *Actinoplanes utahensis* NBRC 13244^{T}, 98.5%.

11. **Actinoplanes digitatis** (Couch 1963) Stackebrandt and Kroppenstedt 1988, 328^{VP} (Effective publication: Stackebrandt and Kroppenstedt 1987, 113.) ["*Ampullaria digitata*" Couch 1963, 61; *Ampullariella digitata* (Couch 1963) Couch 1964, 29]

di.gi.ta′tis. L. masc. adj. *digitatis* (*sic*) having fingers.

Sporangia are usually digitate, sometimes subcylindrical or lobed, rarely bottle shaped, and 3.0–9.0 × 6.0–14.0 µm. Spore chains are arranged in parallel rows within the sporangia. Formation of sporangia occurs on Czapek agar. The motile spores are rod-shaped (0.5–1.0 × 2.0–4.0 µm).

Good growth occurs on Czapek, peptone Czapek, and tyrosine agars. Colonies are flat, wrinkled, or convoluted, and frequently ridged. The margin is sometimes fimbriate. The color of substrate mycelium is pinkish cinnamon or red-cinnamon to blackish brown, sometimes red with black sectors or very dark with red sectors, flesh-colored, or dirty buff. The marginal areas are usually lighter in color. Soluble yellowish, greenish, and brownish pigments may be produced on various media.

Inositol and raffinose are utilized, but D-mannitol is not utilized. Melanoid pigments are produced.

Source: the type strain was isolated from soil (Sheboygan, Michigan, USA); two further strains from soil were collected in Parfrey's Glen, Wisconsin, USA, and from garden soil (Highfield Cresent, Hindhead, UK). D. Schäfer (Marburg, Germany) isolated a total of 29 strains from soil samples originating from: Germany (11), Corsica (1), Portugal (3), Austria (3), Uruguay (1), England (2), Switzerland (3), Italy (3), Sardinia (1), and the Azores (1) (Kothe, 1987).

DNA G+C content (mol%): 73.0 (T_m).

Type strain: ATCC 15349, DSM 43149, NBRC 12512, JCM 3060, NRRL B-3345, VKM Ac-649.

Sequence accession no. (16S rRNA gene): AB037000.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes cosettensis* NBRC 14913^T, 98.8%; *Actinoplanes humidus* NBRC 14915^T, 98.8%; *Actinoplanes auranticolor* NBRC 12245^T, 98.7%.

12. **Actinoplanes durhamensis** Goodfellow, Stanton, Simpson and Minnikin 1990a, 320^{VP} (Effective publication: Goodfellow, Stanton, Simpson and Minnikin 1990b, 33.)

dur.ham.en′sis. N.L. masc. adj. *durhamensis* of or belonging to Durham, a city in the north-east of England.

Sporangia are globose; sporogenous hyphae are arranged irregularly within sporangia. Spores are motile.

Light to dark orange substrate mycelium is formed on modified Bennett's agar. Melanin is produced on ISP 7 medium.

Arbutin, casein, lecithin, and starch are degraded; L-arabinose, dextrin, D-fructose, D-galactose, D-glucose, *myo*-inositol, D-lactose, maltose, D-mannitol, D-mannose, melezitose, methyl β-D-glucoside, raffinose, L-rhamnose, D-sorbitol, D-xylose, and *p*-hydroxybenzoic acid are used as sole carbon sources, but not cellobiose, erythritol, catechol, coumarin, *o*-hydroxybenzoic acid, sodium fumarate, sodium succinate, syringaldehyde, syringic acid, or vanillin. Hydrogen sulfide and urease are not formed. Sensitive to a number of antibiotics and chemical inhibitors. Shows activity against *Staphylococcus aureus*. Grows between 4 and 30°C, but not at 37°C.

The peptidoglycan contains *meso*- and hydroxy-diaminopimelic acid. The principal cell-wall sugars are arabinose, galactose, glucose, mannose, and xylose. The organism contains a mixture of straight- and branched-chain fatty acids, with octadecanoic, 14-methylpentadecanoic, and 14-methylhexadecanoic acids predominating. Tetrahydrogenated menaquinones with nine isoprene units are the predominant isoprenologue, and major amounts of diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol are present.

Source: the type strain and four further strains were isolated from sediments of the River Derwent, Allensford, Durham, UK.

DNA G+C content (mol%): 70.8 (HPLC).

Type strain: ATCC 49800, DSM 43939, NBRC 14914, JCM 7625, LA 139, NCIB (NCIMB) 20041, NRRL B-16689.

Sequence accession no. (16S rRNA gene): AB037001.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes ferrugineus* NBRC 15555^T, 98.3%; *Actinoplanes digitatis* NBRC 12512^T, 97.7%.

13. **Actinoplanes ferrugineus** Palleroni 1979, 55^{AL}

fer.ru.gi′ne.us. L. masc. adj. *ferrugineus* of the color of iron rust.

Sporangia are globose to irregular, 4.0–12.0 µm in diameter, and develop on the surface of substrate mycelium. Abundant production of sporangia is observed on minimal media supplemented with single carbon sources like L-rhamnose, D-galactose, or D-fructose. Spores are spherical (0.9–1.0 µm), motile by means of a tuft of flagella. Rudimentary aerial mycelium may be formed on ISP medium 7.

Abundant growth occurs on various ISP agar media, Czapek-glucose, and potato-glucose agars. Colonies have flat to wrinkled surface, elevated in the center, and edges penetrating into the agar. Colors vary from amber to deep brown. On ISP 7 agar medium, a reddish-brown soluble pigment is produced.

Produces the proline analog L-azetidine-2-carboxylic acid.

Source: the type strain was isolated from a red soil sample collected at Dorrigo Mountain, Australia.

DNA G+C content (mol%): 70.5 (HPLC).

Type strain: ATCC 29868, DSM 43807, NBRC 15555, JCM 3277, NRRL B-16718, X-14695.

Sequence accession no. (16S rRNA gene): AB037002.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes tereljensis* MN07-A0371^T, 98.6; *Actinoplanes toevensis* MN07-A0368^T, 98.6%.

14. **Actinoplanes globisporus** (Thiemann 1967) Stackebrandt and Kroppenstedt 1988, 328^{VP} (Effectively published: Stackebrandt and Kroppenstedt 1987, 113.) (*Amorphosporangium globisporus* Thiemann 1967, 239)

glo.bi.spo′rus. L. n. *globus* a ball, sphere; Gr. n. *spora* a seed, and in biology a spore; N.L. masc. adj. *globisporus* round spored.

Sporangia (4.0–7.0 µm wide and 3.0–5.0 µm long) develop on short sporangiophores directly from the substrate mycelium, highly irregular in shape, resembling masses of spores not surrounded by a sporangial envelope. Spores are spherical, 0.8–1.0 µm, and motile (*fide* Palleroni, 1989). Production of chlamydospore-like structures is quite frequent.

Colors of the colonies vary from ivory, creamish, pale orange to orange.

Good growth occurs on Bennett's and Hickey–Tresner agars; moderate growth occurs on glucose asparagine, glycerol asparagine, oatmeal, starch, tyrosine, skim milk, and calcium malate agars. No growth is observed on Czapek, peptone iron, or cellulose agars. Grows on synthetic media only if supplemented with vitamin solution.

Source: the type strain was isolated from soil (Appiano Gentile, Como, Italy).

DNA G+C content (mol%): 70.2 (HPLC).

Type strain: ATCC 23056, DSM 43857, NBRC 13912, JCM 3186.

Sequence accession no. (16S rRNA gene): AB037003.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes deccanensis* NBRC 13994^T, 96.9%; *Actinoplanes ferrugineus* NBRC 15555^T, 96.5%.

15. **Actinoplanes humidus** Goodfellow, Stanton, Simpson and Minnikin 1990a, 320^{VP} (Effective publication: Goodfellow, Stanton, Simpson and Minnikin 1990b, 34.)

hu′mi.dus. L. masc. adj. *humidus* moist, damp, wet.

Abundant production of spherical sporangia; sporogenous hyphae are arranged irregularly within sporangia. Spores are motile.

Light to yellow-orange brown substrate mycelium is formed on modified Bennett's agar and a dark diffusible

pigment is produced on Bacto Tryptic soy agar supplemented with RNA.

Degrades arbutin, casein, DNA, elastin, lecithin, pectin, RNA, starch, and tyrosine. Utilizes D- and L-arabinose, dextrin, D-fructose, D-galactose, D-glucose, D-lactose, maltose, D-mannitol, D-mannose, methyl β-D-glucoside, D-sorbitol, D-xylose, *p*-hydroxybenzoic acid, sodium fumarate, and sodium succinate as sole carbon sources, but not cellobiose, erythritol, *myo*-inositol, catechol, coumarin, *m*- and *o*-hydroxybenzoic acid, syringaldehyde, syringic acid, or vanillin. Nitrate is reduced. Tolerant to a range of antibiotics and chemical inhibitors. Grows at 4 and 30°C, but not at 37°C.

Peptidoglycan contains *meso*- and hydroxy-diaminopimelic acid. The main cell-wall sugars are arabinose, galactose, mannose, and xylose. Contains complex mixtures of straight- and branched-chain fatty acids, with straight-chain components predominating. Tetrahydrogenated menaquinones with nine isoprene units are the predominant isoprenologue, and major amounts of diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and two uncharacterized glycolipids are present.

Source: the type strain and eight further strains were isolated from sediments of the River Derwent (Allensford, Durham, UK).

DNA G+C content (mol%): not known.

Type strain: ATCC 49801, DSM 43938, NBRC 14915, JCM 7555, LA 6, NCIB (now NCIMB) 20000, NRRL B-16690.

Sequence accession no. (16S rRNA gene): AB037004.

Additional comments: the type strain shows the highest sequence similarity to following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes cosettensis* NBRC 14913^T, 100.0%; *Actinoplanes digitatis* NBRC 12512^T, 98.8%.

16. **Actinoplanes italicus** Beretta 1973, 42^{AL}

i.ta′li.cus. L. masc. adj. *italicus* of or pertaining to Italy.

Sporangia are produced abundantly on starch (ISP 4) and skim milk agars, supported by straight sporangiophores arising from substrate mycelium. They are irregular in shape, varying from globose to oval and pyriform, 6.0–11.0 μm in diameter. Sporangiospores are spherical to oval, with a diameter of 1.0–2.0 μm, and highly motile.

Colonies on starch agar have a smooth surface and a dome-shaped center. Cherry-red substrate mycelium is produced on most media, but on ISP 2 and ISP 7 media (Shirling and Gottlieb, 1966), the color is orange; on Hickey–Tresner, Bennett's and nutrient agars, colonies are amber-brown to brown.

Production of a cherry-red soluble pigment is seen on oatmeal and starch agars; colors vary on other media from yellowish pink, rose, and amber to deep orange yellow. No pigment is produced on Bennett's, nutrient, or calcium-malate agar media.

Source: the type strain was isolated from a soil sample collected in an orchard at Pontelongo, Italy.

DNA G+C content (mol%): not known.

Type strain: A 5221, ATCC 27366, DSM 43146, NBRC 13911, JCM 3165, NRRL B-16722.

Sequence accession no. (16S rRNA gene): AB037005.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes couchii* GW8-1761^T, 99.2%; *Actinoplanes rectilineatus* NBRC 13941^T, 98.6%.

17. **Actinoplanes liguriensis** Wink, Kroppenstedt, Schuhmann, Seibert and Stackebrandt 2006, 2128^{VP} ("*Actinoplanes liguriae*" Parenti, Pagani and Beretta 1976, 505)

li.gu.ri.en′sis. N.L. masc. adj. *liguriensis* of or pertaining to the Italian region of Liguria.

Sporangia are globose to oval, 15.0–25.0 μm in diameter. Spore chains are coiled within the sporangia. Spherical motile spores (1.5–2.0 μm) with smooth surfaces are found. A rudimentary aerial mycelium is formed on ISP 6 medium. Abundant growth occurs on various agar media. Color of substrate mycelium is yellow-orange on ISP media 2, 3, 4, 5, 6, and 7. A yellow soluble pigment is produced on ISP media 4 and 5, and a red one on ISP 7.

Peptidoglycan contains *meso*-diaminopimelic acid; diagnostic sugars are xylose and arabinose. MK-9(H_4) and MK-10(H_4) are the principal menaquinones. The major phospholipid is phosphatidylethanolamine.

Produces the antibiotics gardimycin (Parenti and Coronelli, 1979) and Ala (*O*)-actagardine (Vértesy et al., 1999).

Source: the type strain was isolated from garden soil, Liguria region, Italy (Parenti et al., 1976).

DNA G+C content (mol%): not known.

Type strain: A/6353, ATCC 31048, BCRC 12121, CBS 355.75, DSM 43865, FH 2244, JCM 3250, KCC A-0250, NRRL B-16723.

Sequence accession no. (16S rRNA gene): AB047497.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes rectilineatus* NBRC 13941^T, 98.7%; *Actinoplanes regularis* NBRC 12514^T, 98.7%; *Actinoplanes palleronii* NBRC 14916^T, 98.5%.

18. **Actinoplanes lobatus** (Couch 1963) Stackebrandt and Kroppenstedt 1988, 328^{VP} (Effective publication: Stackebrandt and Kroppenstedt 1987, 113.) ["*Ampullaria lobata*" Couch 1963, 59; *Ampullariella lobata* (Couch 1963) Couch 1964, 29]

lo′ba.tus. N.L. masc. adj. *lobatus* lobed.

Strains have sporangia that vary in size and shape, are typically lobed and/or irregular, sometimes cylindrical, and are 4.0–20.0 × 12.0–23.0 μm. They often have a papillate appearance at the proximal end because of the varying length of the spore chains, which are arranged in parallel rows within the sporangia. The lobed sporangia sometimes are divided in several parts, giving the appearance of fused sporangia. Formation of sporangia occurs only on Czapek agar. The motile spores are rod-shaped (0.5–1.0 × 2.0–4.0 μm). Oval moniliform conidia may also be produced.

Colonies are up to 25 mm in diameter on Czapek agar or peptone Czapek agar and up to 10 mm on casein or tyrosine agars after 6 weeks' incubation. They are flattish or convoluted, and frequently ridged. The color of the substrate mycelium varies from coral red to dragon's blood red, jasper red, coral red, and brick red. Albino cultures may occur. On casein agar, the color is light coral red to

ferruginous. Soluble pale yellowish green pigments are produced on Czapek agar. Casein and tyrosine agars are slightly darkened. D-Mannitol and raffinose are utilized, but not inositol. Gelatin is liquefied.

Source: the type strain and a further strain were isolated from soil samples collected at Madison, Wisconsin, USA. Another isolate originated from pasture near Charleston, West Virginia, USA.

DNA G+C content (mol%): not known.

Type strain: ATCC 15350, DSM 43150, NBRC 12513, JCM 3061, NRRL B-3346, VKM Ac-676.

Sequence accession no. (16S rRNA gene): AB037006.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes sichuanensis* 03-723^{T}, 99.5%; *Actinoplanes campanulatus* NBRC 12511^{T}, 99.3%.

19. **Actinoplanes missouriensis** Couch 1963, 69^{AL}

mis.sou.ri.en′sis. N.L. masc. adj. *missouriensis* of or pertaining to the state of Missouri.

Sporangia are subglobose to globose, sometimes irregular, 6.0–14.0 µm in diameter. Spores are arranged in irregular coils within the sporangia, subspherical (1.0–1.2 µm), weakly motile by a tuft of polarly inserted flagella. Hyphae are less than 1.0 µm in diameter and branched. Production of palisade hyphae is rare.

Growth on Czapek agar is very good; colonies have an elevated center and flat border. Color is mostly ochraceous salmon, with whitish areas on the surface, where sporangia are abundant. Also, very good growth is observed on peptone Czapek agar (color zinc-orange to ochraceous orange). Production of sporangia is restricted to limited areas.

Produces the antibiotic 5-azacytidine.

Source: the type strain was isolated from soil collected near Hamilton, Missouri, USA. Members of the species also appeared in ten soil collections from the Mississippi Valley to the West Coast, USA.

DNA G+C content (mol%): not known.

Type strain: ATCC 14538, DSM 43046, NBRC 13243, JCM 3121, NBRC 102363, NRRL B-3342, UNCC 431.

Sequence accession no. (16S rRNA gene): AB037008.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes auranticolor* NBRC 12245^{T}, 99.2%; *Actinoplanes cosettensis* NBRC 14913^{T}, 98.6%; *Actinoplanes digitatis* NBRC 12512^{T}, 98.6%; *Actinoplanes humidus* NBRC 14915^{T}, 98.6%.

20. **Actinoplanes palleronii** Goodfellow, Stanton, Simpson and Minnikin 1990a, 320^{VP} (Effective publication: Goodfellow, Stanton, Simpson and Minnikin 1990b, 34.)

pal.le.ro′ni.i. N.L. gen. masc. n. *palleronii* of Palleroni, named after Noberto Palleroni, a distinguished taxonomist.

Sporangia are spherical; sporogenous hyphae are arranged irregularly within the sporangia. Spores are motile.

Light to yellow-brown substrate mycelium is formed on modified Bennett's agar. Melanoid pigments are produced on ISP 7 medium. Degrades arbutin, casein, lecithin, pectin, and starch; utilizes D-fructose, D-glucose, maltose, D-mannose, and D-xylose as sole carbon sources, but not D-arabinose, cellobiose, dextrin, erythritol, D-galactose, methyl β-D-glucoside, D-ribose, D-sorbitol, catechol, coumarin, *m*-, *o*- or *p*-hydroxybenzoic acid, sodium acetate, sodium fumarate, sodium succinate, syringaldehyde, syringic acid, or vanillin. Hydrogen sulfide and urease are not formed. Sensitive to potassium tellurite (0.005%, w/v), gentamicin sulfate (0.5%, w/v), and methacycline hypochloride (0.25%, w/v). Grows between 4 and 30°C, but not at 37°C.

The peptidoglycan contains *meso*- and hydroxy-diaminopimelic acid. The principal wall sugars are arabinose, galactose, glucose, rhamnose, ribose, and xylose. Contains complex mixtures of straight- and branched-chain fatty acids, with 12-methyltetradecanoic acid predominating. Tetrahydrogenated menaquinones with nine isoprene units are the predominant isoprenologue, and major amounts of diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol are present.

Source: the type strain and five further strains were isolated from sediments of the River Derwent at Allensford, Durham, UK.

DNA G+C content (mol%): not known.

Type strain: ATCC 49797, DSM 43940, NBRC 14916, JCM 7626, LA 83, NCIB (now NCIMB) 20021, NRRL B-16691.

Sequence accession no. (16S rRNA gene): AB037009.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes regularis* NBRC 12514^{T}, 99.4%; *Actinoplanes rectilineatus* NBRC 13941^{T}, 99.0%.

21. **Actinoplanes rectilineatus** Lechevalier and Lechevalier 1975, 371^{AL}

rec.ti.li.ne.a′tus. L. adj. *rectus* straight, upright; L. adj. *lineatus* striped, marked by fine parallel lines; N.L. masc. adj. *rectilineatus* marked with straight lines.

Sporangia are cylindrical, 8.0–15.0 µm, containing straight, longitudinally arranged rows of spores. Sporangiospores are globose, 1.5–2.0 µm in diameter, motile, and equipped with a polarly inserted tuft of about 30 flagella.

Color of the colonies vary from white, grayish tan, yellow-tan to yellow-brown (Lechevalier and Lechevalier, 1975), or pale, ochre, light-orange to orange (Kothe, 1987), depending on the agar medium used. White aerial mycelium is formed on some media. Grows between 10 and 37°C; abundant growth is observed at 23–28°C.

Source: the type strain was isolated from garden soil collected in Somerset, New Jersey, USA. The effective description (not validly published) of the species "*Actinoplanes penicillatus*" (Schäfer, 1973) was based on 15 strains, isolated from soil and characterized as having the same morphological features as *Actinoplanes rectilineatus.* The strains originated from Kenya (12), Australia (1, type strain), Corsica (1), and Spain (1).

DNA G+C content (mol%): 69 (T_m).

Type strain: ATCC 29234, DSM 43808, NBRC 13941, IMRU 3919, JCM 3194, NRRL B-16090, LL 7-10.

Sequence accession no. (16S rRNA gene): AB037010.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes couchii* GW8-1761^{T}, 98.9%; *Actinoplanes liguriensis* NBRC 13997^{T}, 98.7%.

22. **Actinoplanes regularis** (Couch 1963) Stackebrandt and Kroppenstedt 1988, 328[VP] (Effective publication: Stackebrandt and Kroppenstedt 1987, 113.) ["*Ampullaria regularis*" Couch 1963, 57; *Ampullariella regularis* (Couch 1963) Couch 1964, 29]

re.gu.la′ris. L. masc. adj. *regularis* regular.

Sporangia are mostly cylindrical, measuring 5.0–14.0 × 8.0–30.0 µm. The base of the sporangia is frequently mound shaped and resembles a corked bottle. Formation of sporangia occurs on Czapek and casein agars. Spores are arranged in parallel rows inside the sporangia, and are rod-shaped, 0.5–1.0 µm wide and 2.0–4.0 µm long, and motile by a polarly inserted tuft of flagella. Brushlike conidiophores may be produced on Czapek agar.

Good growth occurs on Czapek, peptone Czapek, casein, and tyrosine agars. Colonies are flat, frequently convoluted in the center with radial ridges on the margin. The color of the substrate mycelium is orange, red, brownish, ochre, or salmon to coral-pink, sometimes with white or gray areas on the surface, where the sporangia are produced. Soluble yellowish, greenish, or brownish (perhaps melanoid) pigments may be produced on various media.

Inositol, D-mannitol, and raffinose are not utilized by the type strain as sole carbon sources. Gelatin is liquefied.

Three strain variants are distinguishable on casein and tyrosine agars (Couch, 1963). The first variant utilizes casein and tyrosine and darkens both agars. The second variant utilizes casein and tyrosine, but darkens only the tyrosine agar. The third variant utilizes casein and tyrosine, but darkens only casein agar. The type strain of *Actinoplanes regularis* is from the first variant.

Source: the type strain was isolated from soil collected from a white pine grove, University of Wisconsin Arboretum, Madison, Wisconsin, USA. A further 28 strains were isolated, most from forest soils from North and South Carolina, Virginia, Mississippi, Wisconsin and Canada. D. Schäfer (Marburg, Germany) isolated a total of 26 strains from soil samples, originating from Germany (1), Kenya (3), Ceylon (1), Corsica (2), Tenerife (1), Austria (1), USA (3), Argentina (2), the Philippines (2), Taiwan (1), Uruguay (1), Cameroon (1), Mexico (1), France (2), the Azores (1), South Africa (1), and Yugoslavia (1) (Kothe, 1987).

DNA G+C content (mol%): 72.3 (Bd).

Type strain: CBS 193.64, DSM 43151, NBRC 12514, JCM 3062, NRRL B-3347, UNCC 65, VKM Ac-650.

Sequence accession no. (16S rRNA gene): AB037011.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes palleronii* NBRC 14916[T], 99.4%; *Actinoplanes rectilineatus* NBRC 13941[T], 98.9%.

23. **Actinoplanes sichuanensis** Sun, Dong, Zhang, Wei, Li, Yu, Klenk and Zhang 2009, 2766[VP]

si.chu.a.nen′sis. N.L. masc. adj. *sichuanensis* of or pertaining to Sichuan Province, southwest of China, soil of which was the source of the type strain.

Spherical sporangia are formed. The sporangiospores are motile and the surface is smooth. Aerial mycelium is absent. Color of substrate mycelium is cream to reddish orange on ISP 2, 3, 4, 5, 6, 7, yeast extract-starch agar, nutrient agar, Czapek solution agar, and modified Bennett's agar. Grows in the presence of 0–4% NaCl, but not in 5–10% NaCl. Growth occurs at initial pH of 6.5–10.5 and between 10 and 37°C, but not at pH 4.5–6.0 or at 40°C. Soluble pigments and melanin are not formed.

Esculin is hydrolyzed and nitrate is reduced to nitrite. Amylase and gelatinase are produced. H_2S is not produced. MK-9(H_4) (94.4%) is the predominant menaquinone, with MK-9(H_6) (3.7%) and MK-10(H_6) (1.9%) present as minor components. The major phospholipids are phosphatidylethanolamine and phosphatidylinositol. The predominant cellular fatty acids (>10%) are $C_{15:0}$ iso (22.2%), $C_{16:0}$ iso (15.3%) and *cis*-9-$C_{17:1}$ (11.1%); other fatty acids occurring in relatively small amounts (>5%) are $C_{14:0}$ (6.2%), $C_{16:0}$ (7.7%) and *cis*-9-$C_{18:1}$ (7.5%).

The organism is sensitive to filter-paper disks soaked in 1 ml of (µg/ml) erythromycin (15), gentamicin (10), and kanamycin (30), whereas it is resistant to ciprofloxacin (5), novobiocin (5), oxacillin (1), streptomycin (10), and tobramycin (10).

Source: the type strain was isolated from soil (Sichuan Province, China).

DNA G+C content (mol%): 70.4 (T_m).

Type strain: 03-723, CCM 7526, KCTC 19460.

Sequence accession no. (16S rRNA gene): EU531458.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes lobatus* NBRC 12513[T], 99.5%; *Actinoplanes philippinensis* NBRC 13878[T], 99.0%.

24. **Actinoplanes teichomyceticus** Wink, Kroppenstedt, Schuhmann, Seibert and Stackebrandt 2006, 2129[VP]

tei.cho.my.ce′ti.cus. Gr. n. *teichos* wall; Gr. n. *mukês -êtos* fungus; L. adj. suff. *-icus* suffix used with the sense of belonging to; N.L. masc. adj. *teichomyceticus* literally belonging to a fungus cell wall (referring to inhibition of cell-wall synthesis by teichomycin, produced by the type strain).

Spherical to oval sporangia (15.0–25.0 µm) are produced abundantly on many agar media, mainly on the dome of the colonies. Spores are highly motile, globose to oval, and 1.5–2.0 µm in diameter.

Abundant growth occurs on various agar media. Colonies may have a central protuberance or dome, and a smooth to wrinkled surface. Color of substrate mycelium may vary from beige on ISP media 5 and 6, pastel yellow on ISP media 2, 3, 4, and 7, and light orange on Bennett's and Czapek agars to deep orange on peptone glucose agar. On Hickey–Tresner, potato, and skim milk agars, it is light brownish to amber.

White aerial mycelium is produced on ISP 3 medium and Hickey–Tresner agar, rudimentary aerial mycelium with light pink or rose tinge is formed on Bennett's, Czapek glucose, and glycerol asparagine agars. A red-colored soluble pigment is formed on ISP medium 5, a yellow pigment on ISP media 4 and 5, and brown (melanoid) on ISP media 3 and 6.

Peptidoglycan contains *meso*-diaminopimelic acid; diagnostic sugars are xylose and arabinose; MK-9(H_4) and MK-10(H_4) are the principal menaquinones. Major phospholipid is phosphatidylethanolamine.

Produces the antibiotic teicoplanin RS-1 to RS-4, originally described as teichomycin A_1 and A_2 (Parenti et al., 1978).

Source: the type strain was isolated from a soil sample collected at Nimodi Village, Indore, India (Parenti et al., 1978).

DNA G+C content (mol%): not known.

Type strain: AB8327, ATCC 31121, BCRC 12106, DSM 43866, FH 2149, NBRC 13999, JCM 3252, KCC A-0252, NCIMB 12640, NRRL B-16726.

Sequence accession no. (16S rRNA gene): AB047513.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes liguriensis* NBRC 13997^T, 98.4%; *Actinoplanes palleronii* NBRC 14916^T, 98.3%. An earlier description of "*Actinoplanes teichomyceticus*" (Parenti, Beretta, Berti and Arioli 1978, 277) was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980) and therefore treated in *Bergey's Manual of Systematic Bacteriology* (1st edition) under "*Species incertae sedis*" (Palleroni, 1989). Both species descriptions are based on the same type strain.

25. **Actinoplanes tereljensis** Ara, Yamamura, Tsetseg, Daram and Ando 2010, 925^{VP}

te.rel.jen′sis. N.L. masc. adj. *tereljensis* of or pertaining to the Mongolian region of Terelj, where the type strain was isolated.

Numerous irregular sporangia are formed on the surface of water agar, ISP 3 and 4, and Bennett's agar media; spores are motile. Cells grow well on ISP 2, 3, and 7, Bennett's, and yeast extract-starch agars, forming well-developed, extensively branched, and non-fragmented substrate hyphae. Optimal growth is at 20–28°C; no growth occurs at 37°C. Growth pH is 6–9. Tolerates up to 3% NaCl. Color of substrate mycelium is moderate grayish brown to dark brownish red on different agar media. A pale pinkish brown soluble pigment produced on ISP 7 and aerial mycelium is not observed.

The menaquinone system consists of MK-9(H_6) (85%) with a minor amount of MK-9(H_8) (15%). The polar lipid profile contains diphosphatidylglycerol, phosphatidylethanolamine, phosphatidyl-*N*-methylethylethanolamine, and phosphatidylinositol; phosphatidylcholine and phosphatidylglycerol have not been detected (phospholipid type PII). Major fatty acid methyl esters are $C_{16:0}$ iso (19%), $C_{17:0}$ anteiso (15%), $C_{15:0}$ anteiso (12%), and $C_{15:0}$ iso (11%).

Source: the type strain was isolated from soil (Terelj, Mongolia).

DNA G+C content (mol%): 70.6 (HPLC).

Type strain: MN07-A0371, NBRC 105297, VTCC D9-010.

Sequence accession no. (16S rRNA gene): AB468944.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes toevensis* MN07-A0368^T, 99.7%; *Actinoplanes ferrugineus* NBRC 15555^T (AB037002), 98.6%.

26. **Actinoplanes toevensis** Ara, Yamamura, Tsetseg, Daram and Ando 2010, 924^{VP}

to.e.ven′sis. N.L. masc. adj. *toevensis* of or pertaining to the Mongolian region of Töv Province, where the type strain was isolated.

Numerous globose to oval sporangia are formed on the surface of water agar, ISP 3 and 4, and Bennett's agar media. Spores formed in the sporangium are motile. Cells grow well on ISP 2, 3, and 4, Bennett's, and yeast extract-starch agar, forming well-developed, extensively branched, and non-fragmented substrate hyphae. Aerial mycelium is not observed. Optimal growth is at 25–30°C; no growth occurs at 40°C. Growth pH is 6–11. Tolerates up to 2% NaCl. Color of substrate mycelium is moderate yellow brown to orange brown on different agar media. A pale pinkish brown soluble pigment is produced on ISP 7 agar.

The menaquinone system consists of MK-9(H_6) (97%) with a minor amount of MK-9(H_8) (3%). The polar lipid profile contains diphosphatidylglycerol, phosphatidylethanolamine, phosphatidyl-*N*-methylethylethanolamine, and phosphatidylinositol; phosphatidylcholine and phosphatidylglycerol have not been detected (phospholipid type PII). Major fatty acid methyl esters are $C_{17:0}$ anteiso (25%), $C_{16:0}$ iso (22%), $C_{15:0}$ iso (13%), and $C_{15:0}$ anteiso (12%).

Source: the type strain was isolated from soil (Töv Province, Mongolia).

DNA G+C content (mol%): 70.6 (HPLC).

Type strain: MN07-A0368, NBRC 105298, VTCC D9-011.

Sequence accession no. (16S rRNA gene): AB468943.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes tereljensis* MN07-A0371^T, 99.7%; *Actinoplanes ferrugineus* NBRC 15555^T, 98.6%.

27. **Actinoplanes utahensis** Couch 1963, 67^{AL}

u.tah.en′sis. N.L. masc. adj. *utahensis* of or pertaining to the state of Utah.

Sporangia are very irregular in size and shape, lobed, pyriform, club-shaped, or digitate, 5.0–18.0 µm in diameter. Spores are arranged in irregular coils within the sporangia, subglobose, 1.0–2.0 µm in diameter, motile by polarly inserted polytrichous flagella. Microspores may be produced on peptone Czapek agar.

Good growth occurs on Czapek, peptone Czapek, casein, and tyrosine agars. Colonies are convoluted or flat; surfaces are slippery moist with minute or conspicuous bumps. Sporangial development is sparse and only on Czapek, oatmeal, and starch-casein agars. Color of the substrate mycelium is apricot-orange to salmon-orange. On peptone Czapek agar, the color may become ferrugineus toward the center. Substrate mycelium on oatmeal agar is amber colored and on peptone Czapek agar is slightly darkened.

Produces cyclic peptide antibiotics.

Source: the type strain was isolated from soil taken from Liberty Park, Salt Lake City, Utah, USA, together with two isolates from distinct samples from the same site. A further isolate originated from a soil sample collected between Carlin and Dunphy, Nevada, USA.

DNA G+C content (mol%): 70 (T_m).

Type strain: ATCC 14539, DSM 43147, NBRC 13244, JCM 3122, NRRL B-16727, UNCC 260, VKM Ac-674.

Sequence accession no. (16S rRNA gene): AB037012.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes regularis* NBRC 12514^T, 98.7%; *Actinoplanes palleronii* NBRC 14916^T, 98.6%.

28. **Actinoplanes xinjiangensis** Sun, Dong, Zhang, Wei, Li, Yu, Klenk and Zhang 2009, 2767^{VP}

xin.ji.an.gen′sis. N.L. masc. adj. *xinjiangensis* of or pertaining to Xinjiang Uyghur Autonomous Region, north-west China, soil of which was the source of the type strain.

Spherical to oval sporangia are formed. The sporangiospores are motile and the surface is almost smooth. Aerial mycelium is absent.

Grows well on ISP 2, 3, 4, 5, and 7, yeast extract-starch agar, nutrient agar, Czapek solution agar, and modified Bennett's agar; grows moderately on ISP 6 agar. Grows in the presence of 0–7% NaCl. Growth occurs at an initial pH value of 6.5–8.5 and between 10 and 37°C.

Esculin is hydrolyzed and nitrate is reduced to nitrite. Amylase is not produced but gelatinase is produced. H_2S production is positive. Melanin is produced on ISP 6 agar, but soluble pigment is not formed.

MK-9(H_4) (96.1%) is the predominant menaquinone and MK-10(H_6) (3.9%) is present as a minor component. The major phospholipid is phosphatidylethanolamine. The predominant cellular fatty acids (>10%) are $C_{15:0}$ iso (10.8%), $C_{16:0}$ iso (16.0%) and *cis*-9-$C_{17:1}$ (21.5%); other fatty acids occurring in relatively small amounts (>5%) are $C_{15:0}$ (6.7%), $C_{16:0}$ (6.5%) and *cis*-9-$C_{16:1}$ (5.9%).

The organism is sensitive to filter-paper disks soaked in 1 ml of (µg/ml) kanamycin (30), but resistant to (1 ml; µg/ml) ciprofloxacin (5), erythromycin (15), gentamicin (10), novobiocin (5), oxacillin (1), streptomycin (10), and tobramycin (10).

Source: the type strain was isolated from soil from Xinjiang Uyghur Autonomous Region, north-west China.

DNA G+C content (mol%): 71.0 (T_m).

Type strain: 03-8772, CCM 7527, KCTC 19461.

Sequence accession no. (16S rRNA gene): EU531457.

Additional comments: the type strain shows the highest sequence similarity to the following *Actinoplanes* species (based on ~1470 nt): *Actinoplanes sichuanensis* 03-723^T, 99.0%; *Actinoplanes lobatus* NBRC 12513^T, 98.9%.

Species and subspecies *incertae sedis*

The following list contains species and subspecies of *Actinoplanes*, *Ampullariella*, and *Amorphosporangium* that are effectively, but not validly published.

1. **"Actinoplanes arizonaensis"** Karwowski, Jackson, Theriault, Prokop, Maus, Hansen and Hensey 1988, 1210

   Produces arizonins.

   Type strain: AB660-122, ATCC 49796, NBRC 14837, JCM 9648.

2. **"Actinoplanes awaijnensis"** Torikata and Enokita 1978 *in* Torikata, Enokita, Imai, Itoh, Nakajima, Haneishi and Arai (1978)

   Produces 5-azacytidine.

   Type strain: ATCC 33917, JCM 9334, SANK 90277.

3. **"Actinoplanes awaijnensis subsp. mycoplanecinus"** Torikata, Enokita, Okazaki, Nakajima, Iwado, Haneishi and Arai 1983, 959

   Produces mycoplanecins.

   Type strain: ATCC 33919, NBRC 14279, JCM 6112.

4. **"Actinoplanes coloradoensis"** Jackson, Karwowski, Theriault, Fernandes, Semon and Kohl 1987, 1381

   Produces coloradocin.

   Type strain: AB 921J-26.

5. **"Actinoplanes deccanensis subsp. azaserinus"** Torikata, Enokita, Imai, Itoh, Nakajima, Haneishi and Arai (1978)

   Produces azaserine.

   Type strain: ATCC 33916, JCM 9333.

6. **"Actinoplanes friuliensis"** Aretz, Meiwes, Seibert, Vobis and Wink 2000, 813

   Produces friulimycins.

   Type strain: DSM 7358, HAG 010964.

   Additional comment: strain HAG 010964 (= DSM 7358) is a patent strain (EP 0 629 636, Hoechst AG, 1994). This strain can be obtained from the DSMZ for scientific research by a special agreement. According to Rules 27(3) and 30, "*Actinoplanes friuliensis*" is not validly published because, at the time of publication, the type strain was not deposited in two publicly accessible service collections in different countries.

7. **"Actinoplanes garbadinensis"** Parenti, Pagani and Beretta 1976, 502

   Produces gardimycin.

   Type strain: ATCC 31049, NBRC 13995, Lepetit A/10889.

8. **"Actinoplanes ianthinogenes"** Coronelli, Pagani, Bardone and Lancini 1974, 161

   Produces purpuromycin.

   Type strain: ATCC 21884, NBRC 13996, Lepetit A/1668.

9. **"Actinoplanes ianthinogenes subsp. octamycini"** Gause and Sveshnikova 1979 *in* Gause, Sveshnikova, Maksimova and Olkhovatova 1979

   Produces purpuromycin and octamycin.

   Type strain: ATCC 43632, NBRC 14524, JCM 9649.

10. **"Actinoplanes nipponensis"** Routien 1977 *in* Celmer, Moppett, Cullen, Routien, Jefferson, Shibakawa and Tone 1977a

    Produces antibiotic 41012.

    Type strain: ATCC 31145, DSM 43867, NBRC 14063, JCM 3264.

11. **"Actinoplanes nirasakinensis"** Torikata, Enokita, Imai, Itoh, Nakajima, Haneishi and Arai 1978, 92

    Produces actinomycins.

    Type strain: ATCC 33918, JCM 9335.

12. **"Actinoplanes pallidoaurantiacus"** Ruan, Zhang and Jiang 1976, 297

    Type strain: DSM 46145, NBRC 13968, JCM 3242.

13. **"Actinoplanes penicillatus"** Schäfer 1973, 185

    Type strain: CBS 558.75, DSM 46142, SE 2.

    Additional comments: the species "*Actinoplanes penicillatus*" (type strain: SE 2^T), was described by Schäfer (1973), describing

the same morphological features as those described for *Actinoplanes rectilineatus* (type strain: 7-10). A second investigation of both type strains (7-10 and SE 2) concluded in the description of a novel subspecies "*Actinoplanes rectilineatus* subsp. *penicillatus*" (*ex* Schäfer) nov. (sic!) rev. comb. nov. (Kothe, 1987).

14. **"Actinoplanes purpeobrunneus"** Ruan and Jiang 1979, 236
Type strain: NBRC 14020, JCM 3253, A58.

15. **"Actinoplanes pyriformis"** Ruan and Jiang 1979, 236
Type strain: NBRC 14030, JCM 3262, A68.

16. **"Actinoplanes rectilineatus subsp. penicillatus"** Kothe 1987, 70
See: "*Actinoplanes penicillatus*".

17. **"Actinoplanes roseosporangius"** Ruan, Zhang and Jiang 1976, 292
Type strain: DSM 46143, NBRC 13969, JCM 3243, 71-C29.

18. **"Actinoplanes rutilosporangius"** Ruan, Zhang and Jiang 1976, 298
Type strain: DSM 46151, NBRC 13970, JCM 3244, 71-C6.

19. **"Actinoplanes sarveparensis"** Japanese Patent (Kokai) 53-2402, 1978
Produces antibiotic L 13365.
Type strain: Lepetit A/13826, DSM 43901, NBRC 13993.

20. **"Actinoplanes tuftoflagellus"** Ruan and Jiang 1979, 235
Type strain: NBRC 14021, JCM 3254, A5.

21. **"Actinoplanes violaceus"** Jiang, Xu and Ruan 1983a
Type strain: ATCC 43537, NBRC 14458, JCM 3353, Y80-610.

22. **"Actinoplanes yunnanensis"** Jiang, Xu and Ruan 1983b, 212
Type strain: ATCC 43538, NBRC 14459, JCM 3354, Y79-21.

23. **"Ampullariella kinshanensis"** Ruan and Zhang 1974, 35
Type strain: DSM 46147, NBRC 13661, JCM 3173, 71-C11.

24. **"Ampullariella kunmingensis"** Jiang, Xu and Ruan 1983b, 214
Type strain: ATCC 43539, JCM 3355, Y79-15.

25. **"Ampullariella regularis subsp. intermedia"** Nonomura, Iino and Hayakawa 1979, 84
Type strain: DSM 43898, NBRC 14065, JCM 3235.

26. **"Ampullariella regularis subsp. mannitophila"** Itoh, Enokita, Okazaki, Iwado, Torikata, Haneishi and Arai 1981, 930
Produces candiplanecin.
Type strain: ATCC 33986, JCM 9336.

27. **"Ampullariella violaceochromogenes"** Nonomura, Iino and Hayakawa 1979, 84
Type strain: DSM 43899, NBRC 14066, JCM 3236.

28. **"Amorphosporangium castaneum"** Jiang and Yan 1984
Type strain: ATCC 43631, DSM 43914, NBRC 14428, JCM 3341, B-133.

Genus IV. **Asanoa** Lee and Hah 2002, 970[VP]

The Editorial Board

As.a.n′a. N.L. fem. n. *Asanoa* named after Kozo Asano, the Japanese microbiologist who made the original description of the genus *Catellatospora*.

Weakly sporulating branched vegetative hyphae (0.3–0.4 µm in diameter). **Gram-stain-positive**. Nonmotile. **Aerobic**. Mesophilic. Cell wall contains diamino acids *meso*-diaminopimelic acid and 3-hydroxydiaminopimelic acid. Orange colony mass. Sporulation only occurs on tap-water agar and glycerol/calcium malate agar. Aerial mycelium and globose bodies are not observed. Possess a glycolylated peptidoglycan and whole-cell sugars of arabinose, rhamnose, ribose, xylose, galactose, mannose and glucose. Catalase-positive. Urease-negative. Nitrate is not reduced to nitrite. H_2S is not produced. Mycolic acids are not present. MK-10(H_6, H_8) are the major menaquinones. Polar lipid profile comprises phosphatidylethanolamine (a phospholipid type PII pattern). The fatty acid pattern is 2d type.

DNA G+C content (mol%): 69–71.5.

Type species: **Asanoa ferruginea** Lee and Hah 2002, 970[VP].

Further descriptive information

Phylogenetic analysis of the 16S rRNA gene positions the genus within the family *Micromonosporaceae*. The closest phylogenetic neighbor is *Micromonospora auratinigra* strain TT1-11 (97.8% sequence similarity, accession no. NR028659), which was isolated from a peat swamp forest in Thailand (Thawai et al., 2004b). An environmental clone with high 16S rRNA gene sequence similarity has been detected in cellulosic waste from a simulated low-level-radioactive-waste site (98.4 %, accession no. GQ263486) (Field et al., 2010).

Enrichment and isolation procedures

Asanoa ferruginea strain 6257-C[T] was isolated by a dilution method from woodland soil samples collected in Yamanashi, Japan (Asano and Kawamoto, 1986).

Maintenance procedures

Strains are cultivated on oatmeal agar (International *Streptomyces* Project, ISP, medium 3), inorganic salts/starch agar (ISP medium 4) and tap-water agar at 28°C for 21 d or on yeast extract/glucose broth for 3 d at 30°C. Stock cultures are maintained on yeast extract/malt extract agar (ISP medium 2) at 4°C or as a suspension in 20% (v/v) glycerol at −20°C (Asano and Kawamoto, 1986).

Differentiation of the genus *Asanoa* from closely related genera

Production of chains of nonmotile spores only from the vegetative mycelium differentiates *Asanoa* from phylogenetically related genera: *Micromonospora* produce single nonmotile spores on the vegetative hyphae (Luedemann, 1974); *Actinoplanes*, *Ampullariella*, *Amorphosporangiurn*, and *Pilimelia* form unique globose or cylindrical sporangia containing numerous motile spores (Couch, 1950, 1963, 1964); *Dactylosporangiurn* produce finger-shaped sporangia containing three to four motile spores arranged in a single row; and *Glycomyces* form chains of nonmotile spores on the aerial mycelium (Asano and Kawamoto, 1986). *Asanoa* possess major menaquinones MK-10(H_6, H_8), while members of the related genus *Catellatospora* have the major menaquinones MK-9(H_4, H_6) or MK-10(H_4).

List of species of the genus *Asanoa*

1. **Asanoa ferruginea** (Asano and Kawamoto 1986) Lee and Hah 2002, 970[VP] (Basonym: *Catellatospora ferruginea* Asano and Kawamoto 1986, 516.)

fer.ru.gi′ne.a. L. fem. adj. *ferruginea* rust-colored.

Growth occurs at mesophilic temperature. Does not grow on 3% NaCl or 0.01% lysozyme. Grows on 0.001% brilliant green and 0.0001% crystal violet. Antibiotic susceptibility (μg/ml): 50, gentamicin; 5, neomycin; and 100, streptomycin. Antibiotic resistance (μg/ml): 50, novobiocin; 20, vancomycin; and 10, tetracycline. Utilizes D-arabinose, L-arabinose, dextran, D-cellobiose, D-fructose, D-galactose, D-glucose, D-lactose, maltose, D-mannose, melibiose, methyl α-D-glucoside, D-raffinose, L-rhamnose, D-ribose, salicin, starch, sucrose, D-trehalose, D-xylose, adonitol, and D-mannitol. Does not utilize gluconate, inulin, D-melezitose, L-sorbose, dulcitol, butanol, *meso*-erythritol, ethanol, glycerol, *meso*-inositol, 2-propanol, 1-propanol, D-sorbitol, or D-xylitol. Hydrolyzes elastin and starch, but not casein, DNA, or gelatin. Does not decompose adenine, hippurate, hypoxanthine, DL-tyrosine, or xanthine. The phospholipid profile comprises diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannoside, phosphatidylethanolamine, phosphatidylglycerol, and an unknown phospholipid. The major fatty acids are $C_{15:0}$ anteiso (21%), $C_{17:0}$ (20%), $C_{16:0}$ iso (18%), $C_{17:1}$ (15%), and $C_{15:0}$ iso (10%) acids. Minor fatty acids are $C_{15:0}$ (5%), $C_{18:0}$ (4%), $C_{16:0}$ (3%), $C_{14:0}$ iso (2%), and $C_{17:0}$ iso (1%).

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 71.5 (HPLC).

Type strain: IMSNU 22009, NBRC 14496, DSM 44099.

Sequence accession no. (16S rRNA gene): AF152108.

2. **Asanoa iriomotensis** Tamura and Sakane 2005, 726[VP]

i.ri.o.mo.ten′sis. N.L. fem. adj. *iriomotensis* of or belonging to Iriomote Island, Okinawa, Japan, the origin of the soil sample from which the type strain was isolated.

Spore chains borne on the tip of short sporophores arising directly from the agar surface form on water agar and HV agar. Growth occurs optimally between 20 and 30°C; no growth at 15 or 37°C. Does not grow on 4% NaCl. Hydrolyzes starch. Does not reduce nitrate. Utilizes D-mannitol, D-melibiose, D-maltose, L-rhamnose, methyl α-D-glucoside, D-raffinose, D-galactose, D-mannose, and glucose. Does not utilize L-erythritol, adonitol, D-lactose, L-inositol, D-sorbitol, or dulcitol. Phosphatidylethanolamine is present as the diagnostic phospholipid. Unsaturated fatty acids and 10-methylated fatty acids are not detected. Major fatty acids are $C_{15:0}$ anteiso (22%), $C_{17:0}$ anteiso (20), $C_{15:0}$ iso (18%), $C_{17:0}$ (14%), and $C_{16:0}$ iso (12%). Minor fatty acids are $C_{17:0}$ iso, $C_{16:0}$, $C_{18:0}$, $C_{15:0}$, and $C_{14:0}$ iso.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 69.0 (HPLC).

Type strain: TT 97-02, NBRC 100142, DSM 44745.

3. **Asanoa ishikariensis** Lee and Hah 2002, 971[VP] (Basonym: '*Catellatospora ishikariense*'.)

ish.i.ka.ri.en′sis. N.L. fem. adj. *ishikariensis* of or belonging to Ishikari-gun, Hokkaido, Japan, the origin of the soil sample from which the type stain was isolated.

Growth occurs at mesophilic temperatures below 37°C. Grows on 0.001% Brilliant green, but not on 0.0001% crystal violet, 3% NaCl or 0.01% lysozyme. Antibiotic susceptiblity (μg/ml): 50, gentamicin; 5, neomycin; 100, streptomycin; and 10, tetracycline. Antibiotic resistance (μg/ml): 50, novobiocin and 20, vancomycin. Utilizes D-arabinose, L-arabinose, dextran, D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-lactose, maltose, D-mannose, melibiose, methyl α-D-glucoside, D-raffinose, L-rhamnose, D-ribose, starch, sucrose, D-trehalose, D-xylose, adonitol, dulcitol, and D-mannitol. Does not utilize inulin, D-melezitose, salicin, L-sorbose, butanol, *meso*-erythritol, ethanol, glycerol, *meso*-inositol, 2-propanol, 1-propanol, D-sorbitol, or D-xylitol. Hydrolyzes casein, gelatin and starch but not DNA or elastin. Does not decompose adenine, hippurate, hypoxanthine, DL-tyrosine, or xanthine. The phospholipid profile consists of diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannoside, phosphatidylethanolamine, and an unknown phospholipid. A trace amount of phosphatidylglycerol is also detected. The major fatty acids are $C_{15:0}$ anteiso (25%), $C_{17:1}$ (24%), $C_{15:0}$ iso (16%) and $C_{17:0}$ (12%) acids. Minor fatty acids are $C_{17:0}$ iso (6%), $C_{16:0}$ iso (4%), $C_{15:0}$ (3%), $C_{18:0}$ (2%), $C_{16:0}$ (1%), and $C_{19:0}$ (1%).

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 71.1 (HPLC).

Type strain: IMSNU 22004, NBRC 14551.

Sequence accession no. (16S rRNA gene): AJ294715.

Genus V. **Catellatospora** Asano and Kawamoto 1986, 516[VP] emend. Lee and Hah 2002, 971[VP] emend. Ara, Bakir and Kudo 2008a, 1958[VP]

Fred A. Rainey

Ca.tel.la.to.spo′ra. L. n. *catella* small chain; Gr. n. *spora* a seed and in biology a spore; N.L. fem. n. *Catellatospora* (organism forming) small chain of spores.

Gram-stain-positive, forming chains of nonmotile spores that arise singly or in tufts from vegetative hyphae. Vegetative hyphae are branched but not fragmented. Substrate mycelia are light yellow to bright yellow. Aerial mycelia are absent. **Aerobic** and **chemo-organotrophic**. **Mesophilic**. **Catalase-positive**. The diagnostic amino acids of the peptidoglycan are ***meso*-diaminopimelic acid** and 3-hydroxydiaminopimelic acids. The muramic acid *N*-acyl type is glycolyl. The cell-wall hydrolysates contain arabinose, galactose, ribose, mannose, glucose and xylose. Rhamnose is present in some species. Mycolic acids are not present. The major fatty acids are $C_{17:0}$, $C_{17:1}$ ω8*c*, $C_{15:0}$ iso and $C_{16:0}$ iso. The polar lipids can include phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylinositol and phosphatidylinositol mannosides. **Menaquinone MK-9(H_4)** is the major menaquinone. Species of the genus have been isolated from sandy and woodland soils from Japan and Bangladesh. Based on 16S rRNA gene sequence phylogeny the species of the genus form a distinct lineage within the family *Micromonosporaceae*.

DNA G+C content (mol%): 70.7–71.4.

Type species: **Catellatospora citrea** Asano and Kawamoto 1986, 516[VP].

List of species of the genus *Catellatospora*

1. **Catellatospora citrea** Asano and Kawamoto 1986, 516[VP]

cit′re.a. L. fem. adj. *citrea* of or pertaining to the citrus-tree, intended to mean lemon yellow.

Aerobic, Gram-stain-positive staining, short chains of nonmotile spores arise singly or in tufts from vegetative hyphae. Sporulation observed on Tyrosine agar, oatmeal agar, 1/5 yeast extract-starch agar, oatmeal-nitrate agar, tap-water agar and sucrose-nitrate agar. Yellow vegetative hyphae on oatmeal and Hickey–Tresner agar medium. Soluble or melanin-like pigments are not produced.

The cell-walls contain *meso*-diaminopimelic and 3-hydroxydiaminopimelic acids. The muramic acid *N*-acyl type is glycolyl. The cell-wall sugars are arabinose, galactose, rhamnose, ribose and xylose. Whole-cell fatty acids when grown at 30°C on yeast extract-starch broth include: $C_{15:0}$ (3.9%), $C_{16:0}$ (1.5%), $C_{17:0}$ (8.1%), $C_{18:0}$ (2.2%), $C_{16:1}$ 2-OH (5.5%), $C_{17:1}$ ω8*c* (7.8%), $C_{18:1}$ ω9*c* (2.2%), $C_{14:0}$ iso (2.4%), $C_{15:0}$ iso (28.4%), $C_{15:0}$ anteiso (5.3%), $C_{15:1}$ iso (2.6%), $C_{16:1}$ iso(1.8%), $C_{16:0}$ iso (10.5%), $C_{17:1}$ iso ω9*c* (1.4%), $C_{17:0}$ iso (3.3%), $C_{17:0}$ anteiso (4.3%), 10-methyl $C_{18:0}$ (1.0%) and summed feature 6 (1.5%) (Ara and Kudo, 2006). The polar lipid profile consists of phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides. MK-9(H_4) is the major menaquinone with minor amounts of MK-9(H_6). Growth occurs between 20 and 37°C, with optimal growth at 31°C. Growth occurs between pH 6 and 9. Growth does not occur in the presence of 1 % (w/v) NaCl. Negative for milk coagulation and peptonization. Gelatin is not liquefied. Substrates used as sole carbon sources include: L-arabinose, glycerol, lactose, D-galactose, D-glucose, maltose, D-mannose, α-D(+)-melibiose, methyl α-D-glucoside, L-rhamnose, salicin, starch, sucrose, trehalose, and D-xylose. Adonitol, erythritol, D-(+)-raffinose, are not used as sole carbon sources. Utilization of D- fructose, *myo*-inositol, D-mannitol and D- ribose has been reported as both positive and negative for the type strain. Sensitive to the following antibiotics: novobiocin (20 μg/ml), vancomycin (50 μg/ml), gentamicin (50 μg/ml), demethylchlortetracycline (500 μg/ml) and streptomycin (100 μg/ml). Growth occurs in the presence of crystal violet at 0.0001% (w/v) but not at 0.001% (w/v).

Isolated from woodland soil collected in Itsukaichi-shi Tokyo, Japan.

DNA G+C content (mol%): 71.5 (T_m).

Type strain: 6183-E, ATCC 49964, CIP 107011, DSM 44097, NBRC 14495, JCM 7542, NRRL B-16429, VKM Ac-1421.

Sequence accession no. (16S rRNA gene): X93197.

2. **Catellatospora bangladeshensis** Ara and Kudo 2006, 399[VP]

ban.gla.desh.en′sis. N.L. fem. adj. *bangladeshensis* of or pertaining to Bangladesh, the origin of the soil from which the type strain was isolated.

Aerobic, Gram-stain-positive staining, short chains of nonmotile spores arise singly or in tufts from vegetative hyphae. Spores are spherical to cylindrical; spore surface is smooth. Forms well developed branched substrate mycelium. Sporulation observed on sucrose-nitrate agar and oatmeal-nitrate agar. Light yellow to bright yellow substrate mycelium form on yeast extract starch agar. Soluble or melanin-like pigments are not produced. The cell-walls contain *meso*-diaminopimelic and 3-hydroxydiaminopimelic acids. The muramic acid *N*-acyl type is glycolyl. The cell-wall hydrolysates contain arabinose, galactose, rhamnose, ribose, mannose, glucose and xylose. Mycolic acids are not present. Whole-cell fatty acids when grown at 30°C on yeast extract-starch broth include: $C_{15:0}$ (1.7%), $C_{17:0}$ (3.1%), $C_{17:1}$ ω8*c* (8.8%), $C_{18:1}$ ω9*c* (3.0%), $C_{14:0}$ iso (5.2%), $C_{15:0}$ iso (19.8%), $C_{15:0}$ anteiso (2.5%), $C_{16:1}$ iso (3.7%), $C_{16:0}$ iso (35.4%), $C_{17:1}$ iso ω9*c* (1.8%), $C_{17:0}$ iso (2.8%), $C_{17:0}$ anteiso (2.0%), $C_{18:0}$ iso (1.2%), 10-methyl $C_{18:0}$ (2.3%), and summed feature 3 (1.2%). The polar lipid profile consists of phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides. Glucosamine containing phospholipids and phosphatidylcholine are absent. MK-9(H_4) is the major menaquinone with minor amounts of MK-9(H_6) and MK-9(H_2). Growth occurs between 25 and 30°C

and between pH 6.8 and 7.2. Growth does not occur in the presence of 1 % (w/v) NaCl. Substrates used as sole carbon sources include: L-arabinose, D-glucose, D-galactose, lactose, D-mannose, maltose, α-D(+)-melibiose, L-rhamnose, salicin, sucrose, trehalose, and D-xylose. Weakly positive utilization of adonitol, glycerol, and D-mannitol. Erythritol, D- fructose, *myo*-inositol, methyl α-D-glucoside, D-(+)-raffinose, and D- ribose are not used as sole carbon sources.

Isolated from sandy soil collected at Chokoria, Bandladesh.

DNA G+C content (mol%): 71.0 (HPLC).

Type strain: 2-70(23), JCM 12949, DSM 44899.

Sequence accession no. (16S rRNA gene): AB200233.

3. **Catellatospora chokoriensis** Ara and Kudo 2006, 397[VP]

cho.kor.i.en′sis. N.L. fem. adj. *chokoriensis* of or pertaining to Chokoria, Bangladesh, the origin of the soil from which the type strain was isolated.

Aerobic, Gram-stain-positive staining, short chains of spores are borne directly on substrate mycelium. Spores are spherical to cylindrical and nonmotile. Forms well developed branched substrate mycelium. Aerial mycelium is absent. Sporulation observed on glycerol-asparagine agar, tyrosine agar, yeast-malt extract agar, oatmeal agar, Bennett agar, water agar, sucrose-nitrate agar, 1/5 yeast-starch agar and oatmeal-nitrate agar. Light yellow to bright yellow substrate mycelium form on yeast extract starch agar. Soluble or melanin-like pigments are not produced. The cell-walls contain *meso*-diaminopimelic and 3-hydroxydiaminopimelic acids. The muramic acid *N*-acyl type is glycolyl. The cell-wall hydrolysates contain arabinose, galactose, rhamnose, ribose, mannose, glucose and xylose. Mycolic acids are not present. Whole-cell fatty acids when grown at 30°C on yeast extract-starch broth include: $C_{15:0}$ (2.2%), $C_{17:0}$ (10.9%), $C_{18:0}$ (4.3%), $C_{17:1}$ ω8*c* (3.5%), $C_{14:0}$ iso (3.6%), $C_{15:0}$ iso (30.3%), $C_{15:0}$ anteiso (6.3%), $C_{16:1}$ iso (2.5%), $C_{16:0}$ iso (22.9%), $C_{17:0}$ iso (5.5%), and $C_{17:0}$ anteiso (7.9%). The polar lipid profile consists of phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides. Glucosamine containing phospholipids and phosphatidylcholine are absent. MK-9(H_4) is the major menaquinone with minor amounts of MK-9(H_6) and MK-9(H_2). Growth occurs between 15 and 30°C, between pH 6.0 and 9.0, and in the presence of 1 % (w/v) NaCl. Substrates used as sole carbon sources include: L-arabinose, D-glucose, D-galactose, lactose, D-mannose, maltose, α-D(+)-melibiose, salicin, sucrose, trehalose, and D-xylose. Weakly positive utilization of adonitol. Erythritol, D- fructose, glycerol, *myo*-inositol, D-mannitol, methyl α- D-glucoside, D-(+)-raffinose, L-rhamnose, and D-ribose are not used as sole carbon sources.

Isolated from sandy soil collected at a forest-side waterfall, Chokoria, Bangladesh.

DNA G+C content (mol%): 71.0 (HPLC).

Type strain: 2-25(1), JCM 12950, DSM 44900.

Sequence accession no. (16S rRNA gene): AB200231.

4. **Catellatospora coxensis** Ara and Kudo 2006, 398[VP]

cox.en′sis. N.L. fem. adj. *coxensis* of or pertaining to Cox's Bazar, Bangladesh, the origin of the soil from which the type strain was isolated.

Aerobic, Gram-stain-positive staining, short chains of nonmotile spores arise singly or in tufts from vegetative hyphae. Spores are spherical to cylindrical and nonmotile. Forms well developed branched substrate mycelium. Aerial mycelium is absent. Sporulation observed on oatmeal agar, water agar, 1/5 yeast-starch agar and oatmeal-nitrate agar. Light yellow to bright yellow substrate mycelium form on yeast extract starch agar. Soluble or melanin-like pigments are not produced. The cell-walls contain *meso*-diaminopimelic and 3-hydroxydiaminopimelic acids. The muramic acid *N*-acyl type is glycolyl. The cell-wall hydrolysates contain arabinose, galactose, rhamnose, ribose, mannose, glucose and xylose. Mycolic acids are not present. Whole-cell fatty acids when grown at 30°C on yeast extract-starch broth include: $C_{15:0}$ (4.8%), $C_{16:0}$ (1.6%), $C_{17:0}$ (14.4%), $C_{18:0}$ (1.8%), $C_{19:0}$ (1.2%), $C_{17:1}$ ω8*c* (7.9%), %), $C_{18:1}$ ω9*c* (1.6%), $C_{14:0}$ iso (4.8%), $C_{15:0}$ iso (22.2%), $C_{15:0}$ anteiso (7.4%), $C_{16:0}$ iso (18.5%), $C_{17:0}$ iso (2.2%), and $C_{17:0}$ anteiso (4.5%). The polar lipid profile consists of phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides. Glucosamine containing phospholipids and phosphatidylcholine are absent. MK-9(H_4) is the major menaquinone with minor amounts of MK-9(H_6) and MK-9(H_2). Growth occurs between 20 and 30°C and between pH 6.0 and 9.0. Growth does not occur in the presence of 1 % (w/v) NaCl. Substrates used as sole carbon sources include: L-arabinose, D-glucose, D-galactose, glycerol, lactose, D-mannose, maltose, α-D(+)-melibiose, L-rhamnose, D-ribose, sucrose, trehalose, and D-xylose. Weakly positive utilization of D- fructose, and methyl α- D-glucoside. Adonitol, erythritol, *myo*-inositol, D-mannitol, D-(+)-raffinose, salicin, and are not used as sole carbon sources.

Isolated from sandy soil collected at a forest-side waterfall, Chokoria, Cox's Bazar, Bangladesh.

DNA G+C content (mol%): 71.0 (HPLC).

Type strain: 2-29(17), JCM 12951, DSM 44901.

Sequence accession no. (16S rRNA gene): AB200232.

5. **Catellatospora methionotrophica** (*ex* Asano and Kawamoto 1988) Ara and Kudo 2006, 399[VP] (*Catellatospora citrea* subsp. *methionotrophica* Asano and Kawamoto 1988)

me.thi.o.no.tro′phi.ca. N.L. n. *methioninum* methionine; Gr. adj. *trophikos* nursing, tending or feeding; N.L. fem. adj. *methionotrophica*, methionine auxotroph.

Aerobic, Gram-stain-positive staining, straight chains of smooth surfaced spores. Light yellow to bright yellow vegetative hyphae formed. Soluble or melanin-like pigments are not produced. Forms well developed, branched substrate mycelium. Aerial mycelium is absent. The cell-walls contain *meso*-diaminopimelic and 3-hydroxydiaminopimelic acids. The muramic acid *N*-acyl type is glycolyl. The cell-wall hydrolysates contain arabinose, xylose, galactose, ribose, mannose, and glucose. Mycolic acids are absent. Whole-cell fatty acids when grown at 30°C on yeast extract-starch broth include: $C_{15:0}$ (2.9%), $C_{16:0}$ (1.3%), $C_{17:0}$ (8.9%), $C_{18:0}$ (1.7%), $C_{16:1}$ 2-OH (1.4%), $C_{17:1}$ ω8*c* (9.3%), $C_{18:1}$ ω9*c* (2.9%), $C_{14:0}$ iso (1.4%), $C_{15:0}$ iso (37.6%), $C_{15:0}$ anteiso (7.5%), $C_{16:0}$ iso (5.7%), $C_{17:1}$ iso ω9*c* (3.2%), $C_{17:0}$ iso (4.5%), $C_{17:0}$ anteiso (5.0%) and summed feature 6 (1.4%). The polar lipid profile consists of phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol,

phosphatidylinositol mannosides. Glucosamine containing phospholipids and phosphatidylcholine are absent. MK-9(H_4) is the major menaquinone with minor amounts of MK-9(H_6) and MK-9(H_2). Growth occurs between 20 and 34°C and between pH 6.8 and 7.2. Growth does not occur in the presence of 1 % (w/v) NaCl. Negative for milk coagulation and peptonization. Gelatin is not liquefied. Requires methionine which cannot be replaced by cysteine or homoserine. Substrates used as sole carbon sources include: D-arabinose, L-arabinose, cellobiose, lactose, D-galactose, D-glucose, maltose, D-mannose, L-rhamnose, salicin, starch, sucrose, trehalose, and D-xylose. Weakly positive utilization of erythritol, glycerol, D-fructose, methyl α-D-glucoside and D-(+)-raffinose. Adonitol, ethanol, gluconate, D-mannitol, melezitose, melibiose, α-D(+)-melibiose, methanol, methyl α-D-glucoside, D- ribose and sorbitol are not used as sole carbon sources. Sensitive to the following antibiotics: novobiocin (50 μg/ml), vancomycin (50 μg/ml), gentamicin (50 μg/ml), demethylchlortetracycline (500 μg/ml) and streptomycin (100 μg/ml). Growth occurs in the presence of crystal violet at 0.0001% (w/v) but not at 0.001% (w/v).

Isolated from a woodland soil sample collected in Yamanashi, Japan.

DNA G+C content (mol%): 71.0 (HPLC).

Type strain: 6257-B, ATCC 49965, CIP 107012, NBRC 14553, NRRL B-16431, VKM Ac-2008, IMSNU 22006, JCM 7543, DSM 44098.

Sequence accession no. (16S rRNA gene): AF152107.

Genus VI. **Catenuloplanes** Yokota, Tamura, Hasegawa and Huang 1993, 809[VP]

THE EDITORIAL BOARD

Ca.te.nul.o.plan′es. L. fem. n. *catenula* short chain; Gr. masc. n. *planes* a wanderer; N.L. masc. n. *Catenuloplanes* a short chain wanderer; intended to signify a motile short chain.

Gram-stain-positive. Not acid-fast. **Strictly aerobic**. **Forms branching and non-fragmenting vegetative hyphae**. Aerial mycelium is rudimentarily developed or absent. If produced, spores are arranged in chains, which arise from the vegetative hyphae or are formed on the rudimentary aerial hyphae. The spore chains are aggregated into clusters and may be enveloped by outer sheaths. The configuration of spore chains is curly or spiral with one or two turns and sometimes branched, The spores are rod-shaped, straight or curved (0.6–0.8 × 2–4 μm) with smooth surfaces, and motile by means of peritrichous flagella. **Cell-wall type is VI and the peptidoglycan contains D-glutamate**, **D-serine**, **L-serine, glycine**, **D-alanine, and L-lysine**. **Cell-wall sugars are mannose, xylose, ribose and glucose**. The muramic acid in the glycan moiety is N-glycolated. The Mycolic acids are absent. Major menaquinones are MK-10(H_4) and MK-11(H_4); some strains may also possess small amounts of MK-10, MK-10(H_2), MK-10(H_8), MK-10(H_6), MK-11(H_2) and MK-11(H_6). The major cellular fatty acids are $C_{18:1}$, $C_{16:0}$, and $C_{17:0}$ anteiso. Small amounts of $C_{17:0}$, $C_{16:1}$, $C_{16:0}$ iso, and $C_{18:0}$ may also be present. The diagnostic phospholipid is phosphatidylcholine.

DNA G+C content (mol%): 70.0–72.0.

Type species: **Catenuloplanes japonicas** Yokota, Tamura, Hasegawa and Huang 1993, 810[VP].

Further descriptive information

Phylogenetic analysis of the 16S rRNA gene classifies the genus within family *Micromonosporaceae.* The closest phylogenetic neighbor is *Asanoa iriomotensis* (97.3%, accession no. AB112081).

Enrichment and isolation procedures

Isolated from soil or leaf litter in Japan, India, and Nepal. Many strains were isolated on a medium containing 1.0% soluble starch, 0.1% casein, 0.05% K_2HPO_4, and 1.5% agar (pH 7.0–7.5) supplemented with (per ml) 25 μg nalidixic acid, 12.5 μg kanamycin, 5.0 μg cefsulodin, and 6.25 μg kabicidin (Yokota et al., 1993).

Maintenance procedures

Strains are cultivated on yeast extract/starch agar containing 2 g yeast extract (Difco), 10 g soluble starch and 15 g agar per l distilled water (pH 7.3) at 28°C for 14 d and maintained at 8°C.

Differentiation of the genus *Catenuloplanes* from closely related genera

Spore motility differentiates *Catenuloplanes* from closely related genera with nonmotile spores: *Actinocatenispora*, *Asanoa*, *Catellatospora*, *Krasilinkovia*, *Longispora*, *Luedemannella*, *Micromonospora*, *Polymorphospora*, *Salinispora*, and *Verrucosispora*. Sporangia or spore vesicles are absent in *Catenuloplanes*, but are present in *Actinoplanes*, *Dactylosporangium*, *Luedemannella*, *Pilimelia*, *Virgisporangium*, and *Planosporangium*. Within the family, only *Catenuloplanes* and *Couchioplanes* contain the diamino acid L-Lys in their cell walls. All other genera contain *m*-DAP. *Catenuloplanes* is differentiated from *Couchioplanes* by phospholipid type (III and II, respectively) and major menaquinones [MK-10(H_4) and MK-11(H_4) versus MK-9(H_4), respectively].

Taxonomic comments

Planopolyspora crispa was described nearly simultaneously with *Catenuloplanes japonicas* (Petrolini et al., 1993; Yokota et al., 1993). Because the name *Catenuloplanes japonicas* was validated first, it has priority, and *Planopolyspora crispa* was transferred to the genus *Catenuloplanes* as *Catenuloplanes crispus* by Kudo et al. (1999).

List of species of the genus *Catenuloplanes*

1. **Catenuloplanes japonicus** Yokota, Tamura, Hasegawa and Huang 1993, 810[VP]

ja.pon'i.cus. N.L. masc. adj. *japonicus* of or pertaining to Japan.

Vegetative mycelia of the strains are pale orange to orange yellow, and the aerial mycelia are white to pale yellow. They produce a pale yellowish soluble pigment on Czapek-sucrose agar, glucose-asparagine agar, and calcium malate agar. H_2S is produced. Nitrate is not reduced to nitrite. Gelatin liquefaction is positive. Hydrolyzes starch, but not hippurate. Decomposes calcium malate, tyrosine, esculin, and urea, but not adenine, xanthine, hypoxanthine, or cellulose. Susceptible to lysozyme. Milk is coagulated and peptonized. Utilizes acetate, lactate, malate, pyruvate, succinate, L-arabinose, cellobiose, fructose, galactose, glucose, glycerol, inositol, lactose, maltose, mannitol, melezitose, melibiose, α-methyl-D-glucoside, raffinose, L-ribose, salicin, starch, sucrose, trehalose, and D-xylose. Does not utilize benzoate, citrate, mucate, oxalate, ribitol, galactitol, L-erythritol, sorbitol, or L-sorbose. Growth occurs optimally at 21–28°C. Major fatty acids are $C_{18:1}$, $C_{16:0}$ and $C_{17:0}$ anteiso.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 71.0 (HPLC).

Type strain: N381-16, NBRC 14176, ATCC 31637, DSM 44102, JCM 9106, VKM Ac-875.

Sequence accession no. (16S rRNA gene): X93201.

2. **Catenuloplanes crispus** Kudo, Nakajima and Suzuki 1999, 1858[VP]

cris'pus. L. masc. adj. *crispus* curly.

Yellow to brown vegetative mycelia on most media. Yellowish diffusible pigment is produced in glycerol/asparagine agar. Decomposes casein, elastin, esculin, testosterone, and urea, but not adenine, DNA, hypoxanthine, tyrosine, or xanthine. Utilizes L-arabinose, D-cellobiose, D-fructose, D-galactose, D-glucose, glycerol, *myo*-inositol, D-lactose, maltose, D-mannitol, D-mannose, L-rhamnose, salicin, starch, sucrose, D-trehalose, D-xylose, fumarate, L-malate, and succinate. Does not utilize adonitol, dulcitol, iso-erythritol, D-melezitose, methyl-α-D-glucoside, D-raffinose, citrate, mucate, benzoate, oxalate, or L-tartrate. Acids produced from L-arabinose, D-fructose, D-galactose, D-glucose, *myo*-inositol, L-rhamnose, sucrose and D-xylose, but not from D-melezitose, melibiose, methyl α-D-glucoside, D-raffinose, D-ribose or L-sorbose. No growth in the presence of 2% NaCl. Antibiotic susceptibility (20 μg/ml): ampicillin, benzylpenicillin, cephalexin, novobiocin, and kanamycin.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 70.0 (HPLC).

Type strain: JCM 9312, ATCC 51431, DSM 44128, NBRC 15622, IPV 2867, NCB 1173, VKM Ac-1992.

Sequence accession no. (16S rRNA gene): AB024701.

3. **Catenuloplanes niger** Tamura, Yokota, Huang, Hasegawa and Hatano 1995, 860[VP]

ni'ger. L. masc. adj. *niger* black, referring to the production of a black soluble pigment.

The morphological, physiological, and chemotaxonomic characteristics are the same as those given previously for *Catenuloplanes japonicus*. Additionally, *Catenuloplanes niger* grows at 37°C and produces a black soluble pigment in peptone-yeast extract-iron agar (ISP medium 6) and nutrient agar, but does not produce any pigment in inorganic salts-starch agar (ISP medium 4). Resistant to penicillin, cephaloridine, cephalexin, and benzylpenicillin.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 72.2 (HPLC).

Type strain: N406-14, NBRC 14177, ATCC 31638, DSM 44711, JCM 9533, VKM Ac-1964.

Sequence accession no. (16S rRNA gene): AB523881.

4. **Catenuloplanes indicus** Tamura, Yokota, Huang, Hasegawa and Hatano 1995, 860[VP]

in'di.cus. L. masc. adj. *indicus*, of or pertaining to India, where the organism was isolated.

The morphological, physiological, and chemotaxonomic characteristics are the same as those given previously for *Catenuloplanes japonicus*. Additionally, *Catenuloplanes indicus* grows at 37°C and does not produce any soluble pigment in inorganic salts-starch agar (ISP medium 4), tyrosine agar (ISP medium 7), Bennett agar, and Bennett agar containing maltose. Susceptible to penicillin, cephaloridine, cephalexin, and benzylpenicillin.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 71.3–71.9 (HPLC).

Type strain: RA328^T, NBRC 15575, IMSNU 22099, ATCC 700014, DSM 44709, JCM 9534, VKM Ac-1999.

Sequence accession no. (16S rRNA gene): AJ294717.

5. **Catenuloplanes atrovinosus** Tamura, Yokota, Huang, Hasegawa and Hatano 1995, 860[VP]

at.ro.vi.no'sus. L. adj. *ater -tra -trum* dark; L. masc. adj. *vinosus* full of wine; N.L. masc. adj. *atrovinosus*, full of dark wine, dark wine color (red).

The morphological, physiological, and chemotaxonomic characteristics are the same as those given previously for *Catenuloplanes japonicus*. Additionly, *Catenuloplanes atrovinosus* grows at 37°C and produces a black soluble pigment in peptone-yeast extract-iron agar (ISP medium 6) and a pale brown soluble pigment in nutrient agar, but does not produce any soluble pigment in Bennett agar and Bennett agar containing maltose. It forms reddish colonies on inorganic salts-starch agar (ISP medium 4) and glycerol-asparagine agar (ISP medium 5). Galactose, mannose, xylose, and glucose are present as whole-cell sugars. Resistant to penicillin, cephaloridine, cephalexin, and benzylpenicillin.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 72.2–72.7 (HPLC).

Type strain: RA332^T, NBRC 15579, IMSNU 22012, ATCC 700015, DSM 44707, JCM 9535, VKM Ac-1972.

Sequence accession no. (16S rRNA gene): AJ294716.

6. **Catenuloplanes castaneus** Tamura, Yokota, Huang, Hasegawa and Hatano 1995, 860[VP]

cas.ta'ne.us. L. masc. adj. *castaneus* chestnut-colored.

The morphological, physiological, and chemotaxonomic characteristics are the same as those given previously for *Catenuloplanes japonicus*. Additionally, *Catenuloplanes castaneus*

grows at 37°C and produces a scarlet soluble pigment in glycerol-asparagine agar (ISP medium 5), but does not produce any soluble pigments in inorganic salts-starch agar (ISP medium 4), tyrosine agar (ISP medium 7), and Bennett agar. Resistant to penicillin and benzylpenicillin, but susceptible to cephaloridine and cephalexin.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 72.0–72.4 (HPLC).

Type strain: RA344, NBRC 15584, ATCC 700016, DSM 44708, JCM 9537, VKM Ac-1973.

Sequence accession no. (16S rRNA gene): AB523883.

7. **Catenuloplanes nepalensis** Tamura, Yokota, Huang, Hasegawa and Hatano 1995, 860[VP]

ne.pal.en′sis. N.L. masc. adj. *nepalensis* of or pertaining to Nepal, where the organisms were isolated.

The morphological, physiological, and chemotaxonomic characteristics are the same as those given previously for *Catenuloplanes japonicus*. In addition, *Catenuloplanes nepalensis* does not produce a soluble pigment in inorganic salts-starch agar (ISP medium 4), tyrosine agar (ISP medium 7), Bennett agar, and Bennett agar containing maltose. Resistant to penicillin, cephaloridine, and benzylpenicillin, but susceptible to cephalexin.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 71.1 (HPLC).

Type strain: RA343, NBRC 15583, ATCC 700017, DSM 44710, JCM 9536, VKM Ac-1996.

Sequence accession no. (16S rRNA gene): AB523882.

Genus VII. **Couchioplanes** Tamura, Nakagaito, Nishii, Hasegawa, Stackebrandt and Yokota 1994, 199[VP]

Tomohiko Tamura

Couch.i.o.pla′nes. N.L. masc. n. *Couchius* a personal name, referring to J.N. Couch (1896–1986), a mycologist who contributed to the taxonomy of the family *Actinoplanaceae*; Gr. masc. n. *planes* a wanderer; N.L. masc. n. *Couchioplanes* a wanderer organism of the family *Actinoplanaceae* named after J.N. Couch.

Gram-stain-positive bacterium producing fine, nonfragmenting, branching mycelia. Not acid-fast. Strictly aerobic. The spore chains and aerial mycelia often **aggregate into clusters resembling sporangia**, but true sporangia are not observed (Figure 214, Figure 215, Figure 216 and Figure 217). Aerial mycelia with short spore chains are **arranged in spirals** that have one to five turns and are hooked or rarely flexuous (Figure 214). Several spores are present per spore chain, and the spores are **oval to short rods** (0.5–0.9 × 1.0–1.5 µm) and smooth. Upon immersion in water or phosphate buffer including soil extract, **motile spores** are released from the spore chain, but in many instances motility begins over 30–60 min after spore release. **Polar flagella** are present in motile spores (Figure 217). Cell wall contains D-**glutamic acid**, D- **and** L-**serine, glycine**, L-**alanine, and** L-**lysine** (molar ratio approx. 1:1:1:1:1). Xylose, arabinose, and galactose are present in whole-cell hydrolysates. Phosphatidylglycerol and phosphatidylethanolamine are present, but phosphatidylcholine is absent. $C_{16:0}$ iso and $C_{17:0}$ anteiso are the major cellular fatty acids. The major menaquinone is MK-9(H_4); in addition, small amounts of MK-9(H_6), MK-9(H_8), and MK-9(H_2) are also present. The acyl type of the cell-wall polysaccharides is glycolyl. Mycolic acid is absent.

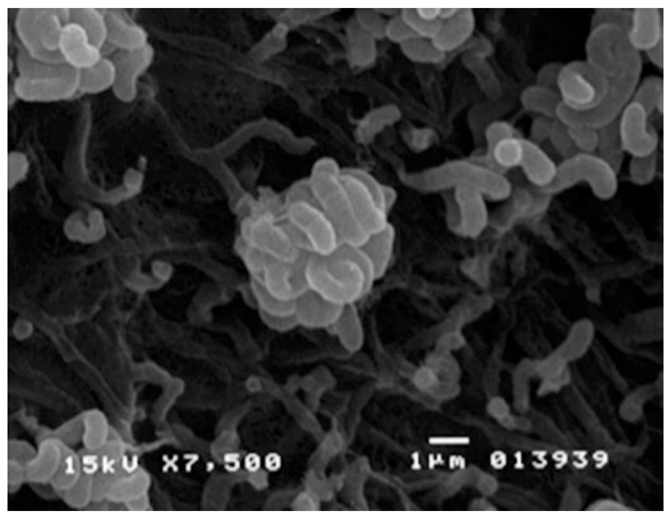

FIGURE 215. Scanning electron micrograph of *Couchioplanes caeruleus* subsp. *caeruleus* showing spore-chain clusters. Bar = 1 µm.

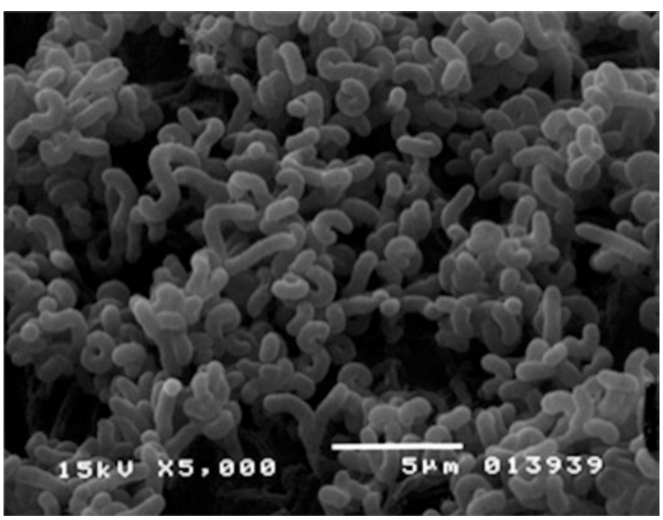

FIGURE 214. Scanning electron micrograph of *Couchioplanes caeruleus* subsp. *caeruleus* showing spiral, hook and/or rarely flexuous spore-chain forms. Bar = 5 µm.

DNA G+C content (mol%): 70–72 (HPLC).

Type species: **Couchioplanes caeruleus** (Horan and Brodsky 1986a) Tamura, Nakagaito, Nishii, Hasegawa, Stackebrandt and Yokota 1994, 200[VP] (*Actinoplanes caeruleus* Horan and Brodsky 1986a, 189).

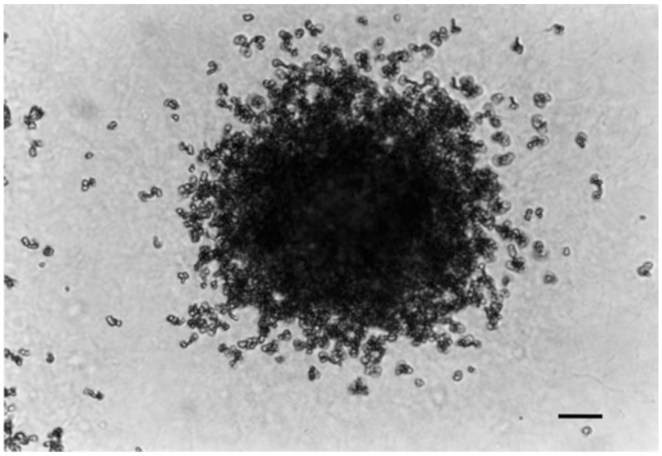

FIGURE 216. Light micrograph of the colony of *Couchioplanes caeruleus* subsp. *caeruleus*. Spore-chain cluster and aerial mycelium look like a sporangium. Bar = 10 µm.

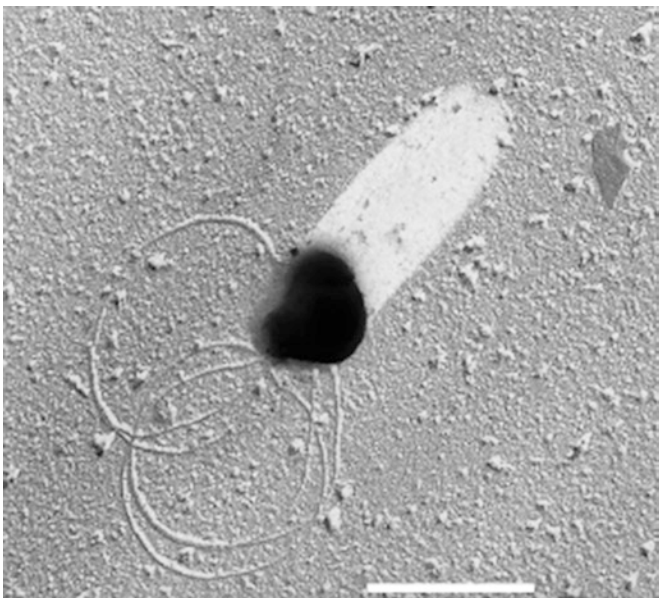

FIGURE 217. Transmission electron micrograph of a shadowing motile spore of *Couchioplanes caeruleus* subsp. *caeruleus* showing the polar flagellum. Bar = 1.0 µm.

Further descriptive information

In general, the vegetative mycelia of the strains are pale to yellowish orange in young cultures and change to a dark blue color in mature cultures. The aerial mycelia are white to gray. The zoospore exhibits active motility after incubation at 28°C for 1 h in 0.01 M phosphate buffer (pH 7.0) containing 10% soil extract. Using light microscopy (Figure 216), the physical appearance of spore chains and aerial mycelia may look like the sporangia of the genus *Actinoplanes*.

Good growth occurs at temperatures between 22 and 28°C. Grows well on yeast extract-malt extract agar, inorganic salts-starch agar, glycerol-asparagine agar, and Bennett's agar. Cultures grow well in yeast extract-glucose broth, consisting of yeast extract (1%) and D-glucose (1%) (pH 7.0), at 28°C on a rotary shaker for 4 d.

The wall chemotype is type VI according to the classification of Lechevalier and Lechevalier (1970a), and the peptidoglycan type is type A (most probably type A3α) according to the classification of Schleifer and Kandler (1972).

Enrichment and isolation procedures

The currently known strains of *Couchioplanes* have been isolated from soil. Generally, the enrichment and isolation methods for actinomycetes producing motile spores, such as centrifuge and capillary methods, may be applicable for strains of the genus *Couchioplanes*.

Maintenance procedures

Strains of the genus *Couchioplanes* are maintained by freezing in water containing 10–30% glycerol at −70°C. Lyophilization of suspensions in 10% skim milk +1% monosodium glutamate and L-drying in 0.01 M potassium phosphate buffer (pH 7.0) containing 3% monosodium glutamate (Sakane and Kuroshima, 1997) are also recommended for long-term preservation.

Differentiation of the genus *Couchioplanes* from other genera

The genera *Couchioplanes* and *Catenuloplanes* differ from other genera of the family *Micromonosporaceae* because their cell-wall peptidoglycan contains L-lysine instead of *meso*-diaminopimelate. These genera are also similar in the formation of motile arthrospores. However, the arthrospores of the genus *Couchioplanes* are oval to short rods with polar flagella, whereas the *Catenuloplanes* arthrospores are rods with peritrichous flagella. The genera *Couchioplanes* and *Catenuloplanes* also differ in their menaquinone systems [MK-9(H_4) vs MK-9(H_8), MK-10(H_8)], phospholipid types (PII vs PIII), and cellular fatty acids ($C_{16:0}$ iso and $C_{17:0}$ anteiso vs $C_{18:1}$, $C_{16:0}$ and $C_{17:0}$ anteiso) (Yokota et al., 1993).

Taxonomic comments

Although *Couchioplanes caeruleus* differs from other species of the genus *Actinoplanes* by forming a deep blue pigment in the vegetative mycelia, by the absence of diaminopimelic acid in its cell wall, by its ability to hydrolyze adenine and hypoxanthine, by its resistance to lysozyme, and by its inability to utilize L-arabinose, D-xylose, and succinate as sole carbon sources, Horan and Brodsky (1986a) included this organism in the genus *Actinoplanes* for the following reasons. It formed irregular to globose sporangia, which upon wetting released spherical to oval motile spores that were partially flagellated, and arabinose and xylose were present as diagnostic whole-cell sugars. However, Stackebrandt and Kroppenstedt (1987) reported that this organism should not be included in the genus *Actinoplanes* because of its peptidoglycan type. The results of numerical taxonomy studies of the genus *Actinoplanes* performed by Goodfellow et al. (1990b) also supported this conclusion.

Based on 16S rRNA gene sequence analysis, the closest neighbor of the genus *Couchioplanes* is the genus *Actinoplanes*, both of which belong to the family *Micromonosporaceae* of the order *Micromonosporales*.

List of species of the genus *Couchioplanes*

1. **Couchioplanes caeruleus** (Horan and Brodsky 1986a) Tamura, Nakagaito, Nishii, Hasegawa, Stackebrandt and Yokota 1994, 200[VP] (*Actinoplanes caeruleus* Horan and Brodsky 1986a, 189)

ca.e.ru′le.us. L. masc. adj. *caeruleus* dark blue, referring to the blue vegetative mycelial pigment.

A yellow to pale brownish soluble pigment is produced on peptone-yeast extract-iron agar. Hydrogen sulfide is produced. Reduces nitrate to nitrite. Gelatin liquefaction is positive. Hydrolyzes starch. Does not decompose calcium malate. Does not coagulate milk. Fructose, glucose, inositol, and sucrose are utilized as carbon sources, but arabinose, raffinose, and xylose are not.

Source: soil.

DNA G+C content (mol%): 70–72 (HPLC).

Type strain: SCC 1014, ATCC 33937, DSM 43634, NBRC 13939, JCM 3195, NRRL 5325, VKM Ac-1257.

Sequence accession no. (16S rRNA gene): D85479.

The species has subsequently been divided into subspecies.

1a. **Couchioplanes caeruleus subsp. caeruleus** (Horan and Brodsky 1986a) Tamura, Nakagaito, Nishii, Hasegawa, Stackebrandt and Yokota 1994, 201[VP] (*Actinoplanes caeruleus* Horan and Brodsky 1986a, 189)

A yellow to pale brownish soluble pigment is produced on glycerol-asparagine agar and glucose-asparagine agar, but this pigment is not produced on yeast extract-malt extract agar. Rhamnose and mannitol are utilized as carbon sources. A novel heptaene antifungal antibiotic is produced (Wagman et al., 1975), which has a broad spectrum of activity against pathogenic fungi (Wright et al., 1977). No growth occurs in the presence of 2% NaCl.

Source: soil.

DNA G+C content (mol%): 70 (HPLC).

Type strain: SCC 1014, ATCC 33937, DSM 43634, NBRC 13939, JCM 3195, NRRL 5325, VKM Ac-1257.

Sequence accession no. (16S rRNA gene): D85479.

1b. **Couchioplanes caeruleus subsp. azureus** Tamura, Nakagaito, Nishii, Hasegawa, Stackebrandt and Yokota 1994, 201[VP]

a.zu′re.us. N.L. masc. adj. *azureus* azure blue, referring to the blue vegetative mycelial pigment.

A yellow to pale brownish soluble pigment is produced on yeast extract-malt extract agar, but this pigment is not produced on glycerol-asparagine and glucose-asparagine agar. Growth occurs in the presence of 2% NaCl. Rhamnose is not utilized as a carbon source, and mannitol is weakly utilized. A mixture of antibiotics, which includes a number of macrocyclic lactones and depsipeptides, is produced (Celmer et al., 1977b). The individual compounds exhibit significant antibiotic activity. The crude antibiotic mixture or combinations of a pure macrocyclic lactone and a pure depsipeptide demonstrate marked synergistic antibiotic activity. These antibiotics act as growth promotants in chicks and swine and are effective in the treatment of swine dysentery. "*Actinoplanes azureus*" (Celmer et al., 1977b) is the basonym of this subspecies.

Source: soil.

DNA G+C content (mol%): 72 (HPLC).

Type strain: ATCC 31157, DSM 43900, NBRC 13993, JCM 3246, VKM Ac-2019.

Sequence accession no. (16S rRNA gene): D85478, X93202.

Genus VIII. **Dactylosporangium** Thiemann, Pagani and Beretta 1967, 43[AL]

Gernot Vobis

Dac.ty.lo.spo.ran′gi.um. Gr. n. *daktylos* finger; Gr. n. *spora* a seed, and in biology a spore; Gr. neut. n. *angeion* (L. translit. *angium*) vessel; N.L. neut. n. *Dactylosporangium* an organism with finger-shaped, spore-containing vessels (sporangia).

Finger-shaped to claviform sporangia (0.6–1.4 × 2.5–6.0 µm) are **formed on short sporangiophores on the substrate mycelium**. They develop singly or in clusters above the surface of the substrate. **Each sporangium contains a single row of normally three to four spores**. **The spores are oblong, ellipsoidal, ovoid, or slightly pyriform** (0.4–1.3 × 0.5–1.8 µm) and **motile** by means of a polarly inserted tuft of flagella. True aerial mycelium is not formed. Hyphae of the substrate mycelium are 0.5–1.0 µm in diameter, branched, and rarely septate. Large single spores, **globose bodies** (1.7–2.8 µm in diameter) are formed on short branches on substrate mycelium. Organisms are Gram-stain-positive and not acid-fast. The peptidoglycan of the cell walls contains ***meso*-diaminopimelic acid** (***meso*-DAP) and glycine, with xylose and arabinose** as characteristic sugars of whole-cell hydrolysates. Colonies grow on various agar media. They are compact, somewhat tough and leathery, and mostly flat or sometimes elevated with a smooth to slightly wrinkled surface. **The color of the substrate mycelium is pale orange to deep orange, rose or wine-colored to brown**. Aerobic, chemo-organotrophic, with optimum growth between 25 and 37°C and at pH 6.0–7.0.

DNA G+C content (mol%): 71–73 (T_m).

Type species: **Dactylosporangium aurantiacum** Thiemann, Pagani and Beretta 1967, 43[AL].

Further descriptive information

Phylogeny. The genus belongs to the family *Micromonosporaceae*. Based on 16S rRNA gene sequence analysis, it comprises six species with validly published names: *Dactylosporangium aurantiacum*, *Dactylosporangium fulvum*, *Dactylosporangium matsuzakiense*, *Dactylosporangium roseum*, *Dactylosporangium thailandense*,

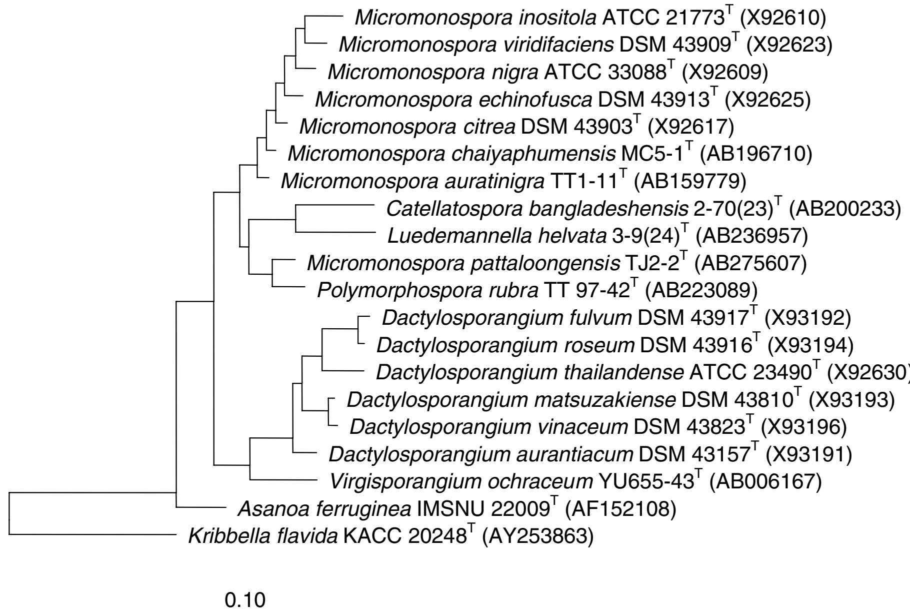

FIGURE 218. Phylogenetic tree showing the relationship of type strains of the genus *Dactylosporangium* and type strains of related genera of the family *Micromonosporaceae*. The tree was reconstructed with the maximum-likelihood method using the software environment ARB (Ludwig et al., 2004) and the corresponding SILVA SSURef 95 database (release July 2008; Pruesse et al., 2007). Bar = 0.10 substitutions per site.

and *Dactylosporangium vinaceum*. Sequence similarities between species range from 99.7 to 97.8%. The nearest genera of the family *Micromonosporaceae* are *Asanoa*, *Catellatospora*, *Luedemannella*, *Micromonospora*, *Polymorphospora*, and *Virgisporangium*, with sequence similarities between type strains of the genus *Dactylosporangium* and type strains of related genera ranging from 97.2 to 96.6% (genus *Polymorphospora*), 97.1 to 94.5% (genus *Micromonospora*), 97.1 to 95.7% (genus *Virgisporangium*), 96.8 to 96.1% (genus *Asanoa*), 96.5 to 94.4% (genus *Catellatospora*), and 96.5 to 95.4% (genus *Luedemannella*). A phylogenetic tree is shown in Figure 218.

Cell morphology and fine structure. The substrate hyphae are 0.5–1.0 µm in diameter and irregularly branched. They are rarely septate and do not separate into fragments either in agar or in liquid cultures. A true aerial mycelium is not formed; however, short hyphae in contact with the air are observed occasionally (Shomura et al., 1983b; Thiemann et al., 1967). *Dactylosporangium fulvum* develops rudimentary aerial mycelium (Shomura et al., 1986). The substrate hyphae may form coremia, also bearing sporangia and globose bodies (Shomura et al., 1986). The cell walls of the hyphae, the globose bodies, and the zoospores each consist of a single layer (Miyadoh et al., 1997; Vobis, 1987). The mesosomes are tubular-vesicular (Williams et al., 1973). Crystalline phage particles have been detected in the cytoplasm of the substrate hyphae of a strain of *Dactylosporangium thailandense* (Higgins and Lechevalier, 1969).

The oligosporous sporangia of the genus *Dactylosporangium* are formed on the surface of the colonies, singly or, more frequently, in tufts (Figure 219A). They are club- or finger-shaped, 0.6–1.4 µm in diameter, and 2.5–6.0 µm in length. The short sporangiophores are 0.5–1.5 µm long and usually branched (Figure 219B). Scanning and transmission electron micrographs have revealed a collar-like structure (Figure 219A, B) at the sporangiophore–sporangium juncture (Ensign, 1978; Sharples et al., 1974; Shomura et al., 1980; Vobis and Kothe, 1985). Each sporangium contains a single straight chain of three to four spores. A minimum of two spores and a maximum of five are produced (Shomura et al., 1980, 1983b, 1985; Thiemann, 1974; Thiemann et al., 1967). The formation of the sporangiospores corresponds to the scheme of spore formation as proposed for the sporangiate actinomycetes by Lechevalier and Holbert (1965). Inside a thin, expanding envelope, the unbranched sporogenous hypha grows up to the final length of the sporangium (Figure 219B). It is then divided into spore-shaped sections, which round off immediately (Miyadoh et al., 1997). The separating cross walls are double-layered (Vobis, 1989c; Vobis and Kothe, 1985). New sporangia are formed by lateral branches of the sporangiophore in a subterminal position at the base of an older sporangium (Figure 219B) (Ensign, 1978; Vobis and Kothe, 1985). Strains with abnormally long and branched sporangia are described by Thiemann (1970a).

The sporangiospores (zoospores) produced inside the sporangia have a smooth surface and are variable in shape, from oblong, ellipsoidal, and ovoid to slightly pyriform (Figure 219A, B, C). They measure 0.4–1.3 µm in diameter and 0.5–1.8 µm in length (Shomura et al., 1985; Shomura et al., 1980; Shomura et al., 1983b; Thiemann et al., 1967). Young spores are thin-walled and include various reserve substances in their cytoplasm (Vobis, 1987). The zoospores are motile by means of a polar tuft of flagella (Figure 219C) (Higgins et al., 1967; Lechevalier and Lechevalier, 1970; Shomura et al., 1985; Thiemann, 1974).

In addition to the zoospores, large globose bodies or aleuriospores of 1.7–2.8 µm in diameter are formed singly on substrate

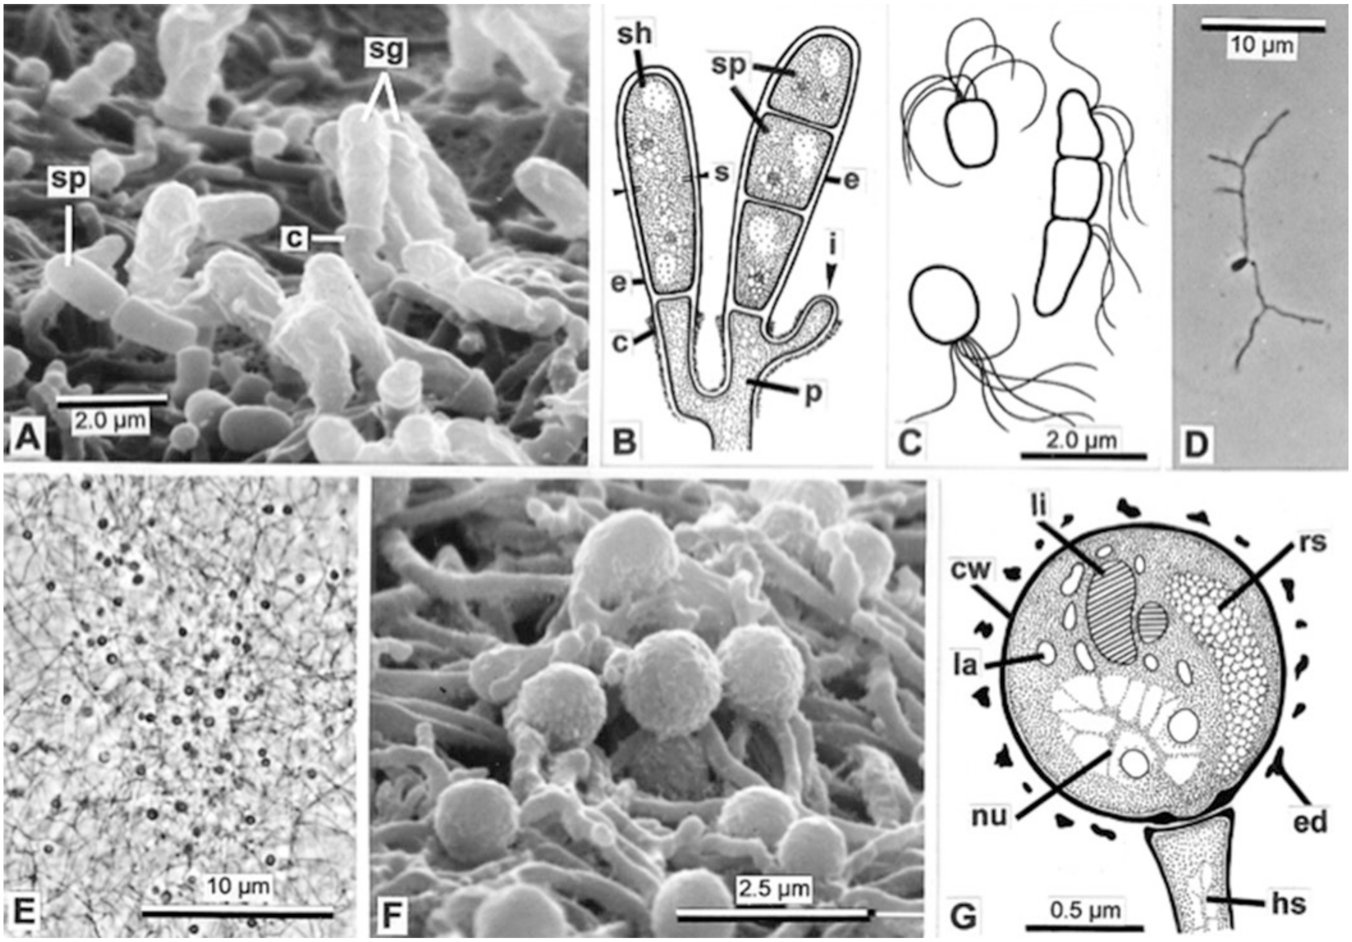

FIGURE 219. Morphological aspects of *Dactylosporangium*. A, Oligosporous sporangia (sg) with collars (c) and sporangiospores (sp) on the surface of the colony of *Dactylosporangium thailandense* (strain ATCC 23490[T]; SEM); B, scheme of sporangial development (c, collar; e, envelope; i, initium; p, sporangiophore; s, septum; sh, sporogenous hypha; sp, spore); C, flagellated sporangiospores (zoospores); D, germinated zoospore with hyphae developed after 36 h in distilled water (strain MB-VS 704; PHACO); E, globose bodies produced by substrate mycelium (strain MB-VS 699; PHACO); F, substrate hyphae and globose bodies, partially covered with granular deposits (strain A 1486; SEM); G, scheme of the ultrastructure of a globose body (cw, cell wall; ed, extracellular deposit; hs, hyphal stalk; la, light area; li, lamellate inclusion; nu, area of DNA; rs, reserve substance). Abbreviations: PHACO, phase contrast microscopy; SEM, scanning electron microscopy.

hyphae. They can be embedded in the agar or freely exposed on the surface (Figure 219E, F), but are also produced in liquid cultures (Thiemann et al., 1967). When observed by light microscopy using the phase-contrast technique (Figure 219E), they appear as refractile spores (Ensign, 1978; Vobis, 1992). The globose bodies contain nuclear material, large diffuse electron-transparent areas, smaller defined light areas, lamellated, protein-containing paracrystalline inclusions, and possible phage particles (Sharples and Williams, 1974). The deposit of electron-dense material, irregularly distributed and closely attached to the wall surface (Figure 219F, G), is conspicuous (Miyadoh et al., 1997).

Cell-wall composition. The peptidoglycan of the cell wall contains 3-hydroxy-DAP and/or *meso*-DAP and glycine, with xylose and arabinose as diagnostic sugars in whole-cell hydrolysates (Hasegawa et al., 1983; Lechevalier and Lechevalier, 1970b; Shomura et al., 1980, 1983b, 1985, 1986). The chemical composition of cell walls therefore conforms to chemotype II and sugar pattern D in the classification scheme of Lechevalier and Lechevalier (1970). *Dactylosporangium aurantiacum*, *Dactylosporangium thailandense*, and "*Dactylosporangium salmoneum*" possess cell-wall peptidoglycans of the *N*-glycolylmuramic acid type, exhibiting amounts of 74.6, 60.0, and 92.0 nmol glycolyl residues per mg dried bacterial cells, respectively (Uchida and Seino, 1997). An unknown sugar other than 3-*O*-methylrhamnose, which can be related to that found in species of *Catellatospora*, was detected in the type strains of *Dactylosporangium matsuzakiense* and *Dactylosporangium thailandense* (Asano et al., 1989b). This unknown sugar is probably identical to the deoxyhexose reported by Szaniszlo and Gooder (1967).

The polar lipid profile is characterized by the presence of diphosphatidylglycerol, phosphatidylethanolamine (PE), phosphatidylglycerol (PG), phosphatidylinositol, and phosphatidylinositol mannosides (Goodfellow et al., 1990b; Lechevalier et al., 1977). The presence of PG can be variable (Lechevalier et al., 1977). Further uncharacterized glycolipids may be present

and the type strain of *Dactylosporangium thailandense* is additionally characterized by two ninhydrin-positive, phosphate-positive lipids (Goodfellow et al., 1990b). Based upon the presence of PE and the absence of phosphatidylcholine and amino-containing phosphoglycolipid (GluNu) as diagnostic phospholipids, *Dactylosporangium* can be classified as having type II phospholipids of Lechevalier et al. (1981).

Fatty acids. Analysis of the fatty acids of the cytoplasmic membranes show that the principal components are branched iso- and anteiso-fatty acids (Kroppenstedt and Kutzner, 1978; Lechevalier et al., 1977). Cyclopropane and 10-methyl-branched fatty acids are not present (Kroppenstedt, 1979). In some strains, small amounts of unknown unsaturated fatty acids are found, which are assumed to have branched chains (Lechevalier et al., 1977). The type strains of *Dactylosporangium aurantiacum* and *Dactylosporangium thailandense* exhibit relatively high proportions of branched chain fatty acids, mainly iso-15 (4.1–15.8%), anteiso-15 (2.0–29.1%), iso-16 (6.2–18.3%), and anteiso-17 (4.4–14.2%), and smaller amounts of straight-chain constituents (13.7–32.9%) (Goodfellow et al., 1990b). The pattern of fatty acids corresponds to type 2d of the classification system of Kroppenstedt (1985).

The composition of the isoprenoid quinones is characterized by the possession of menaquinones with nine isoprene units (MK-9), whereas isoprenologues with ten units (MK-10) are absent. MK-9(H_2) and MK-9(H_4) are present in minor amounts, and MK-9(H_6) and MK-9(H_8) occupy predominant positions (Collins et al., 1984; Goodfellow et al., 1990b; Ruan et al., 1988). The presence of MK-9(H_4), MK-9(H_6), and MK-9(H_8) indicates that *Dactylosporangium* belongs to the menaquinone type 4b of the classification scheme of Kroppenstedt (1985).

Colonial characteristics. Colonies of *Dactylosporangium aurantiacum* are mostly flat with a smooth surface. The color of the substrate mycelium varies from whitish to pale orange to deep orange. The surface of the colonies of *Dactylosporangium thailandense* is usually smooth, but can be wrinkled on certain media. The substrate mycelium is light orange, amber, or brownish with a rose tinge (Thiemann et al., 1967). Colonies or *Dactylosporangium vinaceum* are compact, tough, and somewhat leathery; the mycelia are wine-colored to brown, depending on the medium (Shomura et al., 1983b). The colonial characteristics of *Dactylosporangium matsuzakiense* are similar to those of *Dactylosporangium vinaceum*; the substrate mycelium is orange (Shomura et al., 1983b). *Dactylosporangium roseum* has a rose-colored substrate mycelium on certain agar media (Shomura et al., 1985). Colonies of *Dactylosporangium fulvum* are yellowish brown (Shomura et al., 1986). Soluble pigments are produced by *Dactylosporangium vinaceum* (wine-colored to deep red), *Dactylosporangium thailandense* (amber to brown), and *Dactylosporangium matsuzakiense* (light brownish pink) (Shomura et al., 1985). Melanoid pigments are not produced (Table 196).

Antibiotic metabolites. The variety of the chemical structures of antibiotics isolated from *Dactylosporangium* strains indicates the great biosynthetic capability of this genus (Lancini and Lorenzetti, 1993). The aminoglycoside antibiotic dactimicin is produced by the type strains of *Dactylosporangium matsuzakiense* (SF-2052^T = ATCC 31570^T) and *Dactylosporangium vinaceum* (SF-2127^T = ATCC 35207^T) (Shomura et al., 1980; Shomura et al., 1983b). Dactimicin, a member of the pseudosaccharide group of antibiotics, is active against wide variety of Gram-stain-positive and Gram-stain-negative bacteria, including resistant strains with aminoglycoside-modifying enzymes (Omoto et al., 1987). *Dactylosporangium thailandense* strain G-367 produces the aminoglycoside antibiotics G-367-1 (2′-*N*-formylsisomicin) and G-367-2, a steric isomer of sisomicin, as well as sisomicin and gentamicin C1a and C2 (Fujii et al., 1982). Further aminoglycosides of the fortimicin antibiotic group are produced by *Dactylosporangium matsuzakiense* ATCC 31570^T (Dairi et al., 1992), and by the unidentified *Dactylosporangium* strain G 308. The antibiotic complex SF-2107 A-1, A_2, B and C, a member of the orthosomycin group, is produced by *Dactylosporangium roseum* strains SF-2107 (= ATCC 31744) and SF-2186^T (= NBRC 14352^T). The SF-2107 series substance is effective against Gram-stain-positive and Gram-stain-negative bacteria (Shomura et al., 1985).

Tiacumicins, a complex of 18-membered macrolide antibiotics, are isolated from strain AB718C-41 (= NRRL 18085), described as *Dactylosporangium aurantiacum* subsp. "*hamendensis*" (Theriault et al., 1987). The diarrhea-associated bacterium *Clostridium difficile* can be combated successfully *in vitro* and *in vivo* with tiacumicins B and C (Swanson et al., 1991).

The three strains FD 25647 (= ATCC 31222), FD 25712 (= ATCC 31223), and FD 25718 (= ATCC 718), determined as "*Dactylosporangium salmoneum*", produce the polycyclic ether antibiotic 44161, which is active against Gram-stain-positive bacteria, fungi, and protozoa, and promotes growth of animals. It exhibits potent anticoccidial activity (Celmer et al., 1978). The compound 44161 is identical to nigerimicin, which is also known as a herbicidal agent (Heisey and Putnam, 1990).

The tetracyclic antibiotic dactylocyclinone Sch 34164 (4α-hydroxy-8-methoxychlortetracycline) has been isolated from a culture of strain SCC 1695 (= ATCC 39499), determined as "*Dactylosporangium vescum*" (Patel et al., 1987). Sch 34164 (dactylocycline A) and dactylocycline B, isolated from strain SC 14051 (= ATCC 53693) have tested positive against tetracycline-resistant bacteria (Tymiak et al., 1993). Another polyketide-derived antibiotic, DK-7814-A (hydroxypurpuromycin), has been isolated from "*Dactylosporangium purpureum*" (Lancini and Lorenzetti, 1993). DK-7814-A, DK-7814-B, and DK-7814-CO are active against Gram-stain-positive bacteria and show antitumor activity.

The polypeptide compound capreomycin can also be obtained from strain D-409-5 (= ATCC 31203), originally described as "*Dactylosporangium variesporium*" (Tomita et al., 1977). Capreomycin is of primary interest for its use as an antituberculosis agent. Strain SF-2253 produces L-threo-β-hydroxyaspartic acid, an antibiotic useful against a wide spectrum of micro-organisms. This amino acid is also an inhibitor of glutamate uptake, frequently used in neurological studies (Alexander et al., 1997).

The type strain of *Dactylosporangium fulvum* (SF 2113^T = ATCC 43301^T) produces pyridomycin (Shomura et al., 1986), which is known as an antimycobacterial antibiotic (Maeda et al., 1953). The acidic substance SF 2185 is an antibiotic against plant pathogens, particularly the causal organisms of cucumber downy mildew and rice blast. The producing strain is SF-2185, determined as *Dactylosporangium aurantiacum* subsp. "*gifuense*" (Matsumoto et al., 1985). *Dactylosporangium aurantiacum* strain SANK 61299 produces the plant growth inhibitors streptol, A-79197-2 (disaccharide of streptol) and A-79197-3 (trisaccharide

of streptol), which inhibit the germination of *Brassica rapa*. The streptol moiety seems to be important for herbicidal activity (Kizuka et al., 2002).

Life cycle. Members of the genus *Dactylosporangium* produce two kinds of spores. The zoospores, which do not seem to be dormant, may function to ensure dissemination of the organisms. The nonmotile globose bodies or aleuriospores, which are constitutively dormant, may function to provide insurance for surviving during long periods (Ensign, 1978).

The few-spored sporangia are developed by substrate mycelium in contact with the air, standing out permanently from the substrate. The short spore chains inside the sporangia are held together by the thin sporangial envelope. They may function as an "aerophilic" survival unit, easily distributed in the soil environment or by the wind. If the sporangia are immersed in water, the zoospores are released after a period of 10–60 min (Thiemann et al., 1967). A solution of soil extract promotes this process (Hayakawa et al., 2000). Spore release is probably initiated by the swelling of an intrasporangial matrix (Thiemann et al., 1967), or by swelling of the substance forming the collar at the base of the sporangium (Figure 219A, B). The short chain of sporangiospores is pressed upward and pushed through the apex of the sporangial envelope. High motility starts after a time lag of about 30 min when the spores first separate from one another (Shomura et al., 1980, 1983b; Thiemann et al., 1967). The cytoplasm of the spores includes reserve material (Vobis, 1987, 1992). Spores are able to swim for up to 30 h. Germination was reported after 24 h on agar medium (Thiemann et al., 1967). It occurs also in distilled water (Figure 219D). By a consequent production of new mycelium and sporangia, the typical "aero-aquatic" live cycle of an actinoplanete is formed (Cross, 1986; Vobis, 1987, 1992).

The globose bodies, which are formed by substrate hyphae, are in general submersed in the substrate, but can also develop very closely attached to the surface (Figure 219E, F). Like the zoospores, they contain reserve material (Figure 219G) (Vobis, 1992). Ensign (1978) demonstrated that the globose bodies can germinate in a 10% (w/v) yeast extract solution and concluded that they have the same function as true, nonmotile spores. Compared with the flagellated sporangiospores, the globose bodies have a different physiological behavior when treated with the chemical germicide benzethonium chloride (BC). After being exposed for 30 min at 30°C in 0.01% solution of BC, 51% of the globose bodies survived, whereas the zoospores of *Dactylosporangium* and *Actinoplanes* did not (Hayakawa, 2003). This is compatible with the ecological observation of Johnston and Cross (1976), namely that *Dactylosporangium* species can survive in lake sediments that contain no viable *Actinoplanes*. Cross (1986) concluded that *Dactylosporangium* has two different types of survival stages.

Cultural characteristics and physiology. *Dactylosporangium* species are aerobic and mesophilic. The optimum temperature for growth is between 25 and 37°C (Table 196). The species *Dactylosporangium aurantiacum*, *Dactylosporangium matsuzakiense*, and *Dactylosporangium roseum* tolerate temperatures up to 42°C; no growth occurs at 45°C (Shomura et al., 1986; Thiemann et al., 1967). Good vegetative growth occurs on various media, e.g. oatmeal agar, Bennett agar, Hickey–Tresner agar, nutrient agar, glucose-asparagine agar, sucrose-nitrate agar, sucrose-yeast extract agar, yeast extract-malt extract agar, and inorganic salt-starch agar. However, individual species grow well on only a small spectrum of these media (Shomura et al., 1980, 1983b, 1985, 1986; Thiemann et al., 1967).

For carbon utilization tests, a different basal media was employed because individual strains do not grow on a common basal medium. A modified M/40 medium of Magni and von Borstel was used for *Dactylosporangium aurantiacum*, which had to be additionally supplemented with vitamins for *Dactylosporangium thailandense* (Thiemann et al., 1967). For other species, carbohydrate utilization was determined on Luedemann–Brodsky basal medium (Shomura et al., 1986). The results of the carbon utilization tests are given in Table 196. *Dactylosporangium* can be characterized as a neutrophilic micro-organism, growing well at pH 6.0–7.0 (Thiemann et al., 1967). Species can grow on Luedemann agar medium containing concentrations of NaCl up to 3%, but do not tolerate a concentration of 4% (Shomura et al., 1986). The ability to degrade polymers of biological origin and other physiological characters are not sufficiently studied. The physiological characteristics are summarized in Table 196.

The development of sporangia depends on the agar media used. They can be formed after 2–3 d under favorable conditions (Ensign, 1978), although normally they are only evident after 5–15 d of incubation (Shomura et al., 1983b). Sporangial formation can be promoted by soil agar, calcium malate agar, and inorganic salts-starch agar (Shomura et al., 1986; Thiemann et al., 1967). Globose bodies appear to be produced mainly on complex agar media that promote the growth of substrate mycelium, but not the formation of sporangia (Ensign, 1978). *Dactylosporangium fulvum* develops globose bodies abundantly on glucose-asparagine agar and tyrosine agar (Shomura et al., 1986).

The physiological behavior of the flagellated sporangiospores has been demonstrated by their chemotactic responses towards chemoattractants (Hayakawa et al., 1991d). The studies were carried out by microcapillary assays and included the type strains of *Dactylosporangium thailandense*, *Dactylosporangium aurantiacum*, *Dactylosporangium vinaceum*, *Dactylosporangium matsuzakiense*, *Dactylosporangium roseum*, and *Dactylosporangium fulcrum*. γ-Collidine at a concentration of 100 mM was the most effective chemical attractant, followed by vanillin (10 or 100 mM), xylose (10 mM), and KCl (10 mM) (Hayakawa, 2003).

Phages. A poorly lytic bacteriophage was discovered in a strain of *Dactylosporangium thailandense* that did not infect other actinomycetes (Higgins and Lechevalier, 1969). Cross-infections with phages of various actinomycetes were not successful (Prauser, 1984; Willoughby et al., 1972).

Ecology. Members of the genus *Dactylosporangium* are distributed worldwide. Thiemann (1970a) reported that out of 454 soil samples from various parts of the world, 140 isolates of *Dactylosporangium* were obtained. They were present in sandy as well as in loamy soils. No correlation could be established between the type of soil, its pH (4.0–9.0), and the incidence of *Dactylosporangium*. A total of 33 strains could be isolated from different soil samples from Thailand, Brazil, and Argentina (Thiemann et al., 1967). Further strains could be isolated from soil of an uncultivated field of grass in Colombia, South America (Shearer, 1987), and from soil samples collected in tropical and subtropical regions in Yunnan, China (Xu et al., 1996).

The dactylocycline producing strain SCC 1695 (=ATCC 39449) was isolated from a soil sample collected in Zambia, Africa. We isolated strains MB-VS 699 und MB-VS 704, presented in Figure 219, from soil samples collected at Lüneburger Heide (Germany). Strain A 1486, together with two further undetermined *Dactylosporangium* strains, were isolated from a soil sample from the Nationalpark Taman Negawa, Malaysia (G. Vobis and J.M. Wink, unpublished results).

The species *Dactylosporangium fulvum*, *Dactylosporangium matsuzakiense*, *Dactylosporangium roseum*, and *Dactylosporangium vinaceum* all originated from soil samples collected at various localities in Japan (see "List of Species"). Hayakawa and Nonomura (1987a) obtained isolates from soil samples from vegetable and corn fields with pH ranging from 5.4 to 6.1, collected in different Prefectures (Nagano, Mie, Gunma, and Iwate) in Japan. Field soils seem to be the most fruitful sources for isolating *Dactylosporangium* strains, together with other diverse rare actinomycete taxa, but they were also isolated frequently from mountainous forest soils. Field, mountain grass-land, and rice paddy with soil of pH 6.0–7.0, organic matter content <5%, and immature brown humic acid <0.8 (Δlog K) are the characteristic soil habitats of *Dactylosporangium* (Hayakawa, 2003).

Only a few sources other than soil were successfully tested as natural substrates inhabited by *Dactylosporangium* or simply utilized as intermediate locations by its resistant structures like the globose bodies. Johnston and Cross (1976) isolated strains from the surface muds of two lakes of the English Lake District in Great Britain. *Dactylosporangium* strains were also found on plant debris (Lechevalier, 1981). Leaf litter in marsh water in New Jersey (USA) was used as substrate to isolate the antibiotic dactylocycline-producing strain SC 14051 (= ATCC 53693). More recently, Okazaki (2003) reported an antibiotic-producing strain of *Dactylosporangium aurantiacum* isolated from fresh plant leaves of *Cucubalus* sp.

Enrichment and isolation procedures

The details of the very effective isolation technique used by Thiemann et al. (1967) were never published. Strains of *Dactylosporangium* can be detected by isolation methods used for other genera of actinoplanetes, including *Micromonospora* (Vobis, 1992). They are characterized as slow-growing organisms, recognizable on poor nutritive agar media (Shomura et al., 1980). In general, the soil samples are pretreated, e.g. with dry heat, and dilutions are spread onto specific selective isolation media, which can be supplemented with antibiotic agents (Hayakawa and Nonomura, 1987a; Nonomura, 1984; Shearer, 1987; Xu et al., 1996). It seems that all these above-mentioned methods, including also the traditional chemotactic technique of Palleroni (1980), have only incidentally recovered *Dactylosporangium* species in soil.

More recently, Hayakawa (2003) summarized his own valuable experiences of isolating rare actinomycetes. To isolate selectively high numbers of strains of *Dactylosporangium* from soil, combinations of several techniques are recommended. At first, the soil samples are dried slowly at room temperature for a week, sieved, and ground slightly in a mortar (Nonomura and Ohara, 1969). After that, the samples can be pretreated physically with dry heat (120°C) for 1 h, followed by treatment with the chemical germicide BC (0.01 or 0.03%), exposed for 30 min at 30°C (Hayakawa et al., 1991a). Especially in the latter case, the globose bodies (aleuriospores) function as the surviving units.

The enrichment procedures profit by the release of zoospores from the sporangia in an aqueous environment. One possibility is an improved chemotactic method employing the capillary technique of Palleroni (1980), but using γ-collidine or vanillin (100 mM) as chemoattractant instead of the traditional 0.01 M KCl (Hayakawa et al., 1991d). A further enrichment method is named "rehydration and centrifugation" (RC) (Hayakawa et al., 2000). The samples are flooded with 10 mM phosphate buffer containing 1% soil extract at 30°C for 90 min. The fluid is centrifuged at 1500 × ***g*** for 20 min and the supernatant, containing actively swimming zoospores, is used for plating.

The preferable selective isolation medium is humic acid-vitamin (HV) agar, containing (per liter) 1.0 g humic acid, 0.02 g $CaCO_3$, 0.5 g NaH_2PO_4, 1.7 g KCl, 0.5 g $MgSO_4 \cdot 7H_2O$, 0.01 g $FeSO_4 \cdot 7H_2O$, 18.0 g agar, and B vitamins (0.5 mg each of thiamine·HCl, riboflavin, niacin, pyridoxin·HCl, inositol, Ca-pentothenate, *p*-aminobenzoic acid, and 0.25 mg biotin); pH 7.2 (Hayakawa and Nonomura, 1987b, 1987a). The HV agar is supplemented with nalidixic acid (20 mg/l) (Hayakawa et al., 1995; Hayakawa et al., 1991d; Nonomura and Hayakawa, 1988), and additionally with leucomycin or tunicamycin (20 mg/l or 30 mg/l) in the case of dry heat and BC pretreatment (Hayakawa et al., 1991a), or trimethoprim (20 mg/l) for the RC enrichment method (Hayakawa et al., 2000). Cycloheximide (50 mg/l) is also generally added as an antifungal compound. The plates are incubated at 30°C for 4–6 weeks.

An alternative source for isolation of *Dactylosporangium* was demonstrated by Okazaki (2003). Instead of soil, leaf samples can be investigated as a habitat for actinomycetes. Freshly picked leaves are cut into several pieces, rinsed with sterile water, and soaked in 70% ethanol for 1 min. They are then washed once more with sterile water, soaked in 1% NaClO for 3 min, and rinsed again with sterile water. After these treatments, the leaf pieces are incubated on 0.8% water agar for several weeks. Although the percentage of *Dactylosporangium* species recovered seems to be very low, a strain of particular interest based on its secondary metabolite production was isolated (Kizuka et al., 2002).

Maintenance procedures

Slant agar cultures can be stored for several weeks at room temperature or at 6°C. For long-term preservation, the strains can be lyophilized or maintained by other techniques recommended for the aerobic actinomycetes.

Differentiation of the genus *Dactylosporangium* from other related genera

The morphological characteristics of *Dactylosporangium*, namely the oligosporous sporangia with 2–5 flagellated sporangiospores and the typical globose bodies, both produced by substrate mycelium, are sufficient to differentiate the genus from other genera of the family *Micromonosporaceae* (Vobis, 1992). The newly described genera *Virgisporangium* (Tamura et al., 2001) and *Planosporangium* (Wiese et al., 2008) have similar sporangia, but small differences are observed (Table 197). Thiemann (1970a) observed *Dactylosporangium*-like strains with deviating morphologies of sporangia, resembling *Planosporangium* or *Virgisporangium* species, and also strains having short chains of nonmotile spores like *Catellatospora* species. He announced the description of new genera, which was never realized. The closely related genera *Dactylosporangium*, *Planosporangium*, *Virgisporangium*, *Catellatospora*,

TABLE 197. Characteristics differentiating *Dactylosporangium* from closely related genera forming either oligosporous sporangia with motile sporangiospores or single, nonmotile spores/globose bodies on substrate mycelium[a,b]

[b]Data compiled from Ara et al. (2008a), Asano and Kawamoto (1986), Lee and Hah (2002), Lee et al. (2000b), Tamura et al. (2001) and Wiese et al. (2008).

[c]Not confirmed with certainty for all species.

[d]According to the classification of Kroppenstedt (1985).

and *Asanoa* can be differentiated by a combination of morphological and chemical characteristics (Table 197).

Taxonomic comments

When the first two species of *Dactylosporangium* were described by Thiemann et al. (1967), the genus was classified in the family *Actinoplanaceae* (Couch, 1955a, 1955b), which comprised all sporangia-forming actinomycetes. Within this morphologically defined family, the three genera *Dactylosporangium*, *Planomonospora*, and *Planobispora* were characterized by having oligosporous sporangia and flagellated sporangiospores (Thiemann, 1970a). At the same time, it could be shown that the *Actinoplanaceae* could be divided into two groups, one characterized by cell-wall chemotype II and the other by chemotype III (Lechevalier and Lechevalier, 1970). By having cell-wall chemotype II, *Dactylosporangium* was closely related to the genus *Actinoplanes*, but could be plainly distinguished from other genera by morphological and chemotaxonomic characteristics (Vobis, 1989b, 1989c). The genus *Dactylosporangium* constantly kept its taxonomic position as the "good little brother" of *Actinoplanes* throughout all changes of classification concepts of generic and suprageneric ranks (Bland and Couch, 1981; Goodfellow, 1989; Goodfellow and Cross, 1984; Goodfellow et al., 1990b; Koch et al., 1996a; Miyadoh et al., 1997, 2001; Stackebrandt and Kroppenstedt, 1987; Stackebrandt et al., 1997; Zhi et al., 2009).

Differentiation of species of the genus *Dactylosporangium*

The species of *Dactylosporangium* have essentially the same morphological characteristics. They cannot be differentiated based on sporangia and zoospores, although globose bodies may or may not be present (Table 196). The formation of coremia is a special morphological characteristic for *Dactylosporangium fulvum* (Shomura et al., 1986).

Species differentiation is mainly based on the color of the substrate mycelium and on the production of soluble pigments. *Dactylosporangium aurantiacum* has orange substrate mycelium and does not produce pigment. *Dactylosporangium thailandense* has orange to brown mycelium and produces pigments on some media that are amber to brown with a reddish tinge (Thiemann, 1974; Thiemann et al., 1967). A wine-colored to deep red diffusible pigment characterizes *Dactylosporangium vinaceum* and the mycelium of this species is similarly colored. *Dactylosporangium matsuzakiense* has orange colonies and produces a light brownish-pink pigment on tyrosine agar (Shomura et al., 1983b). *Dactylosporangium roseum* is characterized by the rose color of its substrate mycelium (Shomura et al., 1985), and *Dactylosporangium fulvum* by a yellowish brown substrate mycelium and light brownish pink diffusible pigment (Shomura et al., 1986). *Dactylosporangium* species differ slightly in their patterns of carbon utilization, e.g. D-mannitol or L-rhamnose, and some physiological properties like degradation of starch and reduction of nitrate (Table 196).

List of species of the genus *Dactylosporangium*

1. **Dactylosporangium aurantiacum** Thiemann, Pagani and Beretta 1967, 43[AL]

au.ran.ti.a′cum. N.L. neut. adj. *aurantiacum* orange colored.

Sporangia (4.0–6.0 µm in length) develop on the surface of soil agar and on calcium malate agar. The zoospores, released 10–15 min after placing the sporangia in water, are oval, oblong, and slightly pyriform (1.5 µm long by 1.0 µm wide). They are extremely vigorous swimmers. Globose bodies are formed by substrate mycelium.

Colonies on agar media are mostly flat with a smooth surface. Abundant to good growth occurs on oatmeal agar and nutrient agar. The color of the substrate mycelium is pale

orange to orange. On Hickey–Tresner agar, growth is moderate with very pale mycelium. On tyrosine, nutrient, and skim milk agars, the colonies are orange to deep orange. Whitish colonies occur on glucose-asparagine agar and on starch agar. On glycerol-asparagine agar and on peptone-iron agar, the colonies are hyaline.

D-Mannitol, L-rhamnose, and melibose are utilized for growth; D-ribose is not. NaCl is tolerated up to 3% (w/v). Nitrate is reduced to nitrite. Litmus milk is not coagulated. No soluble pigments are produced on any media. The type strain shows the highest sequence similarity to *Dactylosporangium matsuzakiense* (98.9%) and *Dactylosporangium vinaceum* (98.6%). All other species show sequence similarities below 98.5%.

Source: the type strain was isolated from soil; no further information is given regarding its origin.

DNA G+C content (mol%): 73 (T_m).

Type strain: ATCC 23491, D-748, DSM 43157, NBRC 12592, JCM 3083, NRRL B-8111.

Sequence accession no. (16S rRNA gene): X93191.

2. **Dactylosporangium fulvum** Shomura, Amano, Yoshida and Kojima 1986, 169^{VP}

ful′vum. L. neut. adj. *fulvum* yellowish brown, referring to the color of the vegetative mycelium.

Sporangia (0.7–1.0 × 2.5–5.0 µm in size) with three to four spores in a single row are produced abundantly on sodium succinate agar, and moderately on calcium malate agar and inorganic salts-starch agar. Sporangiospores are motile. Globose bodies are formed abundantly on glucose-asparagine agar and tyrosine agar (ISP medium 5), and moderately on oatmeal agar, glycerol-asparagine agar and calcium malate agar. Coremia are formed abundantly on inorganic salts-starch agar and oatmeal agar, and moderately on yeast extract-malt extract agar and sucrose-yeast extract agar. Sporangia and globose bodies also develop directly from coremia.

The color of the substrate mycelium is yellowish brown and does not change when treated with alkaline or acid solutions. Except for a light brownish pink color on tyrosine agar, neither melanoid nor distinct diffusible pigments are not produced. Good growth occurs on sucrose-yeast extract agar, yeast extract-malt extract agar, and inorganic salts-starch (ISP medium 4) with light brown to cinnamon color. It grows moderately on Bennett agar, nutrient agar, tyrosine agar (ISP medium 7), oatmeal agar (ISP medium 3), and sucrose nitrate agar.

Decomposes casein and esculin; hydrolyzes starch. Nitrate is reduced to nitrite. Decomposition of xanthine and hypoxanthine, liquefaction of gelatin, and peptonization and coagulation of milk are negative. Optimum growth is between 26 and 34°C. Tolerates 3% NaCl, but no growth occurs on media containing more than 4% NaCl.

Produces pyridomycin. The type strain shows the highest sequence similarity to that of *Dactylosporangium roseum* (99.6%). The type strains of all other *Dactylosporangium* species show sequence similarities below 98.5%.

Source: the type strain was isolated from a soil sample collected in Chiba, Japan.

DNA G+C content (mol%): not determined.

Type strain: ATCC 43301, DSM 43917, NBRC 14381, JCM 5631, NRRL B-16292, SF-2113.

Sequence accession no. (16S rRNA gene): X93192.

3. **Dactylosporangium matsuzakiense** Shomura and Niida *in* Shomura, Kojima, Yoshida, Ito, Amano, Totsugawa, Niwa, Inouye, Ito and Niida 1983a, 672^{VP} (Effective publication: Shomura, Kojima, Yoshida, Ito, Amano, Totsugawa, Niwa, Inouye, Ito and Niida 1980, 928.)

mat.su.za.ki.en′se. N.L. neut. adj. *matsuzakiense* of or pertaining to Matsuzaki-cho, Izu Peninsula, Japan.

Finger-shaped sporangia are 4.0–6.0 × 0.9–1.4 µm in size, formed on short sporangiophores (0.5–1.0 µm), and occurring singly or in clusters. Each sporangium contains usually three spores, arranged in a single row. Sporangiospores are cylindrical to oblong (1.1–1.6 × 0.8–1.3 µm), motile. Abundant production of sporangia occurs on inorganic salts-starch agar, but is rare on Czapek, oatmeal, and tyrosine agars. Formation of globose bodies is not observed.

Colonies grow well on inorganic salts-starch agar, with a russet-orange substrate mycelium. Moderate growth occurs on Czapek agar and on yeast extract-malt extract agar, with an amber to light brown mycelium. Colonies grow moderately on glucose-asparagine agar and on oatmeal agar; the substrate mycelium is russet to orange. Poor growth occurs on glycerol-asparagine, nutrient, and calcium malate agars, the color of substrate mycelium varies from light yellow to light orange. Moderate growth occurs on tyrosine agar; the color of colonies is dusty orange to light brown and a light brownish-pink soluble pigment is produced.

D-Mannitol and L-rhamnose are utilized as sole carbon sources; melibiose is not. Growth occurs between 15 and 42°C. NaCl tolerance is lower than 1.5% (w/v). Gelatin is not liquefied; nitrate is not reduced. Skim milk is neither peptonized nor coagulated.

Produces the aminoglycoside antibiotic dactimicin. The type strain shows the highest sequence similarity to the type strains of *Dactylosporangium vinaceum* (99.7%) and *Dactylosporangium aurantiacum* (98.8%). The type strains of all other *Dactylosporangium* species show sequence similarities below 98.5%.

Source: the type strain was isolated from a soil sample collected at Matsuzaki-cho, Izu Peninsula, Japan.

DNA G+C content (mol%): not determined.

Type strain: ATCC 31570, DSM 43810, FERM-P 4670, NBRC 14259, JCM 3311, NRRL B-16293, SF-2052.

Sequence accession no. (16S rRNA gene): X93193.

4. **Dactylosporangium roseum** Shomura, Amano, Tohyama, Yoshida, Ito and Niida 1985, 4^{VP}

ro′se.um. L. neut. adj. *roseum* rose colored, pink.

Pod-shaped sporangia (2.5–5.5 × 0.8–1.1 µm), containing a single row of spores, are abundantly formed on chemically defined media such as sucrose-nitrate, glucose-asparagine, glycerol-asparagine, inorganic salts-starch, calcium malate, and tyrosine agars, but rarely on yeast extract-malt extract, nutrient, and Bennett agars. Sporangiospores are ellipsoidal (0.8–1.1 × 0.6–1.5 µm) and motile by means of polarly inserted flagella. The formation of globose bodies has not been observed.

Colonies grow well on sucrose-yeast extract agar, and moderately on yeast extract-malt extract, inorganic salts-starch, oatmeal, Bennett, and tyrosine agars. The typical rose color

of the substrate mycelium occurs on sucrose-yeast extract, inorganic salts-starch, and yeast extract-malt extract agars. On Bennett agar, the color of mycelium is pastel orange and on tyrosine agar it is yellowish. Colonies on sucrose-nitrate, glucose-asparagaine, glycerol-asparagine, calcium malate, oatmeal, and nutrient agars are colorless. Soluble pigments are not produced.

D-Mannitol and L-rhamnose are not utilized as sole carbon sources. NaCl is tolerated up to 1.5% (w/v). Growth occurs between 20 and 40°C; the temperature optimum ranges from 28 to 37°C. Nitrate is reduced to nitrite and gelatin is liquefied. Starch is not hydrolyzed; skim milk is neither peptonized nor coagulated. Melanoid pigments are not produced.

Produces antibiotic complex SF-2107, a member of orthosomycin group. The type strain shows the highest sequence similarity to the type strain of *Dactylosporangium fulvum* (99.6%). The type strains of all other *Dactylosporangium* species show sequence similarities below 98.5%.

Source: the type strain was isolated from a sample collected at Shizuoka, Japan; a further strain (SF-2107) was from soil collected at Yokohama, Japan.

DNA G+C content (mol%): not determined.

Type strain: DSM 43916, NBRC 14352, JCM 3364, NRRL B-16295, SF-2186.

Sequence accession no. (16S rRNA gene): X93194.

5. **Dactylosporangium thailandense** Thiemann, Pagani and Beretta 1967, 49[AL]

thai.lan.den′se. N.L. neut. adj. *thailandense* of or pertaining to Thailand. The correct Latin epithet of the species was proposed by Thiemann (1970b).

Abundant sporangial formation occurs on soil agar, calcium malate agar, and starch agar. Colonies grow on various agar media with a wrinkled or smooth surface. Good growth occurs on oatmeal agar with light orange-brown substrate mycelium, producing a light amber diffusible pigment. On Hickey–Tresner agar, growth is also good; the mycelium is brown with a rose tinge and the pigment is brown to reddish pink. Growth on glycerol-asparagine, glucose-asparagine, and starch agars is moderate, with a light orange to orange substrate mycelium. On nutrient agar, growth is good and the mycelium is pale orange.

D-Ribose, D-mannitol, and L-rhamnose are utilized for growth; melibiose is not. Tolerates up to 1.5% (w/v) NaCl. Tyrosine is hydrolyzed. Nitrate is not reduced to nitrite. Milk is not coagulated. No growth occurs at 42°C. Production of brown soluble pigments occurs on some media. Sequence similarities between the type strain and those of all other species of the genus are below 98.5%.

Source: the type strain was isolated from a soil sample collected in Thailand.

DNA G+C content (mol%): 71 (T_m).

Type strain: ATCC 23490, D-449, DSM 43158, NBRC 12593, JCM 3084.

Sequence accession no. (16S rRNA gene): X92630.

6. **Dactylosporangium vinaceum** Shomura, Yoshida, Miyadoh, Ito and Niida 1983b, 312[VP]

vi.na′ce.um. L. neut. adj. *vinaceum* of or belonging to wine, intended to mean wine-colored.

Finger-shaped sporangia (3.0–5.5 × 0.8–1.1 μm), produced singly or in tufts. Sporangia are occasionally apparent on Czapek and oatmeal agars, but less apparent on inorganic salts-starch and on calcium malate agar. Each sporangium contains three sporangiospores arranged in a single row. Spores are cylindrical to oblong (0.9–1.8 × 0.6–0.9 μm) and motile. Globose bodies are produced on glucose-asparagine and nutrient agars.

Colonies grow well on Czapek, glucose-asparagine, inorganic salts-starch, oatmeal, Bennett, and Hickey–Tresner agars. The color of substrate mycelium or reverse color ranges from light to dark wine-colored or occasionally ebony brown. Poor growth occurs on glycerol-asparagine agar with apricot substrate mycelium and no or very light wine-colored pigment production. Production of a wine red-colored diffusible pigment is conspicuous on various agar media, shaded from rose-wine to dark red or cherry. The pigments of the substrate mycelium and the soluble pigment are stable with changes in pH.

D-Mannitol and L-rhamnose are utilized as carbon source for growth. Gelatin and casein are hydrolyzed; milk is coagulated. Nitrate is not reduced to nitrite. NaCl concentrations of up to 3% (w/v) are tolerated.

Produces the pseudodisaccharide antibiotic dactimicin. The type strain shows the highest sequence similarity to the type strains of *Dactylosporangium matsuzakiense* (99.7%) and *Dactylosporangium aurantiacum* (98.6%). The type strains of all other *Dactylosporangium* species show sequence similarities below 98.5%.

Source: the type strain was isolated from a soil sample collected at Sekigahara, Gifu Prefecture, Japan.

DNA G+C content (mol%): not determined.

Type strain: ATCC 35207, DSM 43823, NBRC 14181, JCM 3307, NRRL B-16297, SF-2127.

Sequence accession no. (16S rRNA gene): X93196.

Species *incertae sedis*

1. **"Dactylosporangium salmoneum"** Routien *in* Celmer, Cullen, Moppett, Routien, Jefferson, Shibakawa and Tone 1978, 3 (U.S. Patent 4081532)

sal.mon′e.um. L. n. *salmon -onis* salmon; L. adj. suff. *-eus -a -um* suffix used with various meanings; N.L. neut. adj. *salmoneum* salmon-colored.

The species is not included in the Approved Lists of Bacterial Names and the name is not validly published in the *International Journal of Systematic Bacteriology*.

Finger-like sporangia (5.5–8.0 × 1.6 μm) containing 3–4 ellipsoidal to tear-drop shaped sporangiospores, develop abundantly on calcium malate agar. The color of the substrate mycelium is salmon, pale pink, orange, pink orange, pinkish, or creamish. Soluble pigments are not produced. No growth occurs on starch agar. Three polycyclic ether antibiotic-producing strains have been described as "*Dactylosporangium salmoneum*".

Source: the type strain was isolated from a soil sample collected in Japan.

Type strain: ATCC 31222, JCM 3272, Pfizer FD 25647.

2. **"Dactylosporangium variesporum"** Tomita, Kobaru, Hanada and Tsukiara 1977, 3 (U.S. Patent 4026766)

The species is not included in the Approved Lists of Bacterial Names and the name is not validly published in the *International Journal of Systematic Bacteriology*.

Finger shaped sporangia containing spores of various shapes. The substrate mycelium is orange to light reddish brown, creamy to light yellowish orange. A yellow pale brownish-to reddish-orange diffusible pigment is produced on various agar media. Glycerol, inositol, and D-ribose are utilized as sole carbon sources; L-rhamnose is not utilized. Nitrate is reduced to nitrite.

"*Dactylosporangium variesporum*" was established for a strain producing the antibiotic capreomycin.

Source: the type strain was isolated from a soil sample collected in India.

Type strain: ATCC 31203, Bristol Labs. D409-5, JCM 3273, NRRL B-16296, DSM 43911, NBRC 14104, KCC A-0273, NBRC 14104.

Further comment: "*Dactylosporangium variesporum*" differs in *N*-acyl type of muramyl residues of peptidoglycan from all other *Dactylosporangium* species in having acetyl. The taxonomic position is furthermore doubtful because of the lack of sporangiospore formation (Uchida and Seino, 1997).

Genus IX. **Krasilnikovia** Ara and Kudo 2007, 2449[VP] (Effective publication: Ara and Kudo 2007a, 6.)

Susmitha Seshadri

Kra.sil.ni.kov′i.a. N.L. fem. n. *Krasilnikovia* referring to N.A. Krasil'nikov, a Russian actinomycetologist who contributed to the taxonomy of the family *Micromonosporaceae*.

Aerobic with **branching hyphae**. **Gram-type positive**. Non-acid-fast. Pseudosporangia on short sporangiophores contain **oval to reniform, nonmotile spores** with a smooth surface. Growth occurs between **20–37°C** and **pH 5–9**. Did not grow on 3% NaCl. Cell wall contains ***meso*-diaminopimelic acid**. Major whole-cell sugars are galactose, mannose, xylose, arabinose, ribose, and glucose. The major menaquinone is **MK-9(H_6), and** the predominant fatty acids are **$C_{16:0}$ iso, $C_{14:0}$ iso** and **$C_{18:1}$ (ω9*c*)**. Phosphatidylethanolamine is the diagnostic phospholipid.

DNA G+C content (mol%): 71.

Type species: **Krasilnikovia cinnamomea** Ara and Kudo 2007, 2449[VP] (Effective publication: Ara and Kudo 2007a, 8.).

Further descriptive information

Isolated from sandy soils of a forest-side waterfall at Chokoria, Cox's Bazar, Bangladesh. Light microscopy revealed large, single or clustered spherical to irregularly shaped structures (~2.0–5.0 μm) on the substrate mycelium. These structures are pseudosporangia, i.e. lacking a sporangial wall, containing highly aggregated and hooked spore chains and substrate mycelium. The non-fragmenting substrate mycelium is light yellow to cinnamon in color. The acyl type of the cell-wall peptidoglycan is glycolyl. Most 16S rRNA gene nucleotide signatures of the family *Micromonosporaceae* are present except that a C is at position 222 instead of a U, a C–G pair is at positions 445:489 and 446:488 instead of a G–C pair, a U–A is at 1011:1018 instead of a C–G and G–U is at position 1263:1272 instead of A–U or C–G.

Enrichment and isolation procedures

Isolation was performed after 21 d of growth at 30°C on humic acid-vitamin (HV) agar supplemented with nalidixic acid (20 mg/l), nystatin and cycloheximide (each 50 mg/l). Strain 3-54(41), the type strain, was isolated by standard dilution plating and was further purified on yeast extract-malt extract agar.

Maintenance procedures

Routine subculturing is done on yeast-starch agar containing soluble starch (15.0 g); yeast extract (4.0 g); K_2HPO_4 (0.5 g); $MgSO_4 \cdot 7H_2O$ (0.5 g); and agar (15.0 g) in 1 liter of distilled water (pH 7.2).

Differentiation of the genus *Krasilnikovia* from closely related genera

16S rRNA gene sequence analysis showed that *Krasilnikovia* was 94.2–97.5% similar to the other genera in the family *Micromonosporaceae*. Phylogenetically, the closest relatives are *Couchioplanes* and *Actinoplanes globisporus*. *Krasilnikovia* lacks a true sporangium like *Couchioplanes*. However, its spores are nonmotile, unlike the motile spores of *Couchioplanes* and *Actinoplanes globisporus*. Also, *Krasilnikovia* differs from *Actinoplanes globisporus* in its menaquinone and whole cell sugar hydrolysate content. 16S rRNA gene signature sequences also differentiate this genus from phylogenetically closely related genera. Hence, on the basis of phylogenetic, phenotypic and chemotaxonomic studies, *Krasilnikovia* is classified as a novel genus in the family *Micromonosporaceae*.

List of species of the genus *Krasilnikovia*

1. **Krasilnikovia cinnamomea** Ara and Kudo 2007, 2449[VP] (Effective publication: Ara and Kudo 2007a, 8.)

cin.na.mo′mea. L. n. *cinnamomum* cinnamon; L. fem. suff. *-ea* suffix used with various meanings; N.L. fem. adj. *cinnamomea* cinnamon-colored.

The characteristics are as described for the genus with the following additional information. Spores are oval to short-rods (0.2–0.4 × 0.8–1.0 μm) and nonmotile. Growth is exhibited on glucose-asparagine agar, inorganic salts-starch agar, oatmeal-nitrate agar, sucrose-nitrate agar, yeast extract-starch agar, oatmeal agar, ISP medium 2, Bennett agar, Hickey–Tresner agar and glucose-yeast extract agar. Good sporulation is observed on glucose-asparagine agar, sucrose-nitrate agar and HV agar media. D-glucose, glycerol, D-xylose, D-galactose, D-fructose,

D-mannose, salicin and maltose are utilized, while adonitol, L-rhamnose, D-mannitol, α-D(+)melibiose, D-raffinose and trehalose are poorly utilized, and erythritol, L-arabinose, D-ribose, *myo*-inositol, α-methyl-D-glucoside and lactose are not utilized. In addition to the MK-9(H_6), small quantities of MK-9(H_4) and MK-9(H_8) are present. Saturated fatty acid $C_{18:0}$, $C_{17:0}$ 10 methyl, $C_{15:0}$ iso, $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and saturated $C_{16:0}$ are cellular fatty acids present in low amounts. Phospholipids present include phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol and phosphatidylinositol mannosides.

DNA G+C content (mol%): 71 (HPLC).

Type strain: 3-54(41), JCM 13252, MTCC 8094.

Sequence accession no. (16S rRNA gene): AB236956.

Genus X. **Longispora** Matsumoto, Takahashi, Shinose, Seino, Iwai and Ōmura 2003, 1558[VP]

Yōko Takahashi and Atsuko Matsumoto

Lon.gi.spo′ra. L. adj. *longus* long; Gr. fem. n. *spora* seed and in biology a spore; N.L. fem. n. *Longispora* long spore.

Leathery colonies. **Aerial hyphae bear long spore-chains of more than 20 spores on the tips of short sporophores** that branch from the vegetative mycelia. No fragmentation of vegetative mycelia. **No sporangia, synnemata, or sclerotia formed**. Cells are Gram-stain-positive, aerobic, non-acid-fast and **non-motile**. Cell-wall peptidoglycans contain ***meso*-diaminopimelic acid (DAP)**, glycine, and alanine. Arabinose, galactose, and xylose are detected in whole-cell hydrolysates. The acyl form of muramic acid in the peptidoglycans is **glycolyl**. Predominant menaquinones are **MK-10(H_4) and MK-10(H_6)**; MK-10(H_8) is a minor component. Mycolic acids are not detected. Diagnostic phospholipid is phosphatidylethanolamine (phospholipid type II). Mesophilic.

DNA G+C content (mol%): 70 (HPLC).

Type species: **Longispora albida** Matsumoto, Takahashi, Shinose, Seino, Iwai and Ōmura 2003, 1558[VP].

Further descriptive information

The almost-complete 16S rRNA gene sequence (1496 nt) [positions 10–1506, according to the *Escherichia coli* numbering system of Brosius et al. (1978)] of the type strain of *Longispora albida* has been determined. The phylogenetic tree based on 16S rRNA gene sequences revealed that the genus *Longispora* fell within the cluster of the family *Micromonosporaceae* and belonged to no other genera in the family (Figure 220). The pattern of the 16S rRNA gene signature nucleotides (Stackebrandt et al.,

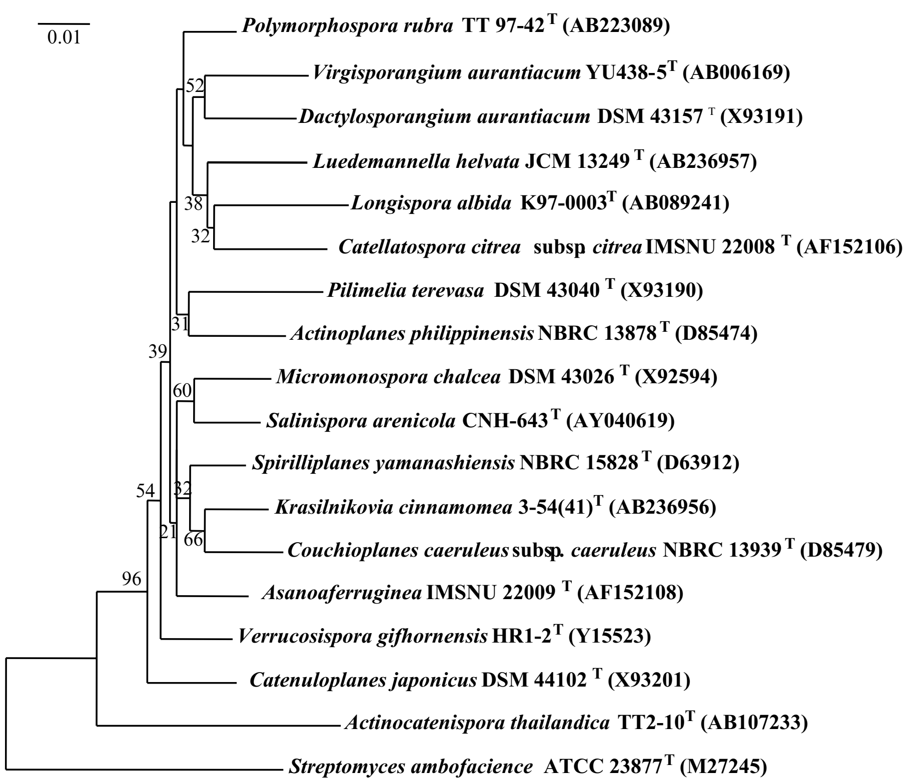

FIGURE 220. Phylogenetic tree based on 16S rRNA gene sequences of 17 genera in the family *Micromonosporaceae. Streptomyces ambofaciens* was used as an outgroup. Numbers at nodes indicate the level (%) of bootstrap support based on neighbor-joining analysis of 1000 resampled datasets. Only values >20% are shown. Bar, 1 nucleotide substitution per 100 nucleotides.

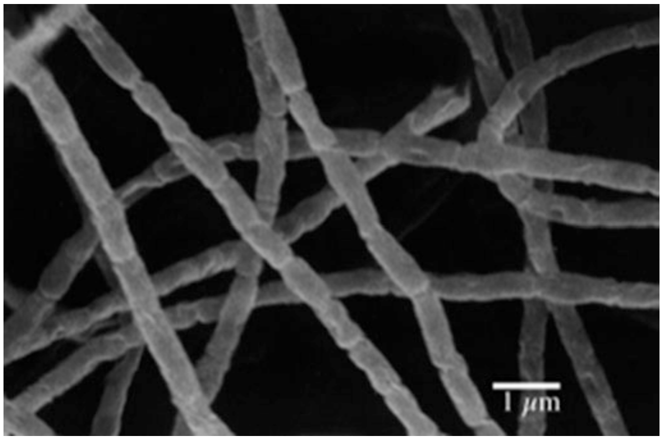

FIGURE 221. Scanning electron micrograph of spore-chains of *Longispora albida* K97-0003^{T} grown on 1/10 V8+$CaCl_2$ gellan gum medium for 20 d at 27°C. Bar = 1 μm.

TABLE 198. Aerial mycelium formation of *Longispora albida* on various media

	Solidifying agent			
	Agar		Gellan gum	
Medium	Growth	Aerial mycelium[a]	Growth	Aerial mycelium[a]
Yeast extract-malt extract (ISP 2)	+	$+^{t}$	++	$+^{t}$
Oatmeal (ISP 3)	+	−	+	−
Tyrosine (ISP 7)	+	−	+	+
Glucose-peptone	+	−	++	−
Nutrient	+	−	+	−
Water/proline	+	−	++	−
1/10 V8	+	−	+	+
1/10 V8 + $CaCl_2$	+	$+^{t}$	+	++

[a]Symbols: $+^{t}$, Trace aerial mycelium observed with a light microscope; +, poor aerial mycelium; ++, aerial mycelium produced (better than +).

1997) only differs from that of the family *Micromonosporaceae* (Koch et al., 1996a) at position 502 (A). The similarity values of the 16S rRNA gene with strains of other members of the family *Micromonosporaceae*, i.e. *Catellatospora citrea* subsp. *citrea*, *Virgisporangium aurantiacum*, *Asanoa ferruginea*, *Dactylosporangium aurantiacum*, *Pilimelia terevasa*, *Catenuloplanes japonicus*, *Verrucosispora gifhornensis*, *Spirilliplanes yamanashiensis*, *Micromonospora chalcea*, *Couchioplanes caeruleus* subsp. *caeruleus*, and *Actinoplanes philippinensis*, were 91.8–93.0%.

Short sporophores branch from the vegetative mycelia. Spore-chains from the sporophores have more than 20 spores per chain. Spores are cylindrical (Figure 221). Whirls, sclerotic granules, sporangia, and flagellated spores are not produced.

Longispora albida grows well on yeast extract/malt extract agar (ISP 2, Shirling and Gottlieb, 1966)*, oatmeal agar (ISP 3)†, peptone/yeast extract/iron agar (ISP 6)‡, and nutrient agar§, but aerial mycelia are not produced. When gellan gum is used as a solidifying agent, aerial mycelia grow slightly on some media. Spores are produced on 1/10 V8 + $CaCl_2$ gellan gum medium consisting of 2% V8 juice (Campbell's soup), 0.03% $CaCO_3$, 0.06% $CaCl_2 \cdot 2H_2O$ and 1.0% gellan gum in tap water (Table 198).

Enrichment and isolation procedures

Longispora albida was isolated from soil sample using water/proline/gellan gum medium consisting of 1% proline and 1% gellan gum in tap water. A feature of this medium is that gellan gum is used instead of agar as a solidifying agent. Samples (100 μl) from soil suspensions diluted with sterilized water were mixed with the water/proline/gellan gum medium kept at 55°C after sterilization at 121°C for 15 min in Petri dishes. The Petri dishes were incubated for 10 d at 27°C (Matsumoto et al., 2003). Although the recommended medium is water/proline/gellan gum medium, agar medium may be attempted for isolation of *Longispora* strains as *Longispora albida* grows on agar media.

Maintenance procedures

The organism can be maintained in the laboratory by transfer to the same media used for isolation. Viability of isolates during long-term storage is improved by addition of stabilizers. Recommended conditions are storage at −80°C or lyophilization in the presence of stabilizers such as 10% skim milk.

Differentiation of the genus *Longispora* from other genera

At the time of writing, the family *Micromonosporaceae* comprised 17 genera. Table 199 lists the characteristics that are useful for distinguishing *Longispora* from other genera in the family *Micromonosporaceae*. The phylogenetic tree revealed that *Longispora* branches within the family *Micromonosporaceae* (Figure 220). Although these genera have similar cultural, morphological, and chemotaxonomic characteristics, there are some differences. Genera that have spore-chains similar to those of *Longispora* are *Actinocatenispora* (Thawai et al., 2006a), *Asanoa* (Lee and Hah, 2002), *Catellatospora* (Asano and Kawamoto, 1986), *Polymorphospora* (Tamura et al., 2006), *Catenuloplanes* (Yokota et al., 1993), *Couchioplanes* (Tamura et al., 1994), and *Spirilliplanes* (Tamura et al., 1997). The latter three genera possess motile spores. The four genera that do not possess motile spores, *Actinocatenispora*, *Asanoa*, *Catellatospora*, and *Polymorphospora*, share this trait with *Longispora*. However, the genera *Asanoa* and *Catellatospora* form distinctive spore-chains that are borne directly from the vegetative hyphae growing on the surface of agar media and do not produce true aerial mycelia. *Actinocatenispora* and *Polymorphospora* contain MK-9 as major menaquinone.

*Yeast extract/malt extract agar: 0.4% yeast extract, 1.0% malt extract, 0.4% glucose, and 2.0% agar in distilled water, pH 7.3.

†Oatmeal agar. Cook 20 g oatmeal in 1.0 l distilled water for 20 min. Filter through gauze. Add distilled water to restore filtrate to 1.0 l, 1.0 ml of trace salts solution (consisting of 0.1 g $FeSO_4 \cdot 7H_2O$, 0.1 g $MnCl_2 \cdot 4H_2O$, 0.1 g, and $ZnSO_4 \cdot 7H_2O$ in 100 ml distilled water), and agar 18 g, pH 7.2.

‡Peptone/yeast extract/iron agar: 3.6% peptone iron agar, dehydrated (Difco), 0.1% yeast extract in distilled water, pH 7.0.

§Nutrient agar: 0.3% beef extract, 0.5% peptone, and 1.5% agar, pH 7.0.

List of species of the genus *Longispora*

1. **Longispora albida** Matsumoto, Takahashi, Shinose, Seino, Iwai and Ōmura 2003, 1558[VP]

al.bi′da. L. fem. adj. *albida* somewhat white.

Longispora albida grows on yeast extract/malt extract agar, oatmeal agar, peptone/yeast extract/iron agar, and nutrient agar, and the color of vegetative mycelium is light ivory to cream. Growth is better on gellan gum media than on agar media. Although aerial mycelia are not produced on these agar media, when gellan gum is used as a solidifying agent instead of agar, aerial mycelia grow on some media. Spores are well-produced on 1/10 V8 gellan gum medium containing $CaCl_2$ (Table 198). Spores are cylindrical (0.4–0.5 × 1.0–1.4 µm) and have a smooth surface (Figure 221). The temperature range for growth is 12–37°C (optimum range is 21–33°C). Growth occurs at pH 6–9. Melanoid pigment is not produced. Positive for nitrate reduction, gelatin liquefaction, milk coagulation, and milk peptonization. D-Glucose is utilized, but L-arabinose, D-fructose, *myo*-inositol, D-mannitol, melibiose, raffinose, L-rhamnose, sucrose, and D-xylose are not utilized. Cellulose is not decomposed. No growth occurs in the presence of 2% NaCl. The predominant components of the cellular fatty acids are $C_{16:0}$ iso, $C_{17:1}$, and $C_{18:1}$. Produces actinohivin, a novel antibiotic active against human immunodeficiency virus (Chiba et al., 2001).

Source: soil.

DNA G+C content (mol%): 70 (HPLC).

Type strain: K97-0003, NRRL B-24201, JCM 11711.

Sequence accession no. (16S rRNA gene): AB089241.

Acknowledgements

We thank Satoshi Ōmura, Akio Seino, and Yuzuru Iwai for their kind suggestions, and Ismet Ara for help with making phylogenetic tree.

Genus XI. **Luedemannella** Ara and Kudo 2007c, 1372[VP]

The Editorial Board

Lu.e.de.man.nel′la. N.L. fem. dim. n. *Luedemannella* here refering to George M. Luedemann, a Russian actinomycetologist who contributed to the taxonomy of family *Micromonosporaceae*.

Single or clustered spherical to irregular sporangia (variable in size, ~3.0–5.0 µm) with branched hyphae, forms a non-fragmenting substrate mycelium. **Gram-stain-positive**. Nonmotile. **Aerobic**. Forms nonmotile spherical to oval shaped spores (0.2–0.4 µm) with a smooth surface and loosely arranged in sporogenous hyphae. Temperature range for growth 20–37°C, pH range 5–9, NaCl tolerance <3%. Cell wall contains the diamino acid *meso*-diaminopimelic acid. The *N*-acyl group of muramic acid is glycolyl. Mycolic acids are not present. MK-9(H_6) and MK-9(H_4) are the major menaquinones, and small amounts of MK-9(H_2) and MK-9(H_8) are present. Polar lipid profile comprises phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol and phosphatidylinositol mannosides.

DNA G+C content (mol%): 71.

Type species: **Luedemannella helvata** Ara and Kudo 2007c, 1372[VP].
